\textbf{Abstract}

\textbf{Background:} Few previous retrospective studies suggest that \textit{Plasmodium ovale wallikeri} seems to have a longer latency period and produces deeper thrombocytopenia than \textit{Plasmodium ovale curtisi}. Prospective studies were warranted to better assess interspecies differences.

\textbf{Methods:} Patients with imported \textit{P. ovale} spp. infection diagnosed by thick or thin film, rapid diagnostic test (RDT) or polymerase chain reaction (PCR) were recruited between March 2014 and May 2017. All were confirmed by DNA isolation and classified as \textit{P. o. curtisi} or \textit{P. o. wallikeri} using partial sequencing of the ssrRNA gene. Epidemiological, analytical and clinical differences were analysed by statistical methods.

\textbf{Results:} A total of 79 samples (35 \textit{P. o. curtisi} and 44 \textit{P. o. wallikeri}) were correctly genotyped. Males predominate in wallikeri group (72.7%), whereas were 48.6\% in curtisi group. Conversely, 74.3\% of curtisi group were from patients of African ethnicity, whilst 52.3\% of Caucasians were infected by \textit{P. o. wallikeri}. After performing a multivariate analysis, more thrombocytopenic patients ($p = 0.022$), a lower number of platelets ($p = 0.015$), a higher INR value ($p = 0.041$), and shorter latency in Caucasians ($p = 0.034$) were significantly seen in \textit{P. o. wallikeri}. RDT sensitivity was 26.1\% in \textit{P. o. curtisi} and 42.4\% in \textit{P. o. wallikeri}. Nearly 20\% of both species were diagnosed only by PCR. Total bilirubin over 3 mg/dL was found in three wallikeri cases. Two patients with curtisi infection had haemoglobin under 7 g/dL, one of them also with icterus. A wallikeri patient suffered from haemophagocytosis. Chemoprophylaxis failed in 14.8\% and 35\% of curtisi and wallikeri patients, respectively. All treated patients with various anti-malarials which included artesunate recovered. Diabetes mellitus was described in 5 patients (6.32\%), 4 patients of wallikeri group and 1 curtisi.

\textbf{Conclusions:} Imported \textit{P. o. wallikeri} infection may be more frequent in males and Caucasians. Malaria caused by \textit{P. o. wallikeri} produces more thrombocytopenia, a higher INR and shorter latency in Caucasians and suggests a more pathogenic species. Severe cases can be seen in both species. Chemoprophylaxis seems less effective in \textit{P. ovale} spp. infection than in \textit{P. falciparum}, but any anti-malarial drug is effective as initial treatment. Diabetes mellitus could be a risk factor for \textit{P. ovale} spp. infection.

Background
Malaria remains a global health problem with more than 212 million new cases in 2016 and 429,000 annual deaths worldwide, mostly driven by *Plasmodium falciparum* and *Plasmodium vivax*, to which most of the research resources are devoted [1]. Conversely, *Plasmodium ovale* spp. infection can be considered a neglected disease and little is known on its real incidence, geographic distribution, global disease burden or interactions with other *Plasmodium* species. The main problems for its study have been that it is frequently misdiagnosed because of usual submicroscopic or low parasitaemia levels, low performance of malaria rapid diagnostic tests (RDT) [2] and a majority of mixed infections with other *Plasmodium* spp. [3]. Nowadays, polymerase chain reaction (PCR) techniques have expanded the knowledge on *P. ovale* spp. epidemiology reporting infections in most of sub-Saharan Africa, Southeast Asia, and the Indian subcontinent [4–6], but not in the Americas, with prevalences as high as 15% in zones of Nigeria or Papua New Guinea [3]. In addition, severe complications, such as acute respiratory distress syndrome (ADRS) [7], spleen rupture, severe anaemia, or death may occur in patients with *P. ovale* spp. malaria [8]. Lastly, the incidence of imported *P. ovale* spp. infection seems to be increasing among travellers returning from West Africa [9–11], in whom chemoprophylaxis failed to work more frequently [12] compared to *P. falciparum* or *P. vivax* [13].

Since the study by Sutherland et al. was published in 2010, *P. ovale* is considered to comprise two genetically different subspecies, named *P. ovale curtisi* and *P. ovale wallikeri* that could have diverged 1–2 million years ago in their evolution [4]. They both are morphologically identical and cannot be differentiated by microscopy. Increasing information from different studies in endemic countries support that both subspecies co-circulate in Africa and Asia and are unable to recombine genetically [14–17]. Once established the genetic differences, the next question was to find out if there were any other differences in epidemiology, microbiology or clinical features between both subspecies. *Plasmodium o. curtisi* and *P. o. wallikeri* do not seem to differ in parasitaemia levels [5, 9, 13] and the absence of Schüffner’s stippling may be a feature specific to *P. o. wallikeri* but only in 30% of blood samples [9]. Clinical differences between both species have not been clearly established, but *P. o. wallikeri* may have a shorter period of latency [13].

Recently, a multicentre, retrospective study in Spain was reported, comparing 21 imported *P. o. curtisi* and 14 *P. o. wallikeri* infections confirmed by PCR and gene sequencing [5]. The only significant finding was more severe thrombocytopenia among patients with *P. o. wallikeri* infection than among those with *P. o. curtisi* (*p* = 0.031). However, non-significant trends showing shorter latency, lower albumin level, higher temperature and markers of more severe haemolysis were found in *P. o. wallikeri* group. Because of the retrospective design and small number of patients, larger, prospective studies were warranted to confirm these findings. Therefore, the results of a multicentre, prospective, comparative study of imported *P. o. wallikeri* and *P. o. curtisi* infections conducted in several European countries during the period 2014–2017 are presented below.

Methods
Study design
A prospective, observational, un-randomized, open-label, multicentre study was performed at European hospitals of TropNet Europe, European Network for Tropical Medicine and Travel Health. Participants were recruited between March 2014 and May 2017. The study was approved by the University Hospital Príncipe de Asturias Ethical Board and at each site as needed. Written informed consent was obtained from the participant or a legal representative before enrolment in the study. The trial was conducted in accord with the Declaration of Helsinki and Good Clinical Practice.

Microbiologic diagnosis
The initial diagnosis of imported *P. ovale* spp. infection was made up by thick and/or thin film and/or second generation RDT and/or PCR available in each hospital. Blood smears were stained by a standard technique with Giemsa solution for 30 min and were reviewed by an expert microbiologist. Parasite count was measured by determining the proportion of parasitized erythrocytes or the number of trophozoites per microlitre. Mixed infections with other *Plasmodium* species were excluded.

Laboratory samples
For cases tested positive, three drops (≈ 50 μL) of full blood left after routine laboratory tests, were dotted on filter paper (Whatman™) and sent by regular mail to the Reference Malaria & Emerging Diseases Laboratory of the National Centre of Microbiology in Madrid. If DNA of *P. ovale* spp. had already been isolated, this was sent into a 1.5 mL screw cap tube with complete closure to the same Reference Laboratory.

Isolation of parasite DNA and molecular diagnosis confirmation
DNA isolation was performed using the QIAamp DNA blood mini kit (QIAGEN®) from whole blood following the manufacturer’s protocol. Molecular diagnosis
confirmation of *P. ovale* spp. was carried out by semi-nested multiplex malaria PCR [18] which allows to distinguish the four more prevalent human malaria species.

**Plasmodium ovale** subspecies characterization and confirmation

Characterization of *P. o. curtisi* and *P. o. wallikeri* was performed by partial sequencing of the ssrRNA gene and ssrRNA amplification was performed by a nested PCR assay specific for *Plasmodium* genus. The first reaction included UNR (5′-GACGGTATCTGATCGTCTTC-3′) and PLF (5′-AGTGTATCCAAATCGAGTTTC-3′) primers [18]. The second PCR reaction incorporates the products of the first reaction along with NewPLFsh (5′-CTATCAGCTTTTGATGTAG-3′) and NewRevsh (5′-CCTTAACCTTTGTCTTG-3′) primers. Infection with different malaria species yields products of different sizes between 710 and 740 bp.

The PCR mixture in both reactions consisted of 75 mM TrisHCl (pH 9.0), 2 mM MgCl₂, 50 mM KCl, 20 mM (NH₄)₂SO₄, 200 µM of dNTP, 0.075 µM of each primer, 1.25 units of *Taq* DNA polymerase (Biotools B&M Labs., S.A., Madrid, Spain), and 5 µL of DNA, extracted by QIAGen kit, was used as template in a reaction volume of 50 µL. For the second reaction mixture, 2 µL of the PCR product of the first reaction was used as template. For both reactions, a GeneAmp® PCR System 2700 thermal cycler (Applied Biosystems Laboratory) was used, beginning with 7 min at 94 °C, followed by (first-round) 40 cycles of 20 s at 94 °C, 20 s at 62 °C, and 30 s at 72 °C, or (second-round) 35 cycles of 20 s at 94 °C, 20 s at 53 °C, and 20 s at 72 °C. The final cycle was followed by an extension time of 10 min at 72 °C.

The amplified products were purified using Illustra DNA and Gel Band Purification Kit (General Electric Healthcare) and sequenced with the Big Dye Terminator v3.1 Cycle Sequencing in an ABI PRISM® 3700 DNA Analyzer. All amplified products were sequenced in both directions twice.

In order to confirm *P. ovale* subtyping, a nested PCR amplification plus sequencing targeting cytochrome b was performed in three samples of each group.

**Data collection**

An anonymized database was designed to input all the medical information and laboratory registries in a prospective way. Data collected included gender, age, ethnicity, underlying diseases, type of patient, dates and purpose of travel, countries visited, malaria chemoprophylaxis, date of admission and diagnosis, presenting clinical signs or symptoms and complications of severe malaria according to criteria of the World Health Organization (WHO) [19] where no threshold of parasitaemia for *P. ovale* spp. was established. The closest possible date of inoculation was defined as the day of departure from a malaria endemic area. The time between date of arrival and onset of illness or diagnoses was calculated once asymptomatic patients were excluded. Patients were classified as an early immigrant if they had stayed in a country without malaria for less than a year prior to diagnosis. An immigrant was a VFR (visiting friends and relatives) if travelled to a country endemic of malaria after a year of stay in a non-malarial area, and VFR traveller if visited his/her first-degree relative’s country of birth having been born in a non-malaria endemic country. Recent *Plasmodium* infection was defined as probable or definite malaria infection in the previous 12 months before *P. ovale* spp. diagnosis.

Laboratory results included microbiological data with parasitaemia count, full blood count with white blood cells, haemoglobin and platelets, values of glucose, creatinine, albumin, transaminases, lactate dehydrogenase (LDH), total bilirubin (tBR) in plasma, the coagulation parameters activated partial thromboplastin time (APTT) and international normalized ratio (INR), glucose-6-phosphate dehydrogenase (G6PDH) activity in red blood cells, as well as serological studies of infection with human immunodeficiency virus (HIV), hepatitis B (HBV) and hepatitis C (HCV). Thrombocytopenia was defined as a platelet count under 150,000/µL. Treatments, clinical and microbiological evolution and duration of hospital stay of those admitted were recorded. Treatments were performed following the guidelines of each country and health centre without a common recommendation.

**Statistical analysis**

Differences of proportions were evaluated by the Chi-squared-test if less than 20% of cells had five or less expected values. If more than 20% of cells had five or less expected values we used the Fisher’s exact test for categorical variables. Differences of means between groups were calculated by the Student’s *t*-test for independent samples if the normal distribution could be assumed. In the Student’s *t* test for independent samples, the Levene’s test for homogeneity of variances was used. If normal distribution was not valid, the non-parametric Mann–Whitney *U*-test was performed. To test for normality, either the Shapiro–Wilks for small samples or the Kolmogorov–Smirnov with Lilliefors’ correction for large samples were used. Values are reported as number of patients and percentage or, for non-parametric distributions, as median and interquartile range (IQR). A multivariate linear regression analysis was performed for continuous variables and multivariate logistic regression for categorical variables to confirm if real differences were found when
non-homogenous population between both groups were identified. A two-sided p value of 0.05 or less was considered to indicate statistical significance. Statistical analysis was performed using the SPSS version 21 (SPSS Inc, Chicago, IL, USA).

Results
During the period of the study, a total of 96 blood samples from 29 hospitals were sent to the reference laboratory. Of them, 13 were excluded because of mixed infections (11 with P. falciparum, 1 with P. vivax and 1 with Plasmodium malariae), 2 samples did not get amplified and data from another 2 were not obtained. At the end, 79 correctly genotyped and with complete patient information were included for statistic analysis. Of them, 35 were identified as P. o. curtisi and 44 as P. o. wallikeri.

Table 1 presents demographic and epidemiological data from both groups. A significant difference in the distribution of gender, ethnicity and type of patients was shown. Males clearly predominate in wallikeri group whereas gender distribution was more evenly matched in the curtisi group. Conversely, on ethnicity, African patients were 74.3% of curtisi group. This ethnic distribution is reflected in the type of patient with a majority of VFR and recent immigrants in the P. o. curtisi infection versus a larger number of displaced for working or cooperation in the other species. The remaining epidemiological data did not differ including country of infection, duration of travel, chemoprophylaxis, latency time, time until diagnoses, recent Plasmodium infection or underlying diseases. There is a wide range of 21 countries as the place of infection, most of them in West Africa.

Microbiological and laboratory information is reported in Table 2. Several analytical parameters showed statistically significant differences such as total leucocyte and platelet count, number of thrombocytopenic patients, haemoglobin, creatinine, LDH or INR values. Even after the multivariate study was performed, eliminating the confounding factor of ethnicity, the number of platelets, thrombocytopenic patients and INR remained significant (Table 3). Latency time was also included in the multivariate analysis because of the significant difference found in a previous report [13]. A statistically shorter latency period also appeared, but only in Caucasians patients with P. o. wallikeri compared to those in the curtisi group. On the other hand, no difference in parasitological data including submicroscopic infection, parasitaemia or sensitivity of the common antigen of RDT was seen.

In respect of the clinical manifestations and time of hospitalization no differences were found in (Table 4). Treatments were widely different according to the protocols of each centre. Primaquine was supplied to most patients in both groups and only three patients showed G6PDH deficiency that contraindicated this treatment. Five patients showed analytical criteria for severe malaria and another one a rare and severe complication (haemophagocytosis). Outcome in nearly all cases was good, although two patients did not receive any anti-malarial treatment due to loss of follow-up.

Discussion
This is the largest prospective study to date on the two species of infection by imported P. ovale trying to overcome recruitment difficulties and limitations of previous retrospective studies.

On the results obtained, significant differences were found in the epidemiological characteristics of sex, ethnicity and type of patients between both groups. Ethnic differences may be the main confounding factor since there is a greater probability that African patients retain some semi-immunity against P. ovale spp. infection (excluding VFR travellers), which would generally result in less clinical and analytical involvement [20]. On the other hand, the difference in sex distribution and type of patients seems to be clearly related to the ethnic origin since in a subgroup analysis, 16 out of 18 (89%) of the patients with P. o. wallikeri who travelled by international cooperation were male and Caucasians, which would bias the characteristics of this group.

This distribution could be a result of chance alone or due to the fact that actually Caucasians patients are more susceptible to infection by wallikeri parasites. However, a previous retrospective study did not show these differences in sex, ethnicity or type of patient [5] and the few studies of imported ovale malaria reporting a significant number of patients showed either equality of sexes (but did not report on ethnicity) [13] or they were nearly all Chinese men who worked in African countries [10].

When performing the multivariate study adjusted by ethnicity to reduce this confounding factor, the number of patients with thrombocytopenia and two of the analytical alterations remained significant. Thrombocytopenia was more pronounced in P. o. wallikeri and INR values were higher in the wallikeri group. The comparison of the rest of analysis variables were not finally significant, over all those that indicate a greater degree of haemolysis, such as LDH, IFR or haemoglobin level.

In the case of thrombocytopenia, these results confirm the main finding of a previous retrospective study where the only difference was more severe thrombocytopenia in P. o. wallikeri infection [5]. Thrombocytopenia is a common finding in patients with malaria of all Plasmodium species ranging from 24 to 94% of incidence, although spontaneous haemorrhages are infrequent and limited to very severe cases [21]. Also it is of note that
### Table 1  Demographic and epidemiological characteristics

|                          | Plasmodium ovale curtisi (n=35) | Plasmodium ovale wallikeri (n=44) | p       |
|--------------------------|---------------------------------|-----------------------------------|---------|
| Sex                      |                                 |                                   | 0.028   |
| Male                     | 17 (48.6)                       | 32 (72.7)                         |         |
| Female                   | 18 (51.4)                       | 12 (27.3)                         |         |
| Age, median years (IQR)  | 35 (23.0–53.0)                  | 38.5 (22.2–52.7)                  | 0.529   |
| Ethnicity                |                                 |                                   | 0.017   |
| African                  | 26 (74.3)                       | 21 (47.7)                         |         |
| Caucasian                | 9 (25.7)                        | 23 (52.3)                         |         |
| Type of patient          |                                 |                                   | 0.034   |
| Early immigrant          | 11 (31.4)                       | 4 (9.0)                           |         |
| Visiting friends and relatives | 14 (40.0)                 | 17 (38.6)                         |         |
| VFR traveller            | 1 (2.9)                         |                                   |         |
| Tourism                  |                                 | 3 (6.8)                           |         |
| Work/cooperation         | 7 (20.0)                        | 17 (38.6)                         |         |
| Expatriate, long-term stay | 2 (5.7)                      | 3 (6.8)                           |         |

thrombocytopaenia seems to be a very common finding in *P. ovale* spp. infection. Of the 79 patients analysed, 53 (67%) had under 150,000 platelets/µL, which corresponds to our previous series findings of 66.6% in 16 imported ovale infection patients [22] and a retrospective study where 26 out of 35 patients (75.3%) suffered from thrombocytopaenia [5]. Only one patient in each group showed under 50,000 platelets/µL again without any haemorrhagic feature.

The pathogenesis of thrombocytopaenia in malaria is not fully understood but is accepted that encompasses several different mechanisms that lead to increased platelet destruction or consumption, such as increased attachment to endothelium and adherence to Von Willebrand factor, clumping and agglutination of infected and uninfected erythrocytes, consumption into the coagulation process and haemolysis, increased diffuse platelet sequestration, decreased nitric oxide

bioavailability, and immune complexes-mediated destruction [23].

Although thrombocytopenia is not among the severity criteria of the WHO, evidence is accumulating that it can predict an adverse outcome, which seems to be driven by a greater severity of illness in *P. falciparum* or *P. vivax* [21, 24] and severe thrombocytopenia can identify an increased risk of death from falciparum or vivax malaria [25]. Therefore, in the case of *P. o. wallikeri* it could indicate a greater intrinsic pathogenicity of this species compared to *P. o. curtisi*, although without evidence of any major significantly worse clinical criteria of severity.

Regarding the other significant finding of this study, the higher INR elevation in *P. o. wallikeri* compared to *P. o. curtisi*, this increase was always mild and in no case exceeded the value of 1.54 nor was related to any bleeding. On the other hand, the APTT values were similar in both groups. No other coagulation factors, fibrinogen levels, fibrin degradation products or D-dimer were measured that could argue in favour of a significant coagulation disorder.

It is well known that *P. falciparum* malaria is associated with significant coagulation activation. The increase in INR or its equivalent, prolongation of prothrombin time, is produced by the activation of the extrinsic pathway of the coagulation cascade and can lead to disseminated intravascular coagulation in the most severe cases of malaria. *Plasmodium falciparum* seems to trigger coagulation activation through multiple different pathways although the mechanisms involved are not well understood [26]. Much less information on coagulation is available in *P. ovale* spp. infection. In the case of INR, the finding of this study might support the hypothesis of a more pathogenic wallikeri parasite, but does not seem to pose a significant clinical difference or severity.

In the initial analysis, no differences were found in the latency period, but when the multivariate analysis was performed a significant shorter time appeared in *P. o. wallikeri* compared to *P. o. curtisi* infection, but only in Caucasians patients. This difference is more significant since only one of the seven Caucasians patients who suffered infection by *P. o. curtisi* had taken adequate prophylaxis versus 11 out of 22 (50%) of the wallikeri group, which should have lengthened their latency. The retrospective study by Nolder et al. in the UK also found significant shorter latency period in wallikeri cases but did not report the ethnicity or patient characteristics [13]. On the contrary, another study in Chinese people (ethnically homogeneous but with unknown previous exposure to malaria or chemoprophylaxis use) encompassing 109 *P. o. curtisi* and *P. o. wallikeri* [10] imported from Africa, did not find any difference in latency. In a previous retrospective study, only a trend to shorter wallikeri latency was found (*p = 0.07*) [5].

These results of different latency times in only Caucasians patients suggest a strong influence of the previous partial immunity to malaria in the time of symptoms of *P. ovale* spp. infection. Finally, note that in both species latencies greater than 1 year have been found as described previously [11].

A complete chemoprophylaxis was reported in 22.8% of ovale spp. infections and up to 35% in *P. o. wallikeri*, a high percentage if compared with data from large series of imported malaria as in USA 2014, where only 7.8% of travellers correctly took prophylaxis [11]. If analysed by *Plasmodium* species, these results are similar to the

### Table 3 Multivariate linear regression and multivariate logistic regression analysis related to ethnicity of parameters with significant differences in univariate analysis and latency time

| Parameter                  | Regression coefficients | 95% confidence interval       | p     |
|----------------------------|-------------------------|--------------------------------|-------|
| Total WBC count, × 10⁹ cells/L | − 850.884               | − 1931.456 to 229.689          | 0.121 |

| Creatinine level, mg/dL     | 0.095                   | − 0.024 to 0.215               | 0.117 |
| LDH level, IU/L             | 12.537                  | − 160.156 to 185.230           | 0.885 |
| INR                        | 0.077                   | 0.003–0.151                    | 0.041 |
| Time from arrival to onset of symptoms, days |                      |                                |       |
| African patients            | − 41.108                | − 127.135 to 44.920            | 0.344 |
| Caucasian patients          | − 75.001                | − 144.040 to − 5.962           | 0.034 |
| Odds ratio                  |                        |                                |       |
| Platelet count < 150,000 cells/µL | 0.314 | 0.117–0.847                    | 0.022 |

Values show the relationship of *P. o. wallikeri* respect to *P. o. curtisi*. Italicface indicates significance

WBC white blood cells, LDH lactate dehydrogenase, INR international normalized ratio
study by Nolder et al. which stated that the proportion of ovale malaria which occurred in patients reporting chemoprophylaxis use (33%) was significantly higher than for \textit{P. falciparum} (6.4%) and \textit{P. vivax} (23.7%) [13].

Also, in a USA and Israel study, up to 73% of imported \textit{P. ovale} spp. used an effective prophylaxis [27]. Moreover, in a recent Spanish study considering only the subgroup of travellers with \textit{P. ovale}/\textit{P. vivax} malaria, these patients had also taken chemoprophylaxis significantly more frequently than those with non-\textit{P. ovale}/\textit{P. vivax} malaria (35.5% vs. 2.7%) [28]. These results reinforce the idea that current prophylaxis does not adequately act on \textit{P. ovale} spp. infection, since it is ineffective against its hypnozoites and, therefore, does not prevent a delayed primary attack or true relapses from occurring when there is no prophylactic medication in blood.

Although the information cannot be completely reliable, over 40% of patients reported an episode of malaria in the previous 12 months. This could have been a primary infection by \textit{P. ovale}, another ovale relapse, a mixed infection with other \textit{Plasmodium} or simply a non-ovale malaria unrelated to the current episode. Since it is not feasible to obtain a previous diagnostic sample, it is impossible to know if the current episode

### Table 4: Clinical and therapeutic characteristics

* This patient had drepanocytosis

b One patient had drepanocytosis and G6PDH deficit and other patient had diabetes
represented a primary infection or a relapse by *P. ovale*. Primary infection could only be diagnosed in the cases of first malarial episode and very short latency period.

Regarding the underlaying conditions, it is worth focusing on diabetes mellitus and drepanocytosis. The prevalence of diabetes mellitus is increasing worldwide, especially in low income countries, as are found in sub-Saharan Africa [29]. The number of diabetics in this study is as high as 6.32% (5/79) in a population with a low average age, especially in wallikeri group. In a retrospective curtisi–wallikeri study up to 8.5% of patients suffered from diabetes [5] and in a previous study of imported *P. ovale* infection 3 out of 16 patients (18.7% with mean age 30.6 years) were also diabetics [22]. A recent Swedish study, reported diabetes in 3.5% of 937 patients with imported *P. falciparum* and 2.5% in 398 imported malaria in a Spanish Tropical Medicine Centre [30]. In a series of 229 *P. falciparum* infections from 2006 to 2015 in Hospital Universitario Príncipe de Asturias (HUPA), 2.6% were diabetics (unpublished data). As diabetes is a known risk factor for malaria due to *P. falciparum* in endemic areas [31], the higher prevalence of this chronic disease in *P. ovale* studies might indicate that would also be a risk factor, and deserves further investigation to confirm this finding.

In endemic areas, carrying the sickle cell trait represents a risk factor for infection by *P. ovale* spp. [20] and a partial protective factor against severe *P. falciparum* infection. In this study, 2 out of 47 African patients (4.2%) had drepanocytosis. Moreover, in the previous comparative retrospective study, 8.3% (2 out of 24) showed drepanocytosis and up to 23% (3/13) in the series of 16 imported *P. ovale* spp. [22]. Gathering African patients from the three studies (7/84) and comparing to 1.35% of patients in 221 African people with imported *P. falciparum* in HUPA during the period 2006–2015 (unpublished data) significant difference can be found (p < 0.005) that would support the results of the study conducted in endemic area.

As in previous studies, no differences were detected in parasitaemias between both groups [6, 9, 32]. Most of them had low parasite counts clearly below 1%, making it even more difficult to find statistically real differences. Surprisingly, two patients reached 2% parasitaemia, a Caucasian traveller without any immunity to malaria and a child with drepanocytosis and intense anaemia that enhanced the proportion of infected red blood cells. Such high parasitaemia has been rarely described, sometimes linked to serious complications such as spleen rupture [33]. Finally, the absence of Schüffner’s stippling in blood smear, which has been described as a possible feature specific to *P. o. wallikeri*, was not studied.

There was also no difference in the sensitivity of RDTs, which was low as described in the literature [2] without exceeding 45% in either group. Almost 20% of the cases in both groups were diagnosed only by PCR, as RDT and/or thick blood smears were negative. In endemic areas this percentage is much higher, especially in asymptomatic patients [3]. Therefore, if the clinical and epidemiological suspicion is high, it would be convenient to repeat the diagnostic tests and request molecular PCR techniques not to miss *P. ovale* spp. diagnosis.

This study confirms that this infection can cause malaria with severity criteria or complications, in this case 7.6% of all patients with no differences between both species. In series of imported malaria by *P. falciparum* the rate of severe cases was around 2–17% [11, 34], but with a much higher incidence of life-threatening complications, such as ADRS, severe anaemia or cerebral malaria than described in *P. ovale* spp. infection [8]. A rare case of haemaphagocytosis was included that had been described only in *P. falciparum* and *P. vivax* infection [35], but not in *P. ovale* spp. Analysing the six patients with severe malaria or complications, two had drepanocytosis (which also produces anaemia) and one was diabetic, which might indicate the possible importance of these risk factors in the severity of *P. ovale* spp. infection.

In cases of malaria with tBR > 3 mg/dL, the WHO severity criteria add parasitaemia levels above 100,000/µL in *P. falciparum* and > 20,000/µL in *P. vivax* and *Plasmodium knowlesi*, but is not known in the case of *P. ovale* spp. In this study, all four cases with tBR > 3 mg/dL had parasitaemias over 4000/µL. In addition, four patients received parenteral artesunate, two of them with tBR > 3 mg/dL and one with unusually high parasitaemias of 2%. It is described that host response may reach full strength at lower parasitaemia in *P. vivax* and *P. ovale* spp. infection than in *P. falciparum* [36] so, perhaps it would be also convenient to establish a threshold of parasitaemia with jaundice and hyperparasitaemia in *P. ovale* spp. in the face of treatment decisions and outcome.

The treatments were very varied, including artemisinins alone or in combination, atovaquone/proguanil, chloroquine or quinine-doxycline, all with good initial clinical evolution, which is compatible with the sensitivity of *P. ovale* spp. described for multiple antimalarials [8]. Over 70% of them received primaquine with good tolerance, although there was no long-term follow-up recorded to assess episodes of relapse or late recrudescence.

The prospective study design has minimized some of the limitations of the previous retrospective study but some of them still remain. First, although it is one of the largest studies carried out worldwide, the number of patients may still lack sufficient statistical power to show
other differences between infections with both *P. ovale* species. Second, only strains of *P. ovale* from Africa, and patients from Africa and Europe were analysed; a study of infections and patients from Asia, Oceania or other places might show different results. Third, the behaviour of these species in endemic countries may be different but it would be difficult to gather a significant number of patients with *P. ovale* spp. monoinfection due to the high prevalence of mixed *Plasmodium* infections and malaria reinfections. Fourth, the date of infection is a minimal approximate and it is virtually impossible to distinguish a primary infection from a relapse. Last, a mix of ethnicities, non-immune and semi-immune patients led to heterogeneous study groups, although the multivariate statistical study has reduced this bias.

**Conclusions**

In this study, imported *P. o. wallikeri* infection was more frequent in males and Caucasian patients than in *P. o. curtisi* group. Malaria caused by *P. o. wallikeri* produced more thrombocytopenic patients, more marked thrombocytopenia and a higher INR than *P. ovale curtisi*, although without other clinical or severity differences. *Plasmodium o. wallikeri* malaria had shorter latency, but only in Caucasian patients. These findings suggest that wallikeri species might be somewhat more pathogenic than *P. ovale curtisi*. Some cases with severity criteria were seen in both species and required treatment with intravenous artesunate. The clinical evolution with any anti-malarial drug was usually good, however, chemoprophylaxis seemed less effective in *P. ovale* spp. infection than in the case of *P. falciparum*. Diabetes mellitus might also be a risk factor for *P. ovale* spp. infection such as drepanocytosis. Current RDT was shown to have low diagnostic sensitivity in both species and PCR was essential for diagnosis in a significant percentage of cases.

**Abbreviations**

ADRS: acute respiratory distress syndrome; APTT: activated partial thromboplastin time; DNA: deoxyribonucleic acid; G6PDH: glucose-6-phosphate dehydrogenase; HBV: hepatitis B virus; HCV: hepatitis C virus; HIV: human immunodeficiency virus; INR: international normalized ratio; IQR: interquartile range; LDH: lactate dehydrogenase; PCR: polymerase chain reaction; RDT: rapid diagnostic test; ssRNA: small-subunit ribosomal ribonucleic acid; tBRI: total bilirubin; VFR: visiting friends and relatives; WHO: World Health Organization.

**Authors’ contributions**

GRM, JMR, JCG and JRMG made substantial contributions to conception and design of this study. GMR, JMR, AA, FG and JCG made substantial contributions to analysis and interpretation of data. SJ, SGB, LRT, NRV, MGR, JMR, MCM, EME, MEG and JLT made substantial contributions to acquisition of data. GRM, JMR, JCG, JSC and RLV were involved in drafting the manuscript. All authors read and approved the final manuscript.

The authors thank Dr. Francisco Javier Villar (Consultant in Infectious Diseases, Pennine Acute Hospital NHS Trusts, Manchester, UK) for reviewing the manuscript.

**Competing interests**

The authors declare that they have no competing interests.

**Availability of data and materials**

The datasets used for analysis of the study are available from the corresponding author upon receipt of reasonable request.

**Consent for publication**

Not applicable.

**Ethics approval and consent to participate**

This study was approved by the University Hospital Principe de Asturias Ethical Board and at each site as needed. Written informed consent was obtained from the participant or a legal representative before enrolment in the study. Each patient was informed of the nature, aims and voluntariness of the study with the option to withdraw at any time. A code number was assigned to each participant and confidentiality was guaranteed on all information obtained. The trial was conducted in accord with the Declaration of Helsinki and Good Clinical Practice.

**Funding**

This study has been funded with a grant FIB-P11 4-04 from the Foundation for Biomedical Research of the Hospital Universitario Principe de Asturias, Alcalá de Henares, Madrid, Spain.
