ABSTRACT

The HIFI instrument on board the Herschel Space Observatory has been used to observe interstellar nitrogen hydrides along the sight-line towards G10.6−0.4 in order to improve our understanding of the interstellar chemistry of nitrogen. We report observations of absorption in NH $N = 1 \leftarrow 0$, and searched unsuccessfully for NH$^+$. All detections show emission and absorption associated directly with the hot-core source itself as well as absorption by foreground material over a wide range of velocities. All spectra show similar, non-saturated, absorption features, which we attribute to diffuse molecular gas. Total column densities over the velocity range $11−54$ km s$^{-1}$ are estimated. The similar profiles suggest fairly uniform abundances relative to hydrogen, approximately $6 \times 10^{-7}$, $3 \times 10^{-7}$, and $3 \times 10^{-8}$ for NH, NH$_2$, and NH$_3$, respectively. These abundances are discussed with reference to models of gas-phase and surface chemistry.

Key words. ISM: abundances – ISM: molecules – Submillimetre: ISM – Molecular processes – Line: formation – Astrochemistry

1. Introduction

Molecular hydrides are important in the chemistry of the interstellar medium since they often appear in the first steps in chains of reactions that lead to other more complex species. The production pathways of nitrogen-bearing molecules are still rather uncertain since key species, such as NH$^+$, NH, and NH$_2$ have not been widely observed. Even the first identified polyatomic interstellar molecule, ammonia (NH$_3$), has been widely observed mainly in its para symmetry form, which leaves its formation mechanism poorly constrained in the diffuse molecular gas. Both gas-phase chemistry and grain surface reactions have been proposed as formation mechanisms, but clearly more observations are needed for a better understanding.

Both NH and NH$_2$ are well known in comets (e.g. Swings et al. 1941; Meier et al. 1998; Feldman et al. 1993), and have been observed in stellar photospheres (e.g. Schmitt 1969; Farmer & Norton 1989) via their electronic, vibration-rotation, and high rotational transitions. Interstellar NH was first detected in the interstellar medium by Meyer & Roth (1991) by optical absorption spectroscopy. Subsequent observations by Crawford & Williams (1997) and Weselak et al. (2009) have yielded six lines of sight where column densities of both NH and H$_2$ are directly measured. The average value of the column density ratio in these diffuse and translucent sightlines is $N($NH$)/N($H$_2$) $= 3 \times 10^{-9}$.

Interstellar NH$_2$ was first observed by van Dishoeck et al. (1993) in absorption towards Sgr B2 in three fine-structure components of the para-NH$_2$ $J = 1 \leftarrow 0$ transition with partially resolved hyperfine structure at frequencies 461 to 469 GHz. Further absorption lines of both ortho and para forms of NH$_2$ and NH were observed through use of the long-wavelength spectrometer aboard the Infrared Space Observatory (ISO: Cernicharo et al. 2000; Goicochea et al. 2004; Polehampton et al. 2007). The ISO observations were unable to resolve the hyperfine structure of either molecule. Ammonia, NH$_3$, was the first polyatomic molecule to be identified in interstellar space (Cheung et al. 1968) by means of its microwave inversion transitions. Although NH$_3$ has been widely observed in dark clouds and star-forming regions, there have been very few measurements of the inversion lines in the diffuse interstellar gas (Nash 1990; Liszt et al. 2006).

With the unique capabilities of Herschel Space Observatory (Pilbratt et al. 2010) transitions between 157 and 625 $\mu$m (0.48–1.9 THz) are available with the Heterodyne Instrument for the Far-Infrared (HIFI; de Graauw et al. 2010) with very high sensitivity. This allows searches for spectrally resolved, ground-state rotational transitions of NH$^+$, NH$_2$, and NH$_3$ with the same instrument. Abundances of these species are key diagnostics for the nitrogen chemistry.

The most sensitive and model-independent method for measuring column densities of interstellar molecules is high-resolution absorption line spectroscopy, which is being exploited by the Herschel PRISMAS key programme (PRobing...
Interstellar Molecules with Absorption line Studies). This paper presents the first observations and analysis of nitrogen hydrides along the sight-line towards the massive star-forming region G10.6−0.4 (W31C) as a part of the PRISMAS program. Observations of interstellar absorption towards seven additional submillimetre-wave continuum sources will be presented and analysed in later publications.

The ultra-compact HII region G10.6−0.4 in the star-forming W31 complex is an extremely luminous submillimetre and infrared continuum source. The source is located within the so-called 30 km s$^{-1}$ arm at a kinematic distance of 4.8 kpc (Fish et al. 2003). The gas associated directly with G10.6−0.4 is detected in the velocity range $V_{\text{LSR}} \approx -15$ to $+5$ km s$^{-1}$, while the foreground gas along the line of sight is detected at $V_{\text{LSR}} \approx 5$ to $55$ km s$^{-1}$. The focus of this paper is on the diffuse interstellar gas traced by the absorption lines.

2. Observations

The observations, which took place in March 2010, are summarised in Table 1. The $2_{0\rightarrow 1}\_0$ and $2_{1\rightarrow 1}$ NH$_3$ transitions were observed in the same band. We used the dual beam switch mode and the wide band spectrometer (WBS) with a bandwidth of 4 GHz and an effective spectral resolution of 1.1 MHz. The corresponding velocity resolution is about 0.3 km s$^{-1}$ at the higher frequencies and 0.6 km s$^{-1}$ at 572 GHz. In addition, simultaneous observations were performed using the high-resolution spectrometer (HRS) with an effective spectral resolution of 0.25 MHz ($\Delta \nu \sim 0.1$ km s$^{-1}$) and a bandwidth of 230 MHz. Three observations were carried out with different frequency settings of the local oscillator (LO) corresponding to a change of approximately 15 km s$^{-1}$ to determine the sideband origin of the lines. Two orthogonal polarisations were used during all observations.

| Species | Frequency$^a$ (GHz) | Band$^b$ | $T_{\text{sys}}$ (K) | $t_{\text{int}}$ (s) | Transition | Transition |
|---------|---------------------|---------|---------------------|---------------------|-----------|-----------|
| NH$^+$  | 1 012.540           | 4a      | 385                 | 47                  | $^2\Pi_{1/2} J = 3/2 \leftrightarrow 1/2$ | $^2\Pi_{1/2} J = 3/2 \leftrightarrow 1/2$ |
| NH     | 974.478             | 4a      | 339                 | 30                  | $N = 1 \leftarrow 0 J = 2 \leftrightarrow 1$ | $N = 1 \leftarrow 0 J = 2 \leftrightarrow 1$ |
| o- NH$_2$ | 952.578           | 3b      | 230                 | 15                  | $1_1$-0$_0$ | $1_1$-0$_0$ |
| o- NH$_3$ | 572.498           | 1b      | 83                  | 276                 | $1_1$-0$_0$ | $1_1$-0$_0$ |
| p- NH$_3$ | 1 214.859      | 5a      | 1 012               | 49                  | $2_{1\rightarrow 10}$ | $2_{1\rightarrow 10}$ |
|         | 1 215.245          | 5a      | 1 012               | 49                  | $2_{1\rightarrow 11}$ | $2_{1\rightarrow 11}$ |

$^a$The NH and NH$_2$ frequencies refer to the strongest hyperfine structure component. $^b$HIFI consists of 7 different mixer bands and two double sideband spectrometers. All transitions were observed in the upper sideband except NH$^+$. $^c$System temperature. $^d$The on-source time for each integration.

The half-power beam width of the telescope is 37, 22, and 17$''$ at 572, 953, and 1 215 GHz, respectively. Pointing was centered at R.A. = 18$^h$10$^m$28$^s$.70, Dec. = −19°55′55″ (J2000). The reference beams were located 3$'$ on either side of the source and the calibration is described by Roelfsema (2010).

We have used the standard Herschel pipeline to Level 2 which provides fully calibrated spectra. The data were first analysed using Herschel interactive processing environment (HIPE$^1$; Ott 2010) version 2.4, and in parallel we also used the software.

---

$^1$ HIPE is a joint development by the Herschel Science Ground Segment Consortium, consisting of ESA, the NASA Herschel Science Center, and the HIFI, PACS and SPIRE consortia.
3. Results

Figure 1 shows the double sideband WBS spectra of all observed transitions. The frequency scale is converted as customary to Doppler velocities relative to the local standard of rest (VLSR). All spectra, except NH$^+$ which is not detected, show emission at negative velocities and a deep absorption at $-1 \text{ km}\text{s}^{-1}$ associated with G10.6$-$0.4 as measured by observations of OH masers. At higher velocities we see a number of absorption features which are also seen in atomic hydrogen (Fish et al. 2003), HCO$^+$, HNC, HCN and CN (Godard et al. 2010). The only transition which does not show absorption components from the foreground material is ortho-NH$_3$ $2_0$ -- $1_0$.

The double-sideband calibrated antenna temperatures shown in Fig. 1 have to be divided by two in order to get the correct continuum levels, $T_A$(cont), which are 0.6, 2.6, 2.6, 3.0 and 3.4 K for NH$_3$ at 572 GHz, NH$_2$, NH, NH$^+$, and NH$_3$ at 1 215 GHz, respectively. The sideband gain ratio has been shown to be close to unity in previous PRISMAS observations (Neufeld et al. 2010b; Gerin et al. 2010), although departures at the 10% level have been seen at some frequencies (Neufeld et al. 2010a). We here adopt a sideband ratio of unity.

Figure 2 shows a comparison of NH, $o$-NH$_3$, and $p$-NH$_3$ at 1 215.2 GHz where the intensities have been normalised to single sideband continuum.

![Fig. 2. Comparison of NH, $o$-NH$_3$, and $p$-NH$_3$ at 1 215.2 GHz where the intensities have been normalised to single sideband continuum.](http://www.sron.rug.nl/~vdtak/radex/index.shtml)

Figure 3 shows a similar comparison of ortho- and para-NH$_3$. Here, too, we see the same absorption pattern in both species, and strong emission and self-absorption in the ortho-line from the source itself. The strongest velocity components in the foreground material lie at $V_{LSR} = 16, 22.5, 27.5, 30$ and $40.5 \text{ km}\text{s}^{-1}$.

The line opacities are calculated as\(^2\)
\[
\tau = - \ln (T_{\text{line}}/T_A(\text{cont}) - 1)
\]
To be conservative and not include absorption from the source itself, we use the velocity interval $11 - 54 \text{ km}\text{s}^{-1}$. The total integrated opacities are $\int \tau dV = 20, 16, 9$, and $3.4 \text{ km}\text{s}^{-1} \text{ for NH, NH$_2$, NH$_3$ at 572 and 1 215 GHz, respectively.}$

Even though unsaturated absorption lines provide straightforward determinations of opacity and column densities, the numerous hyperfine-structure components and velocity features complicate the analysis of both NH and NH$_2$. The spectroscopic properties of NH and NH$_2$ have been studied extensively and references, rest frequencies and molecular properties for NH and NH$_2$ are listed in the Cologne Database for Molecular

the background continuum radiation and not by collisions. The resulting excitation temperatures of the observed submillimetre transitions are typically 4–5 K, which are small enough compared to $hv/k$ that no correction for emission is required. All the optical depths of the hyperfine components that contribute to the line are summed. We have treated ortho- and para-forms of molecules together in the expectation that their relative abundances are fixed by the chemical formation process. Plausible rates of formation and destruction are included explicitly in the excitation calculation. Thus we derive total column densities as summarised in Table 2. The analysis is complicated for NH$_3$ by the existence of metastable excited states, especially in the para species. The entry for NH$_3$ in Table 2 is the sum of the measured column density in $J_K = 0$, the measured column density in the lower inversion sublevel of 1$_1$, and calculated values in the upper inversion sublevel of 1$_1$ and in both sublevels of 2$_2$. All other states are expected to have negligible populations. The uncertainties of measurement and in the excitation analysis do not fully constrain the ortho/para ratio in NH$_3$, but it appears that the effective formation temperature must be greater than 20 K, otherwise the strength of the 1 215 GHz line cannot be explained.

| Species $x$ | $N_x$ (cm$^{-2}$) | $X = N_x/N_H$ |
|-----------|----------------|----------------|
| NH        | 1.5×10$^{14}$   | 5.6×10$^{-9}$   |
| NH$_2$    | 8.0×10$^{11}$   | 3.0×10$^{-9}$   |
| NH$_3$    | 8.7×10$^{13}$   | 3.2×10$^{-9}$   |
| NH$^+$    | $\lesssim 2×10^{13}$ | $\lesssim 8×10^{-10}$ |

*Calculated in the velocity interval 11–54 km s$^{-1}$.

We note that the three neutral nitrogen hydrides have comparable abundances: NH is approximately twice as abundant as NH$_2$ and NH$_3$. To estimate the abundance with respect to hydrogen we use $N_H = 2.7×10^{22}$ cm$^{-2}$ as total column density of hydrogen in all forms (Neufeld et al. 2010b). This value is consistent with the estimated atomic hydrogen column density in this line-of-sight, $N$(H) = 1.2×10$^{22}$ cm$^{-2}$ (Gardiner et al. 2010) inferred from absorption profiles observed with the VLA (Fish et al. 2003), and implies that the absorbing material is mostly molecular even if there is a large variation between the individual velocity components. Our estimate of the abundance of NH relative to total hydrogen is somewhat higher than the NH/H$_2$ ratio of 3×10$^{-9}$ for six lines of sight where both are observed directly. The resulting abundances are found in Table 2. The non-detection of NH$^+$ is used to put an upper limit on its column density and abundance (3$\sigma$). A previous limit on NH$^+$ towards ζ Oph from ultraviolet observations, $N$(NH$^+$/N$_H$ $< 1\times 10^{-6}$, is orders of magnitude less sensitive than our limit (Snow 1979; de Almeida & Singh 1982).

5. Conclusions

Our first detections of spectrally resolved rotational transitions of nitrogen hydrides in the interstellar medium show remarkable similarities of line profiles and abundances towards one background source. The formation mechanisms are, however, difficult to explain. Neither standard gas-phase nor grain-surface chemistry can fully explain our observations, which may suggest that important reactions have been overlooked in the chemistry of interstellar nitrogen. Further analysis of the line profiles will yield abundance ratios in separate velocity components and will

which were formed by neutral-neutral reactions. The standard gas-phase ion-molecule chemistry of nitrogen hydrides is initiated by the reaction N$^+$+H$_2$ → NH$^+$+H, because H$_2^+$ does not react readily with N. Typical steady state dark cloud models ($n = 1×10^3 – 5×10^4$ cm$^{-3}$, $T = 10–40$ K, $A_V \gtrsim 10$), predict an NH$_2$ abundance of (1-10)$×10^{-10}$, an NH abundance 10 times lower, and an NH$_2$/NH$_2$ ratio of 0.3–1.5 for a wide range of assumptions (e.g. Millar et al. 1991; Langer & Graedel 1989), but these are not directly applicable to diffuse molecular gas.

Previous observations of NH in diffuse clouds were taken to imply that NH is produced on grain surfaces (Mann & Williams 1984; Wagenblast et al. 1993; O’Neill et al. 2002). Such models, however, often predict up to 1 000 times more NH$_3$ than NH$_2$ (Hasegawa & Herbst 1993). An additional source of NH and NH$_2$ is fragmentation of ammonia by photodissociation in diffuse clouds. Models of ultraviolet illuminated PDRs predict NH$_2$/NH$_2$<1 and NH$_2$/NH<1 in regions with extinction $A_V < 5$ mag (e.g. Sternberg & Dalgarno 1995). The abundance patterns that we see in diffuse molecular gas are clearly different from those in Sgr B2, where NH$_2$/NH$_2$/NH ≈ 100/10/1 and the fractional abundance of NH is a few times $\times 10^{-9}$ (Cernicharo et al. 2000; Goicoechea et al. 2004).

We have used two different approaches to chemical models in order to compare the nitrogen-hydride abundances with theory. First, we constructed a pseudo-time-dependent model with constant physical conditions including both gas-phase and surface chemistry (Hasegawa et al. 1992) with $A_V = 2$ and 3, $n_H = 500$ and 5 000 cm$^{-3}$, $T_{gas} = 30$ and 50 K, and $T_{dust} = 10$ K. The ultraviolet field is $1 G_0$, and the cosmic ray ionization rate is $\zeta = 1.3×10^{-17}$ s$^{-1}$. The resulting abundances are found in Fig. A.1 (online material). Gas-phase chemistry alone does not match the observed abundances, failing by factors of 10 to 100 for NH and NH$_2$. Inclusion of processes on dust surfaces increases the abundances of the three neutral hydrides to $10^{-8}–10^{-9}$, but fails to match the high NH/NH$_3$ ratio. If the dominant source of NH$_3$ is association on surfaces and if the ortho/para ratio is fixed at a surface temperature below 20 K, then the 1 215 GHz para line should be much weaker relative to the ortho 572 GHz line than is observed. The observed line ratio is perhaps somewhat better explained by a high formation temperature, which points to exoergic gas-phase formation of NH$_3$. A second approach is to construct models of weak photon-dominated regions (PDR) through use of the Meudon PDR code (Le Petit et al. 2006; Goicoechea & Le Bourlot 2007), which is a steady-state, depth-dependent model with pure gas-phase chemistry. We use parameters appropriate for diffuse clouds, $U/V = 0.5–5 G_0$, $n_H = 100–1 000$ cm$^{-3}$, $\zeta = 10^{-17}$–$10^{-15}$ s$^{-1}$, $A_V < 5$ and illuminate one side only. The results of the best fitting model are found in Fig. A.2 (online material). Although the resulting relative abundances of nitrogen-hydrides approach the observed ratios inside the cloud, the abundances relative to hydrogen are still too low.
allow the nitrogen species to be compared directly with tracers of molecular hydrogen like CH and HF. Our sample will also be enlarged with seven additional sight-lines in the PRISMAS project. The chemical models will be refined and the possible role of turbulent dissipation regions will be assessed.

Appendix A: Figures
Fig. A.1. A pseudo-time-dependent model with constant physical conditions taking into account both gas-phase and grain surface chemistry. For all lines: $T_{\text{dust}} = 10$ K and the solid/dashed lines show $T_{\text{gas}} = 30$ and 50 K, respectively. The black thin lines show the observed abundances, and the dashed black line the NH$^+$ upper limit. Black line: gas phase & grain surface chemistry using $A_V = 3$, $n_H = 5000$ cm$^{-3}$. Red line: gas phase & grain surface chemistry using $A_V = 2$, $n_H = 500$ cm$^{-3}$. Grey line: only gas phase chemistry using $A_V = 3$, $n_H = 5000$ cm$^{-3}$. Blue line: only gas phase chemistry using $A_V = 2$, $n_H = 500$ cm$^{-3}$.
Fig. A.2. The cloud depth-dependent Meudon PDR model for pure gas-phase chemistry using $n_\text{H} = 1000 \text{ cm}^{-3}$, $\zeta = 10^{-17} - 10^{-15} \text{ s}^{-1}$, and a UV-field of 10 times the interstellar radiation field in Draine units ($\sim 5 G_0$). The left panel shows the relative abundances of NH/NH$_2$ and NH$_2$/NH$_3$, and the right panel show the absolute abundances.
