(Dated: August 4, 2022)

In the present work, we have reported comprehensive study of the *sd*-shell nuclei Si and P with neutron number varying from $N = 9$ to $N = 20$ using the microscopic effective valence shell interactions, namely, N3LO, JISP16 and DJ16A. These effective *sd*-shell interactions are developed using the *ab initio* no-core shell model wave functions and the Okubo-Lee-Suzuki transformation method. For comparison, we have also performed shell model calculations with the empirical USDB interaction. Energy spectra and electromagnetic properties of these isotopic chains have been studied. Theoretically calculated shell model results are compared with the available experimental data, to check the predictive strength of these microscopic interactions. It is found that the binding energies of the ground states are better reproduced with the DJ16A interaction as compared to other microscopic interactions and a proton subshell closure at $Z = 14$ is obtained in Si. Spin-tensor decomposition of two-body interaction is presented to understand the contributions from central, vector and tensor components into these interactions. Spectroscopic strengths of $^{23}\text{Al}(d,n)^{24}\text{Si}$ are examined for the newly performed experiment at NSCL.

I. INTRODUCTION

Over the last few years nuclear structure study of p- and lower sd-shell nuclei within the framework of \textit{ab initio} no-core shell model (NCSM) approach has achieved a great amount of success [1–13]. In the NCSM calculations, all the constituents of a nucleus are considered to be active particles. No concept of inert core as such is assumed in this approach. When the NCSM approach is implemented to study the properties of heavier-mass nuclei, dimension of the Hamiltonian matrix becomes too large to handle with the currently accessible computational power. So, other \textit{ab initio} approaches such as in-medium similarity renormalization group (IM-SRG) [14, 15], coupled cluster (CC) theory [16, 17] and symmetry-adapted no-core shell model (SA-NCSM) [18–21] are being used to describe the structure of heavier nuclei. Electromagnetic properties, spectroscopic factor strengths and Gamow-Teller (GT) strengths of sd-shell nuclei have been calculated using former two of the aforementioned \textit{ab initio} approaches in Refs. [22–27]. Another \textit{ab initio} approach, known as the \textit{ab initio} shell model with a core, has also been developed in Refs. [28–30].

In the \textit{ab initio} shell model with core approach, effective two-body interaction is constructed by performing \textit{ab initio} NCSM calculation in $N_{\text{max}}$ model space for a nuclei followed by explicit projection onto the $0\hbar\Omega$ space using Okubo-Lee-Suzuki (OLS) transformation method. Thus, the effective Hamiltonian is separated out into inert core, one, and two-body terms. In [29], the J-matrix inverse scattering potential (JISP16) [31] and chiral next-to-next-to-next-to-leading order (N3LO) interactions [32] for sd-shell have been developed and it is demonstrated that low-lying energy spectra of $^{19}\text{F}$ using the NCSM is exactly reproduced with these derived effective interactions. The same interaction has been applied on $^{19}\text{F}$ and the shell model results obtained therefrom are found to be very close to the NCSM results. It has also been reported that the effective Hamiltonian has weak A dependence, which means that this interaction can be applied to the heavier sd-shell nuclei. Further, new effective interactions, Daejeon 16 (DJ16) [33] and its monopole corrected version Daejeon 16A (DJ16A), have been constructed for sd-shell [30] similar to the above mentioned approach. Authors have implemented these microscopic interactions on O isotopes, odd-A F isotopes, $^{26}\text{F}$, $^{22}\text{Na}$, $^{28,29}\text{Si}$, $^{32}\text{S}$, $^{39}\text{K}$ and deformed rotor $^{24}\text{Mg}$. They obtain remarkable consistency between theoretical description and experimental data. Success of these effective microscopic interactions motivates us to fruitfully apply these interactions to study heavier nuclei in sd-shell. We extend their work to study Si and P isotopic chains in sd-shell region. Apart from energy spectra, we have also calculated the nuclear observables for these nuclei. Our present comprehensive study will add more information to the earlier work [30].

Nuclear structure properties of sd-shell nuclei including proton and neutron drip lines have been studied in several theoretical and experimental works [23, 34–40]. In [37], authors have implemented relativistic Hartree Bogoliubov model with density dependent meson-exchange and pairing interactions to study nuclear shapes of Mg, Si, S and Ar. They found existence of magic numbers at $N = 8$ and 20 with spherical shape in these isotopic chains and disappearance of $N = 28$ shell closure with a finite deformation. Prolate-oblate shape coexistence in some isotopes of Mg, Si, S and Ar isotopic chains have also been observed. In [23], it has been reported that excitation of nucleons from sd- to pf-shell plays an important role for “island of inversion” nuclei at $N = 20$. \textit{Ab initio} results with IMSRG and CC methods were seen to be in reasonable agreement with the experimental data for the sd-shell nuclei Ne, Mg and Si except for $N = 20$. Considerable success of the USDA and USDB interactions [38, 39] in describing the nuclear structure properties of sd-shell nuclei has led to the construction of new isospin-breaking USD-type interactions \textit{viz.} the USDC and USDI interactions [40]. These new interactions improve predictions for separation energy in the entire sd-shell.

In [41], a new type of \textit{ab initio} nucleon-nucleon (NN) interaction was developed for sd $–$ pf model space, \textit{viz.} the EEEdfl interaction. This interaction was derived from the fundamental chiral effective field theory (χEFT) [42–45] based on Quantum chromodynamics (QCD) [46] and extended Kuo-Krenciglowa (EKK) method [47–49]. The Fujita-Miyazawa three nucleon forces [50] were also included. It was initially implemented on medium mass nuclei Ne, Mg and Si isotopes [41]. Exotic neutron rich Ne, Mg and Si isotopes were explained in the aforementioned study by particle-hole excitations across two major shells without fitted interaction. Further, this interaction has also been applied for $Z = 9–12$ isotopes to determine the drip line and exotic properties of “island of inversion” nuclei with $Z = 10–12$ and $N = 20–22$ [51]. This work was extended to determine the spectroscopic properties such as magnetic dipole and electric quadrupole moments, charge and matter radii for Na and Mg isotopes, in Ref. [52].

Spectroscopic factor strength describes the nature and occupancy of the single particle orbits in a nucleus that are used to determine the structure of nucleus. In Ref. [53], experimental spectroscopic factor strength for ground state (g.s.) of $^{24}\text{Si}$ from $^{23}\text{Al}(p, \gamma)^{24}\text{Si}$ reaction was obtained. Recently, an experiment has been performed with a transfer reaction $^{23}\text{Al}(d, n)^{24}\text{Si}$ at National Superconducting Cyclotron Laboratory [54] to measure excited states and their spectroscopic factor strengths that might be of astrophysical interest. Motivated with these recent experimental data, we have calculated theoretical spectroscopic factor strengths for g.s. as well as excited states of $^{24}\text{Si}$ for one proton capture reaction $^{23}\text{Al}(d, n)^{24}\text{Si}$ using microscopic N3LO, JISP16 and DJ16A interactions, and have also carried out a comparison with the USDB results, in the present study.

The present work is organized as follows. In Section II, we briefly describe the methodology to develop the mi-
crosscopic effective \( sd \)-shell interaction and details about the interactions used in our calculations. Next, we show
the results of energy spectra of Si and P isotopic chains in Section III. Effective proton single-particle energies of
Si isotopes have been carried out in Section IV. In Section V, monopole parts of the effective interactions and their
spin-tensor components have been presented. We then discuss the electromagnetic properties of Si and P nuclei in
Sections VI. Spectroscopic factor strengths for \( ^{24}\text{Si} \) are studied in Section VII. Finally, we draw conclusion of the
present study in Section VIII.

II. MICROSCOPIC EFFECTIVE \( sd \)-SHELL INTERACTIONS

To describe the nuclear structure properties of \( sd \)-shell nuclei, we have performed the nuclear shell model calculations
with microscopic effective \( sd \)-shell interactions in the present work. The detailed procedure to develop these effective
\( sd \)-shell interactions has been described in Refs. [29, 30], which we have briefly presented here.

In this approach, the microscopic effective valence shell interactions are derived from the \textit{ab initio} NCSM wave
functions. The NCSM Hamiltonian for a nucleus of \( A \) point like nucleons interacting through realistic interaction can
be written as

\[
H_A = \frac{1}{A} \sum_{i<j}^A (\vec{p_i} - \vec{p_j})^2 + \sum_{i<j}^A V_{ij}^{\text{NN}},
\]

where, \( m \) is the mass of a nucleon. This Hamiltonian, which is translationally invariant, has relative kinetic energy term
and two-nucleon interaction term including Coulomb interaction between protons. In these calculations three-body
forces are omitted.

The harmonic oscillator (HO) basis states (slater determinate basis) up to \( N_{\text{max}}, \) which is maximum number of
HO quanta above the unperturbed \( A \) nucleon configuration, are used to solve the eigen value problem of \( A \) nucleon
system. Several realistic NN interactions, \textit{i.e.} charge-dependent Bonn 2000 (CDB2K) [55] and chiral effective field
theory interactions [32] generate strong short-range correlations. To obtain convergent results, large basis states are
required which is constrained by computational limitations. Thus, a renormalization method is employed to soften
the standard realistic interactions. There are two renormalization techniques: OLS similarity transformation [56–59]
and SRG method [60], with the former being implemented in the procedure outlined here.

To make derivation easier, a frequency dependency is introduced in the NCSM calculations. Addition of center-of-
mass HO Hamiltonian to the initial Hamiltonian \( H_1 \) modifies the resultant Hamiltonian as

\[
H_a + H_{\text{c.m.}} = \sum_{i=1}^a \left[ \frac{\vec{p}_i^2}{2m} + \frac{1}{2} m\Omega^2 \vec{r}_i^2 \right] + \sum_{i<j=1}^a \left[ V_{ij}^{\text{NN}} - \frac{m\Omega^2}{2A} (\vec{r}_i - \vec{r}_j)^2 \right].
\]

This \( H_{\text{c.m.}} \) is subtracted out from the final calculations. If \( a = A \) then \( H_a \) becomes the initial Hamiltonian \( H_1 \). The
effective NN interaction for the NCSM calculations is derived from Eq. 2 in a cluster approximation. In these NCSM
calculations, the \( a = 2 \) cluster approximation has been used. First OLS transformation is applied to construct a
primary effective Hamiltonian for \( A = 18 \) system with NCSM parameters \( N_{\text{max}} = 4 \) and \( \hbar\Omega = 14 \) MeV. The lowest
28 eigen states are calculated to perform second OLS transformation. This 18-body Hamiltonian is projected onto \( \hbar\Omega \Omega \)
model space. These eigen states of \( ^{18}\text{F} \) are dominated by the configurations with \( ^{16}\text{O} \) system in the lowest
possible HO orbits and two nucleons in \( sd \)-shell. The secondary effective Hamiltonian reproduces exactly same energy
of the states in \( ^{18}\text{F} \), as generated by the primary effective Hamiltonian. Further, the NCSM calculations have been
performed for \( ^{16}\text{O}, ^{17}\text{O} \) and \( ^{17}\text{F} \) with primary effective Hamiltonian to calculate core and one-body single-particle
energies. These core and one-body components have been subtracted out from secondary effective Hamiltonian of \( ^{18}\text{F} \)
to obtain residual two-body matrix elements for the \( sd \) valence shell.

In this work, three microscopic \( sd \)-valence space interactions have been used, \textit{viz.} N3LO, JISP16 and DJ16A. Together with
these microscopic interactions, we have also used empirical USDB interaction [39] to know how much reliable description of nuclei are
obtained from the microscopic potentials. The calculated results with these interactions are compared with the experimental data. In the case of the empirical USDB interaction, single-particle energies are \( \epsilon(d_3/2) = -3.9257 \) MeV, \( \epsilon(s_1/2) = -3.2079 \) MeV and \( \epsilon(d_5/2) = 2.1117 \) MeV. These single-particle energies of the
USDB interaction are taken for all the microscopic interactions similar to Ref. [30]. We have calculated only positive
parity states of these nuclei. We have performed nuclear shell model calculations using the code KSHELL [61].
Experimental g.s. energies of sd-shell nuclei relative to the g.s. energy of $^{16}$O with the Coulomb energy correction term is determined as:

$$E(A, Z)^r = E(A, Z) - E(^{16}$O$) - E_c(Z),$$

where, \(E(A, Z)^r\) and \(E(A, Z)\) are relative and absolute g.s. energy. \(E(^{16}$O$)\) is the g.s. energy of $^{16}$O, which have the value of -127.619 MeV. \(E_c(Z)\) is the Coulomb correction energy taken from Ref. [38].

III. RESULTS AND DISCUSSION

We have presented a comprehensive nuclear shell model results for $^{23-34}$Si and $^{24-35}$P isotopes using N3LO, JISP16 and DJ16A interactions. The empirical USDB calculations have also been performed for comparison. Here, we have shown the low-lying energy spectra of Si isotopes with \(A = 26 - 34\) in Fig. 1 and P isotopes with \(A = 27 - 35\) in Fig. 2. Experimental spectrum [62] is shown in the last column of each figure.

A. Si isotopes

All microscopic interactions confirm the tentative experimental spin of g.s. as 5/2$^+$ for $^{28}$Si with dominant configuration of \(|\pi(d_{5/2}^5) \otimes \nu(d_{5/2}^1)\rangle\), except for N3LO. In $^{24}$Si, correct g.s. 0$^+$ is obtained with each interaction. For first excited state 2$^+$, DJ16A interaction gives 1.786 MeV excitation energy, while USDB interaction predicts this state to be at 2.111 MeV. Experimental value is 1.879 MeV which indicates that DJ16A interaction provides better agreement for 2$^+$ state of $^{24}$Si, with the experiment. In $^{25}$Si, only g.s. spin-parity is measured experimentally and spin-parity of excited states are unknown. Microscopic interactions are unable to reproduce spin of the g.s. In case of $^{26}$Si, we observe from the spectrum that microscopic interactions produce lower excited states at small excitation energies, specially 0$^+_2$, in comparison with the experiment. The $s_{1/2}$ proton orbital occupancy increases with excitation energy according to the USDB calculations as 0.58 for 0$^+_1$, 0.68 for 2$^+_1$, 1.03 for 2$^+_2$ and with DJ16A as 0.84 for 0$^+_1$, 0.92 for 2$^+_1$, 1.05 for 2$^+_2$. For $^{27}$Si, correct g.s. spin is reproduced with microscopic DJ16A only, which has the configuration of \(|\pi(d_{5/2}^5) \otimes \nu(d_{5/2}^1)\rangle\) with probability of 16.42%. USDB interaction also predicts 5/2$^+$ as the g.s. of $^{27}$Si with the same configuration as found in case of DJ16A interaction with 27.36% probability. The IM-SRG and CCEI give the major configurations in wave functions from \(|\pi(d_{5/2}^5) \otimes \nu(d_{5/2}^1)\rangle\) and \(|\pi(d_{5/2}^5s_{1/2}^1) \otimes \nu(d_{5/2}^1s_{1/2}^1)\rangle\) with probabilities of 9.27% and 13.24%, respectively, as reported in Ref. [22]. With DJ16A, energy of 1/2$^+_1$ is 0.711 MeV which is close to the experimental value of 0.781 MeV. The energy spectra with N3LO interaction is compressed as compared to the other interactions.

$^{28}$Si and $^{29}$Si have been studied in [30], where, small excitation energies of 2$^+_1$ and 4$^+_1$ due to small \(N = 14\) shell gap, and configurations of 0$^+_1$ and 0$^+_2$ states for $^{28}$Si have been described. We have added some excited states with all four interactions and have also studied spectroscopic properties (in Section VI). $^{28}$Si nucleus is the closed subshell nucleus which contains 6 valence protons and 6 valence neutrons. We obtain correct ordering of the states up to 0$^+_2$ in $^{28}$Si with each interaction. Energy difference between g.s. and first excited state is 1.068, 1.145, 1.296 and 1.337 MeV for each interaction. For first excited state 2$^+_1$, DJ16A interaction gives 1.786 MeV excitation energy, while USDB interaction predicts this state to be at 2.111 MeV. Experimental value is 1.879 MeV which indicates that DJ16A interaction provides better agreement for 2$^+$ state of $^{24}$Si, with the experiment. In $^{25}$Si, only g.s. spin-parity is measured experimentally and spin-parity of excited states are unknown. Microscopic interactions are unable to reproduce spin of the g.s. In case of $^{26}$Si, we observe from the spectrum that microscopic interactions produce lower excited states at small excitation energies, specially 0$^+_2$, in comparison with the experiment. The $s_{1/2}$ proton orbital occupancy increases with excitation energy according to the USDB calculations as 0.58 for 0$^+_1$, 0.68 for 2$^+_1$, 1.03 for 2$^+_2$ and with DJ16A as 0.84 for 0$^+_1$, 0.92 for 2$^+_1$, 1.05 for 2$^+_2$. For $^{27}$Si, correct g.s. spin is reproduced with microscopic DJ16A only, which has the configuration of \(|\pi(d_{5/2}^5) \otimes \nu(d_{5/2}^1)\rangle\) with probability of 16.42%. USDB interaction also predicts 5/2$^+$ as the g.s. of $^{27}$Si with the same configuration as found in case of DJ16A interaction with 27.36% probability. The IM-SRG and CCEI give the major configurations in wave functions from \(|\pi(d_{5/2}^5) \otimes \nu(d_{5/2}^1)\rangle\) and \(|\pi(d_{5/2}^5s_{1/2}^1) \otimes \nu(d_{5/2}^1s_{1/2}^1)\rangle\) with probabilities of 9.27% and 13.24%, respectively, as reported in Ref. [22]. With DJ16A, energy of 1/2$^+_1$ is 0.711 MeV which is close to the experimental value of 0.781 MeV. The energy spectra with N3LO interaction is compressed as compared to the other interactions.

$^{28}$Si and $^{29}$Si have been studied in [30], where, small excitation energies of 2$^+_1$ and 4$^+_1$ due to small \(N = 14\) shell gap, and configurations of 0$^+_1$ and 0$^+_2$ states for $^{28}$Si have been described. We have added some excited states with all four interactions and have also studied spectroscopic properties (in Section VI). $^{28}$Si nucleus is the closed subshell nucleus which contains 6 valence protons and 6 valence neutrons. We obtain correct ordering of the states up to 0$^+_2$ in $^{28}$Si with each interaction. Energy difference between g.s. and first excited state is 1.068, 1.145, 1.296 and 1.337 MeV for each interaction. For first excited state 2$^+_1$, DJ16A interaction gives 1.786 MeV excitation energy, while USDB interaction predicts this state to be at 2.111 MeV. Experimental value is 1.879 MeV which indicates that DJ16A interaction provides better agreement for 2$^+$ state of $^{24}$Si, with the experiment. In $^{25}$Si, only g.s. spin-parity is measured experimentally and spin-parity of excited states are unknown. Microscopic interactions are unable to reproduce spin of the g.s. In case of $^{26}$Si, we observe from the spectrum that microscopic interactions produce lower excited states at small excitation energies, specially 0$^+_2$, in comparison with the experiment. The $s_{1/2}$ proton orbital occupancy increases with excitation energy according to the USDB calculations as 0.58 for 0$^+_1$, 0.68 for 2$^+_1$, 1.03 for 2$^+_2$ and with DJ16A as 0.84 for 0$^+_1$, 0.92 for 2$^+_1$, 1.05 for 2$^+_2$. For $^{27}$Si, correct g.s. spin is reproduced with microscopic DJ16A only, which has the configuration of \(|\pi(d_{5/2}^5) \otimes \nu(d_{5/2}^1)\rangle\) with probability of 16.42%. USDB interaction also predicts 5/2$^+$ as the g.s. of $^{27}$Si with the same configuration as found in case of DJ16A interaction with 27.36% probability. The IM-SRG and CCEI give the major configurations in wave functions from \(|\pi(d_{5/2}^5) \otimes \nu(d_{5/2}^1)\rangle\) and \(|\pi(d_{5/2}^5s_{1/2}^1) \otimes \nu(d_{5/2}^1s_{1/2}^1)\rangle\) with probabilities of 9.27% and 13.24%, respectively, as reported in Ref. [22]. With DJ16A, energy of 1/2$^+_1$ is 0.711 MeV which is close to the experimental value of 0.781 MeV. The energy spectra with N3LO interaction is compressed as compared to the other interactions.
FIG. 1. Low-lying energy spectra for Si isotopes in the range $A = 26 - 34$. 
So, we have computed both spin states with all four interactions. In $^{34}$Si, energy spectra obtained with DJ16A and USDB interactions are very similar. The $^{34}$Si has completely filled neutron $sd$ orbitals. For g.s., proton configuration with all four interactions is $|\pi(d_5^6 s_1^1)\rangle$. For the $2^+_1$ and $2^+_2$, the configurations are $|\pi(d_5^6 s_1^1 d_1^3)\rangle$ and $|\pi(d_5^6 d_1^3 d_1^3)\rangle$ with probabilities of 89.71 and 88.77%, respectively, corresponding to DJ16A interaction. The same configuration is achieved by USDB interaction for above mentioned states with 87.61 and 89.84% probabilities, respectively.

**B. P isotopes**

$^{25}$P is the least stable isotope while $^{31}$P is the most stable. For $^{24}$P and $^{25}$P, only g.s. is experimentally measured with unconfirmed spin-parity ($1^+$) and (1/2$^+$), respectively. Nuclear shell model calculations with all four interactions confirm g.s. to be 1/2$^+$ for $^{25}$P. The $^{26}$P has g.s. with tentative spin (3)$^+$, experimentally. The USDB interaction provides confirmation to g.s. spin, while other interactions fail to do so. In case of $^{25}$P, spin-parity of g.s. is 3$^+$ experimentally, which is well reproduced by the empirical interaction, whereas microscopic interactions predict the g.s. to be 2$^+$. First excited state has the spin of (2$^+$), experimentally, which is 105.6 keV above the g.s. The energy difference between $2^+$ and $3^+$ states is 337, 266 and 229 keV corresponding to N3LO, JISP16 and DJ16A interactions, respectively. With USDB interaction, $2^+$ is 13 keV above the $3^+$ state. Analysing the configurations of $3^+$ and $2^+$ states, it seems that both states have the same configuration of $|\pi(d_5^6 s_1^1)\rangle \otimes \nu(d_5^6 d_1^3)\rangle$ with USDB and DJ16A interactions. It is observed that the energy spectra of N3LO and JISP16 interactions are quite compressed. The first $1^+$ state with the configuration $|\pi(d_5^6 s_1^1)\rangle \otimes \nu(d_5^6 d_1^3)\rangle$ obtained from the USDB and DJ16A interactions is found at higher energy in the spectrum than N3LO and JISP16.

In $^{25}$P, dominant configuration of excited state $3/2^+$ comes from the excitation of proton from $s_{1/2}$ to $d_{5/2}$ with probabilities 32.50% and 15.14% using USDB and DJ16A interactions, respectively. Other interactions produce this configuration with very small probabilities. Energy of excited states $3/2^+$ and $5/2^+$ is best reproduced with USDB followed by DJ16A for $^{31}$P. Experimentally, the g.s. spin for odd-P isotopes is $1/2^+$ and the first excited state is $3/2^+$ except in case of $^{25}$P, for which, first excited state is not measured yet. DJ16A and USDB interactions reproduce the g.s. and first excited state correctly for odd-P isotopes, except for $^{27}$P. For $^{27}$P, DJ16A yields the first excited state as $5/2^+$. The proton configurations with USDB and DJ16A interactions are $|\pi(d_5^6 s_1^1)\rangle$ for g.s. and $|\pi(d_5^6 d_1^3)\rangle$ for the first excited state with maximum probabilities. As neutrons increase from $A = 25$ onwards, they sequentially occupy $d_{5/2}$, $s_{1/2}$ and $d_{3/2}$ orbitals for ground and first excited states with maximum probabilities, except for $^{31}$P. For $^{31}$P, the configurations of $3/2^+$ state are $|\pi(d_5^6 s_1^1 d_1^3)\rangle \otimes \nu(d_5^6 d_1^3)\rangle$ and $|\pi(d_5^6 d_1^3)\rangle \otimes \nu(d_5^6 s_1^1 d_1^3)\rangle$ for DJ16A interaction with probabilities of 10.15 and 9.29%. With USDB interaction, the same configuration is obtained with 15.80 and 15.34% probabilities.

Energies of g.s. for Si and P isotopes relative to g.s. of $^{16}$O with mass number $A = 23 - 34$ and $A = 24 - 35$ are depicted in Fig. 3. As the number of neutrons in Si and P isotopes increases from $A = 23/24$ to $A = 34/35$, the energy difference between theory and experiment increases for all three microscopic interactions. The N3LO and JISP16 interactions overbind the g.s., while DJ16A interaction slightly underbinds the g.s. (which is discussed in Section V). It is expected that the N3LO results can be improved by the inclusion of three-body forces. The DJ16A and JISP16 interactions are fitted only up to $A = 16$ nuclei which give rise to deficiencies in results of Si and P isotopes. However, the former is monopole modified version of the DJ16 interaction, it produces better results than the JISP16. To get more accurate results with DJ16A, non-monopole modifications are needed for further tuning of TBMEs. It is also possible to resolve these discrepancies by the use of (i) primary effective Hamiltonian with larger NCSM $N_{\text{max}}$ parameter, (ii) three-body components induced by the OLS transformation ($\alpha = 3$ cluster approximation), and (iii) three-nucleon interaction in the NCSM Hamiltonian in addition to realistic NN interaction.

In Fig. 4, we have shown the excitation energy of $2^+_1$ state for Si isotopes with neutrons $N = 10 - 20$. USDB interaction gives better agreement with the experimental data for Si isotopes, except for $^{34}$Si. We can clearly observe from the experimental data that there is a shell gap at $N = 20$ for Si isotopes. For $^{34}$Si, DJ16A and USDB interactions produce large excitation energy for $2^+$ state compared to that obtained from the experiment by excitation of a proton from $d_{5/2}$ to $s_{1/2}$ orbit which shows a large subshell gap at $Z = 14$, explained in the next section. Hence, $^{34}$Si is a doubly magic nucleus with a major closed neutron shell $N = 20$ and a closed proton subshell $Z = 14$. To reproduce the excitation energy of $2^+$, inclusion of neutron excitations from the $sd$-shell to $pf$-shell across the $N = 20$ shell gap is needed as suggested in Ref. [36].

Similarly, we have plotted energy splitting between $3/2^+_1$ and $1/2^+_1$ states with respect to neutron numbers for phosphorous isotopes in Fig. 5. Excited $3/2^+_1$ state has not yet been found for $N = 10$. So, we have predicted the energy of this state with different interactions. The DJ16A interaction gives the same trend as obtained from experiment for phosphorus isotopes. $^{35}$P has one proton hole beyond $Z = 16$ with $N = 20$, hence, lowest $3/2^+$ excited state is produced by the excitation of proton from $s_{1/2}$ to $d_{3/2}$ orbital. Large energy splitting between $3/2^+_1$ and $1/2^+_1$
FIG. 2. Low-lying energy spectra for P isotopes in the range $A = 27 - 35$. 
FIG. 3. Comparison of experimental g.s. energy [62] with the shell model results for Si and P isotopes with respect to g.s energy of $^{16}$O.

FIG. 4. Excitation energy of first $2^+$ state for Si isotopes from $N = 10$ to 20. Experimental data are taken from [62].

FIG. 5. Energy splitting between $3/2^+$ and $1/2^+$ states for P isotopic chains from $N = 10$ to 20. Experimental data are taken from [62].
at \( N = 20 \) indicates a shell gap at \( Z = 16 \), although this shell gap is smaller than shell gap observed at \( Z = 14 \).

IV. EFFECTIVE SINGLE-PARTICLE ENERGIES: MONOPOLE PROPERTIES

The Hamiltonian can be classified into monopole and multipole (pairing, quadrupole-quadrupole correlations etc.) parts. The monopole part of the Hamiltonian tells about the spherical nuclear mean fields that give information of filling of nucleons in the single particle states. It provides the position of the single particle orbitals which play important role in describing the evolution of shell gap. In this section, we have shown the proton effective single particle energies (ESPEs) corresponding to N3LO, JISP16, DJ16A and USDB interactions for Si isotopes in Fig. 6. ESPEs describe how single particles energies of \( sd \) orbitals vary as we increase neutrons in the silicon nuclei. In calculation of ESPEs, monopole term of two-body interaction is needed which is given by

\[
V(jj') = \frac{\sum_J (2J + 1) \langle jj'; J | V | jj'; J \rangle}{\sum_J (2J + 1)}.
\]  

(4)

Monopole interaction shows an average effect between two nucleons in orbits \( j \) and \( j' \). This monopole interaction changes the single-particle energy and consequently the shell gaps as we add more nucleons. Thus, spin-tensor decomposition of the monopole interaction is carried out in next section to understand the origin of this shell evolution. Effective single-particle energy and role played by different components of the two-body interaction in the shell evolution had been discussed in several papers [51, 63–69].

Si is a mid shell nuclei, for which, configurations of states have contributions from both protons and neutrons. From Fig. 6, we can see that ESPEs of orbitals \( d_{5/2} \) and \( s_{1/2} \) are very close to each other for N3LO interaction due to small difference between \( V^{\text{pn}}_{d_{5/2}d_{5/2}} \) and \( V^{\text{pn}}_{s_{1/2}d_{5/2}} \) centroids at \( ^{28}\text{Si} \). ESPEs of orbitals \( s_{1/2} \) and \( d_{3/2} \) are inverted for N3LO, while for JISP16 and USDB interactions, these orbitals almost overlap in \( ^{28}\text{Si} \). We note...
that $V_{d_5/2}^{pn}$ is less attractive, while $V_{d_3/2}^{pn}$ is more attractive for N3LO and JISP16 than centroids for DJ16A and USDB, thus, proton $d_{5/2} - d_{3/2}$ spin-orbital splitting is smaller for N3LO and JISP16 than obtained from DJ16A and USDB at $N = 14$. As mentioned in the previous section, there is high-lying $2^+_1$ state for $^{34}$Si predicted by DJ16A and USDB interactions, this high excitation energy is due to sufficiently large energy difference between $d_{5/2}$ and $s_{1/2}$ orbitals. So, it can be argued that there is a subshell closure at $Z = 14$ for Si isotopes. This shell gap increases from N3LO to JISP16 to DJ16A to USDB interaction, thus, excitation energy for this state increases accordingly. It is also observed that the shell gap at $N = 16$ between orbitals $s_{1/2}$ and $d_{3/2}$ is very small for microscopic N3LO interaction as compared to other interactions.

V. SPIN-TENSOR DECOMPOSITION OF THE TWO-BODY INTERACTION

To understand the contributions from different components of two-body interactions, we have carried out spin-tensor decomposition. A two-body interaction can be written as

$$V = \sum_{k=0,1,2} (S^{(k)}, Q^{(k)}) = \sum_{k=0,1,2} V^{(k)},$$

(5)

where, $k$ runs over 0, 1, 2. The term with $k = 0$ indicates the central component, the term with $k = 1$ the vector component and the term with $k = 2$ the tensor component. $S^{(k)}$ are spherical tensors of rank $k$ in spin space, constructed for spin-1/2 nucleons and $Q^{(k)}$ are spherical tensors of rank $k$ in coordinate space. The 1 and $(\sigma_1^1, \sigma_2^k)$ operators correspond to the spin part of the central component of the effective interaction. The spin part of the tensor component is given by $[\sigma_1^1 \times \sigma_2^k]^{(2)}$. The vector component includes symmetric spin-tensor forces, which have operators $\sigma_1^1 + \sigma_2^k$ and antisymmetric spin-tensor forces, which have operators $\sigma_1^1 - \sigma_2^k$ and $[\sigma_1^1 \times \sigma_2^k]^{(1)}$.

To determine the spin-tensor decomposition of the two-body interaction, firstly, one has to transform two-body matrix elements to LS-coupling from jj-coupling as follows

$$\langle n_a l_a n_b l_b : L S, J T | V | n_c l_c n_d l_d : L' S', J T \rangle = \sum_{j_a j_b} N_{l_a l_b}^N j_a j_b \sqrt{(2L+1)(2S+1)(2j_a+1)(2j_b+1)} \begin{vmatrix} l_a & l_b & L \\ j_a & j_b & S \end{vmatrix} \begin{vmatrix} l_c & l_d & L' \\ j_c & j_d & S' \end{vmatrix} \langle n_a l_a j_a n_b l_b j_b : J T | V | n_c l_c j_c n_d l_d j_d : J T \rangle,$$

(6)

where, normalization factor $N_{l_a l_b}$ is

$$N_{l_a l_b} = \frac{1}{\sqrt{2(1 + \delta_{l_a l_b})}}.$$
In LS-coupling, matrix elements of each component of the two-body interaction are written as

$$\langle a_1 a_2 n_b | V | n_c l_c n_d d : L' S' J' T' \rangle = (2k + 1)(-1)^{J'} \sum J (-1)^J (2J + 1)$$

$$\times \left\{ \begin{array}{ccc} L & S & J' \\ S' & L' & k \end{array} \right\} \langle a_1 a_2 n_b | V | n_c l_c n_d d : L' S' J' T' \rangle .$$

In this section, we have studied the monopole matrix elements of the total, central, vector and tensor components for T = 0 and T = 1 channels for the N3LO, JISP16, DJ16A and USDB interactions, which are shown in Fig. 7. Total monopole term of T = 0 channel is more attractive for all interactions as compared to T = 1 channel. We can see that the central forces play a dominant role in total two-body interaction. The vector monopole terms of $V_{s_{1/2} s_{1/2}}$ are zero for T = 0 and T = 1 channels. The tensor monopole terms of $V_{d_{5/2} d_{5/2}}$ and $V_{s_{1/2} d_{3/2}}$ are zero corresponding to all interactions for both channels. For $V_{d_{5/2} d_{5/2}}$ centroid, central term is more attractive and tensor term is smaller for DJ16A and USDB than N3LO and JISP16. For the central component, the monopole matrix element of $V_{s_{1/2} s_{1/2}}$ for T = 0 channel of DJ16A interaction is less attractive in comparison with other interactions. Both T = 0 and T = 1 vector monopole terms are relatively flat for all interactions. The T = 0 tensor monopole term of $V_{d_{5/2} d_{5/2}}$.

### TABLE I. Comparison of calculated reduced electric quadrupole transition strengths using different interactions of Si and P nuclei, with the experimental data [62]. The B(E2) values are in e²fm⁴.

| Nuclei | A | $J_i^p \rightarrow J_f^p$ | N3LO | JISP16 | DJ16A | USDB | Exp. |

$V_{d_5/2d_3/2}$ and $V_{d_3/2d_3/2}$ are stronger than $T = 1$ tensor monopole. The total, central, vector and tensor monopoles of $V_{d_5/2d_3/2}$ of $T = 0$ channel for N3LO interaction are -2.079, -2.612, -0.116 and 0.649 MeV, which means tensor forces give significant contribution in total two-body interaction. The DJ16A $T = 1$ total monopoles are similar to those obtained with USDB interaction except for $V_{s_{1/2}s_{1/2}}$, for which, the former is attractive and latter is repulsive but with small variation.

It is noted that the DJ16A interaction underbinds the energies of g.s. for Si and P isotopes. From the above understanding of TBMEs of the interactions, we can say that this underbinding is related to the central part of $T=0$ channel which is more attractive for USDB interaction than DJ16A interaction and overbinding of N3LO and JISP16 results occur due to attractive $T = 1$ centroids.

VI. ELECTROMAGNETIC PROPERTIES

In this section, we have presented reduced electric quadrupole transition strengths, electric quadrupole and magnetic dipole moments for Si and P isotopes. We have shown a comparison between theoretical and available experimental data.

First, we focus on the B(E2) transition strengths for Si and P isotopes. In Table I, B(E2) transition strengths using microscopic as well as USDB interactions for the selected transitions are reported. Each microscopic interaction predicts enhanced transition strength for $2^+_1 \to 0^+_1$ in the case of $^{26,28,30,32,34}$Si, except for DJ16A in $^{30}$Si. Information about collectivity for nuclei can be determined from the B(E2) transition strength. A gradual decrease of B(E2) value for an isotopic chain shows appearance of magic number. Experimentally, as neutrons are increased from $N = 12$ ($^{26}$Si), the B(E2) transition strength from $2^+_1 \to 0^+_1$ decreases in even-even nuclei until the closed shell at $N = 20$ is reached. This trend is observed for the JISP16 and N3LO interactions from $^{28}$Si to $^{34}$Si. Although, the B(E2; $2^+_1 \to 0^+_1$) results for DJ16A are deviated from the experimental pattern, its values are still closer to the experimental data than other two microscopic interactions. For $^{29}$Si and $^{30}$Si, transitions from $3/2^+_1 \to 1/2^+_1$ and $1^+_1 \to 2^+_1$, respectively, obtained from both JISP16 and N3LO interactions, are significantly weaker than that found experimentally. We have also predicted B(E2) transition strength for $5/2^+_1 \to 1/2^+_1$ ($^{29,35}$P), $3^+_1 \to 1^+_1$ ($^{32}$P) and $3/2^+_1 \to 1/2^+_1$ ($^{33}$Si, $^{35}$P). It seems from these data that B(E2) is very sensitive to the details of the wave-functions, thus, further improvement in DJ16A is required.

Now, we discuss the electric quadrupole and magnetic dipole moments of either g.s. or (and) first excited state...
TABLE III. Comparison of calculated shell model spectroscopic factor strengths with the experimental data. Experimental excitation energies and $C^2S$ of the states of $^{28}\text{Si}$ are taken from the Ref. [54]. Different $l$ and $j$ values for each state of $^{31}\text{Si}$ are shown in columns III and IV.

| $E_x$ (KeV) | $J^\pi$ | $l$ | $j$ | N3LO | JISP16 | DJ16A | USDB | Exp. |
|-------------|---------|-----|-----|------|--------|-------|-------|------|
| 0           | $0^+_1$ | 2   | 5/2 | 2.49 | 2.32   | 2.92  | 3.42  | ≤ 2.8 |
| 1874(3)     | $2^+_1$ | 0   | 1/2 | 0.07 | 0.26   | 0.28  | 0.25  | 0.6(2) |
|             |         | 2   | 3/2 | 0.01 | 0.02   | 0.009 | 0.03  | 0.07(2) |

|             |         | 2   | 5/2 | 0.16 | 0.08   | 0.00  | 0.001 | 0.004(3) |
|             | (0$^+_4$) | 2  | 5/2 | 0.23 | 0.47   | 0.17  | 0.24  | 0.8(4) |

(Additionally, 5/2$^+_1$ of $^{31}\text{P}$ also), which are shown in Table II. We have selected only those states for which experimental data of either quadrupole or magnetic moment or both are available, to check the predictive power of our theoretical shell model interactions. Calculated quadrupole moment using all interactions for $^{28}\text{Si}$ and $^{28}\text{P}$ are in reasonable agreement with the experiment. Effective single particle (SP) quadrupole moment of 5/2$^+$ corresponding to last unpaired neutron in $d_{5/2}$ orbital is 0.022 eb for $^{28}\text{Si}$. Experimental and calculated shell model values are quite larger than the SP value. As discussed earlier that probability of the configuration $|\pi(d_{5/2}^0)\otimes\nu(d_{3/2}^1)|$ is very small, so, collective feature is developed in this state. For $^{30}\text{Si}$, sign of quadrupole moment for 2$^+$ is reproduced correctly only by the DJ16A interaction. We also observe a shape change from $^{28}\text{Si}$ to $^{30}\text{Si}$ with DJ16A that supports the experimental data. The $^{28}\text{Si}$ has an oblate deformation, whereas $^{30}\text{Si}$ is found nearly spherical. For 3/2$^+$ in $^{33}\text{Si}$, effective SP quadrupole moment is obtained as 0.018 eb. The experimental data is not available to examine the single particle nature of this state. Thus, we have calculated the quadrupole moment with each interaction and noted that the quadrupole moment decreases from N3LO to JISP16 to DJ16A to USDB, still far from the SP value. We have predicted the quadrupole moment for $^{31}\text{P}$ and $^{33}\text{P}$ that will be helpful in future experimental study.

Magnetic moment of 2$^+$ using all interactions are in good agreement with the experimental data for $^{28}\text{Si}$. The SP magnetic moments for $^{27}\text{Si}$, $^{29}\text{Si}$ and $^{33}\text{Si}$ are -1.913, -1.913 and 1.148 $\mu_N$ for last neutron in $d_{5/2}$, $s_{1/2}$ and $d_{3/2}$ orbitals, respectively. The sign of magnetic moment for 5/2$^+$ state in $^{27}\text{Si}$ has not been confirmed experimentally yet. The N3LO and JISP16 interactions give positive sign of magnetic moment for g.s., while DJ16A and USDB predict negative sign that is favoured by the sign of SP moment. In case of $^{29}\text{Si}$, our microscopic interactions reproduce the correct sign of magnetic moment for 1/2$^+$ state with underestimated values. Since there is large configuration mixing for these states, they show collective behavior. Experimental g.s. magnetic moment of 1.21(3) $\mu_N$ for $^{33}\text{Si}$ is close to the SP magnetic moment. The 3/2$^+$ state has the configuration $|\pi(d_{5/2}^0)\otimes\nu(d_{3/2}^1)\otimes\nu(s_{1/2}^1/2\otimes d_{3/2}^1)|$ with 69.14 % and 77.99 % of probabilities according to DJ16A and USDB interactions, respectively, so, their magnetic moments of 1.325 and 1.206 $\mu_N$ match well with the SP moment. On the other hand, the magnetic moments for N3LO and JISP16 are slightly deviated from the SP magnetic moment because these interactions generate the same configuration with 38.52 % and 48.75 % of probabilities, respectively. $^{33}\text{Si}$ is one neutron hole nuclei beyond N = 20 shell closure, thus, it is more likely to show single particle structure.

Experimental magnetic moment of g.s. for $^{29,31}\text{P}$ is significantly smaller than the SP magnetic moment (2.793 $\mu_N$), revealing mixed configurations in its wave-functions. Magnetic moment of 1/2$^+$ improves from N3LO to JISP16 to DJ16A for $^{29,31}\text{P}$, still difference between calculated and experimental value is large. There is no experimental data available for $^{35}\text{P}$. So, we have given prediction for 1/2$^+$ state using all interactions. The g.s. is dominated by the proton configuration of $|\pi(d_{5/2}^0s_{1/2}^1)|$ with 68-92 % probability using different interactions. SP magnetic moments for 1/2$^+$ is 2.793 $\mu_N$ that is not close to the calculated shell model results. Thus, we have used different effective values [59] as $g^p_t = 1.174$, $g^p_s = 5.00$, $g^n_t = -0.11$, $g^n_s = -3.44$ and obtained magnetic moment for N3LO, JISP16, DJ16A and
USDB are 1.634, 1.696, 1.712 and 1.806 $\mu_N$, respectively. Now, the effective SP moment is 2.5 $\mu_N$ which indicates that difference between the shell model and SP values is reduced.

VII. SPECTROSCOPIC FACTOR FOR $^{24}$Si

In the present study, spectroscopic factor strengths for g.s. and excited states of $^{24}$Si from one proton transfer reaction $^{23}$Al$(d,n)^{24}$Si are calculated within the shell model using microscopic effective N3LO, JISP16, DJ16A and empirical USDB interactions. These results are compared with the extracted experimental values [54] in table III. One proton is captured in $l = 0$ and 2 orbitals to populate the states of $^{24}$Si. Some states of $^{24}$Si are generated by capturing one-proton in $d_{5/2}$ orbital only and some, from the mixing of $d_{5/2}$ and (or) $s_{1/2}$ and (or) $d_{3/2}$ orbitals. In Ref. [54], experimental spectroscopic factors ($C^2S$), which are shown in last column of Table III, have been extracted using the relation:

$$C^2S_{\exp} = \frac{C^2S_{\text{theo}} \times \sigma_{\text{theo}}^i}{\sum_{i'} (C^2S_{\text{theo}}^i \times \sigma_{\text{theo}}^i)} \times \frac{\sigma_{\exp}^i}{\sigma_{\text{theo}}^i}, \quad (8)$$

where, $C^2S_{\text{theo}}$ were calculated corresponding to USDB-cdpn interaction using the shell model [38] and $i$ represents individual quantum numbers. Extracted experimental $C^2S$ [54] for $0^+_1$ state is $\leq 2.8$ which is in good agreement with previous experimental value 2.7(2) of $C^2S$ [53]. The N3LO, JISP16 and DJ16A interactions give the $C^2S$ as 2.49, 2.32 and 2.92, respectively, while the $C^2S$ 3.42 is obtained with USDB which is quite away from the experimental value. The calculated $C^2S$ for g.s. of $^{24}$Si is very large which shows single-particle nature of this state. Experimental excited states of $^{24}$Si are tentative. For first $2^+$, experimentally extracted $C^2S$ is much smaller for $d_{3/2}$ transfer than $d_{5/2}$ and $s_{1/2}$. Except for N3LO interaction, all interactions predict smallest value for $d_{3/2}$ transfer. The calculated $C^2S(s_{1/2})$ for $(2^+_2)$ state is in reasonable agreement with experimental value. For $(0^+_2)$ state, theoretical $C^2S$ is slightly smaller than experimental data.

In the recent work [72], spin-parity assignment has been made for excited states of $^{24}$Si. The second excited state of $^{24}$Si was confirmed to be $2^+_2$. Also, the state at 3471 keV of $^{24}$Si is confirmed as $0^+_3$ instead of $4^+_1$.

VIII. CONCLUSION

In the present work, we have implemented the nuclear shell model with newly constructed microscopic effective interactions to study Si and P isotopes with neutron number $N = 9 – 20$. These microscopic NN interactions, which are obtained from the NCSM wave functions and OLS transformation method, are chiral N3LO, JISP16 and DJ16A. Microscopic results are compared with phenomenological results using USDB interaction and experimentally measured data. We have studied the energy spectra of Si and P isotopes lying in sd-shell. We found that monopole modified DJ16 interaction (DJ16A) results for energy spectra are better than the other microscopic interactions and the proton subshell closure at $Z = 14$ persists in Si. Still, some corrections are needed in DJ16A to reproduce the experimental data. Our calculated results for upper sd shell nuclei will be helpful to further investigate the modifications such as $T = 0$ monopole components, quadrupole-quadrupole and pairing correlations that should be incorporated in this microscopic interaction.

Variation of proton effective single-particle energies for Si isotopes are presented using all the interactions to determine the shell evolution. To understand the contribution from different components of the two-body matrix elements in the shell evolution, we have also studied the spin-tensor decomposition of the effective interactions. Apart from low-lying energy spectra, electromagnetic observables have been also calculated for complete description of these nuclei. Spectroscopic factor strengths for $^{24}$Si are calculated, which is of importance in astrophysical scenario. It is reported that the $C^2S$ for g.s. with microscopic interactions is better reproduced than that obtained from USDB interaction.
