1. INTRODUCTION

We study the problem of point-to-point distance querying for massive scale-free graphs, which is important for numerous applications. Given a directed or undirected graph, we propose to build an index for answering such queries based on a novel hop-doubling labeling technique. We derive bounds on the index size, the computation costs and I/O costs based on the properties of unweighted scale-free graphs. We show that our method is much more efficient and effective compared to the state-of-the-art techniques, in terms of both querying time and indexing costs. Our empirical study shows that our method can handle graphs that are orders of magnitude larger than existing methods.

Problem Definition. Let $G = (V, E)$ be a directed unweighted graph, with vertex set $V$ and edge set $E$. Each edge $(u, v) \in E$ has a length of $\text{dist}_G(u, v) = 1$. Given an edge $(u, v)$, we say that $v$ is an out-neighbor of $u$, and $u$ is an in-neighbor of $v$. A path $p = (v_1, \ldots, v_i)$ is a sequence of $i$ vertices in $V$ such that for each $v_i (1 \leq i < l), (v_i, v_{i+1}) \in E$. We also denote $p$ by $v_1 \sim v_i$. The length of a path $p$, denoted by $\ell(p)$, is the sum of the lengths of the edges on $p$. Given $u, v \in V$, the distance from $u$ to $v$, denoted by $\text{dist}_G(u, v)$, is the minimum length of all paths from $u$ to $v$. If no path $u \sim v$ exists, then $\text{dist}_G(u, v) = \infty$. A path $u \sim v$ with a length of $\text{dist}_G(u, v)$ is a shortest path from $u$ to $v$. We study the following problem: given a static directed unweighted scale-free graph $G = (V, E)$, construct a disk-based index for processing point-to-point (P2P) distance queries, where a P2P distance query $\text{dist}(s, t)$ is: given $s, t \in V$, find $\text{dist}_G(s, t)$.

Although distance querying can be readily handled by Dijkstra’s algorithm [16], the emergence of large networks such as social networks, RDF graphs, and phone networks has created new challenges. The problem of P2P distance querying has been well studied for road networks. Some previous works include [3, 28, 19, 9, 27, 29, 31]. For other graph types, many indexing methods have been proposed. However, the previous works of [12, 14, 15, 20, 30, 33, 34] can only handle relatively small graphs due to high index construction cost and large index storage space. For the 2 largest real graphs tested in these studies, we have $|V| = 581K$ and $|E|/|V| = 2.45$ [12], and $|V| = 694K$ and $|E|/|V| = 0.45$ [20], respectively. The more recent works of IS-Label in [18] and the pruned landmark labeling (PLL) scheme in [7] can handle bigger graphs. Both are 2-hop labeling methods [15].

Challenges. While the labeling technique has been adopted by the state-of-the-art indexing algorithms, there are some major challenges related to this technique. The first challenge is that no existing work has been able to provide a guarantee of a small label size. The total label size is $O(|V|^2)$ and in the worst case, this is the same size as that of a pairwise distance table. For general graphs, it is shown that there exist graphs $G = (V, E)$ for which any 2-hop labeling index must have a total size of $\Omega(|E||V|^{1/2})$ [15]. This high index space complexity will be impractical for large graphs.

The second challenge, which is related to the first, is that no existing work has been able to give an acceptable bounded complexity on the computation time and the runtime memory space required for the label construction. Most existing works are in-memory algorithms and require huge memory consumption. The only existing work that has bounded memory consumption is IS-Label [18]. IS-Label builds a hierarchy from the given graph by extracting at each level an independent vertex set. The remaining graph at each step is augmented with edges to preserve distances among the remaining vertices. Labels are constructed top-down in the hierarchy. The hierarchy need not be completed so that a residual graph $G_k$ may remain in memory and querying is handled by both the labels and a bi-Dijkstra search in $G_k$. However, IS-Label has no guarantee of a small label size, and also no guarantee on the scalability of the label construction time. Another problem of IS-Label is that to limit the number of iterations, $k$, during the label construction, instead of building a full index, a residual graph $G_k$ is kept in main memory. However, this is not a pure indexing method since it requires loading $G_k$ before querying, and the size of $G_k$ can be large.

For the existing in-memory algorithms including [15, 33, 20, 7], the time complexity ranges from $O(|V|^2)$ to $O(|E||V|)$. For the PLL scheme in [7], the actual time performance is much better than the $O(|E||V|)$ bound. However, PLL is main memory based and

is not scalable because of a breadth first search process for every vertex and a pruning process that requires the label index to reside in memory. Hence, a very large main memory is needed that not only can hold the input graph but also the entire label index with extra storage for computation. Using 4GB RAM, the biggest graph reported in [7] to be handled by PLL is a little over 1GB in size since the label size is 22GB. Except for IS-Label, all of the above algorithms assume that the given graph can fit in memory, which may not be true for massive networks. Hence, scalability remains a major challenge.

We propose a new indexing method for distance querying to meet the above challenges. Our design is based on the properties of unweighted scale-free graphs, which are prevalent in the real world [1, 10, 17, 25]. Important applications such as social networks, web and most of the collected datasets in [1] belong to this type of graphs. We offer guaranteed complexity bounds on the label size, the computation costs and I/O costs. With only 4GB RAM, we are able to build an index for a graph of 9GB in size, with hundreds of millions of vertices and edges. Our method is based on a novel iterative process which minimizes the label size growth at each iteration, leading to highly effective labeling for the index.

Our main contributions are summarized as follows: (1) We propose a novel 2-hop labeling indexing method for P2P distance querying on unweighted directed graphs, and have developed I/O-efficient algorithms for index construction when the given graph and the index cannot fit in main memory. (2) Based on the properties of unweighted scale-free graphs, we derive the following complexity bounds for our index: the index size is $O(h|V|)$, the computational cost is $O(|V|\log M(|V|/M) + \log |V|)$, and the I/O cost is $O(|V|\log V/B)$, where $h$ is a constant, $M$ is the memory size and $B$ is the disk block size. (3) We verify the performance of our method with experiments on large real-world scale-free networks.

The paper is organized as follows. Section 2 discusses the relevant properties of scale-free graphs. Section 3 introduces our main algorithm Hop-Doubling. Section 4 describes the I/O-efficient algorithms. Section 5 introduces the Hop-Stepping strategy for performance enhancement. Section 6 is a discussion about the adaptations to un-directed and weighted graphs, and about the use of our method for general graphs. We report our empirical study in Section 7, and conclude in Section 8.

## 2. 2-HOP LABELING FOR SCALE-FREE GRAPHS

The 2-hop labeling technique constructs labels for vertices, and a distance query for $s$, $t$ can be answered by looking up the labels of $s$ and $t$ only. Each label is a set of label entries and each label entry is a pair $(v, d)$ where $v \in V$ and $d$ is a distance value. We say that $v$ is a pivot. For a directed graph $G = (V, E)$, we create two labels $L_{in}(v)$ and $L_{out}(v)$ for each vertex $v \in V$ so that if $\text{dist}_G(s, t) \neq \infty$, then we can find a pivot $u$ such that $(u, d_1) \in L_{out}(s)$, $(u, d_2) \in L_{in}(t)$ and $d_1 + d_2 = \text{dist}_G(s, t)$, and there does not exist any $u'$ such that $(u', d_1') \in L_{out}(s)$, $(u', d_2') \in L_{in}(t)$ and $d_1' + d_2' < \text{dist}_G(s, t)$. We say that the pair $(s, t)$ is covered by $u$. Hence, the distance query $\text{dist}_G(s, t)$ can be answered by looking up $L_{out}(s)$ and $L_{in}(t)$ for such a pivot $u$ with the smallest $d_1 + d_2$.

The set of labels for all vertices is called a 2-hop cover. The complexity of finding a minimum 2-hop cover is shown to be $\text{NP}$-hard [15], and known approximate algorithms are also very costly [20]. However, in the following discussion, we will show that certain ordering of vertices may give rise to a good 2-hop cover, which sheds some light on this hard problem.

## 2.1 Ordering of Vertices for Labeling

The importance of the ordering of vertices can be illustrated by some very simple graphs. In Figure 1, we show a graph $G_R$ for representing a simple road system. $G_R$ is undirected, but we can treat it as directed since each edge can be seen as bidirectional. Table 1 is a 2-hop cover for $G_R$ where $L(v) = L_{in}(v) = L_{out}(v)$. The 2-hop cover is minimal, meaning that we cannot delete any label entry and still maintain the correctness of distance query evaluation. The entries of the form $(v, 0)$ are trivial but are needed for query answering. In Figure 2, we show a star graph, $G_S$. Table 2 is a 2-hop cover for $G_S$ which is also minimal. For example, if we delete $(c, 2)$ from $L(b)$, then for a query of $\text{dist}(b, c)$, we would return an incorrect distance of 4 from $(d, 2)$ in $L(b)$ and $(d, 2)$ in $L(c)$. Note that one can add many useless entries to these covers so that they are still correct but not minimal.

For a given graph, there can be many possible minimal 2-hop covers, and in Tables 3 and 4, we show smaller minimal 2-hop covers for $G_R$ and $G_S$, which reduce the number of non-trivial label entries by half or more when compared with those shown in Tables 1 and 2. Intuitively, for the road network, we are making use of the hub $a$, which lies on the shortest paths for many pairs of vertices. Similarly, we make heavy use of the center $a$ of the star graph, which has a highest degree. The problem of finding a minimum 2-hop cover is to find a smallest set of label entries with pivots that cover the shortest paths for answering all distance queries, and in these special graphs, the hub or center obviously hits the most number of shortest paths. We can set a ranking on the vertices in such a way that higher ranked vertices are likely to hit more shortest paths, and then use higher ranked vertices for pivots, as in the examples. This should result in a smaller label size.

The above idea is more formally treated by the notion of canonical labeling in [4]. If shortest paths are not unique for given $s, t$, we may define canonical labeling as follows. Given a total ranking $r(v)$ of all vertices in $V$, a labeling is canonical if a vertex $v$ is a pivot in $L_{in}(u)$ if and only if there exists a vertex $w$ such that $r(v)$ is the highest among all vertices in all shortest paths from $u$ to $v$, and similarly for $L_{in}(u)$. The labeling is minimal since deleting any pivot creates some uncovered pair of vertices. Canonical labeling calls for the pruning of any entry $(v, d)$ in $L_{out}(u)$ if by looking up $L_{out}(u)$ and $L_{in}(v)$ we find a higher rank pivot $v'$ that gives a
path $p = (u, \ldots, v', \ldots, v)$ with a length $\leq d$. This is because if $v$ is on a shortest path from $u$ to another vertex $w$ which is made up of $p' = (u, \ldots, v)$ of length $d$ and $q = (v, \ldots, w)$, then $v'$ will also be on a shortest path from $u$ to $w$, which is made up of $p$ and $q$. Since $r(v') > r(v)$, $v$ should not be chosen as a pivot here.

Given the importance of ranking as illustrated in the above examples, we expect good indexing results from a good vertex ranking. The independent set approach of IS-Label [18] effectively gives low ranking to low degree vertices. This ordering is found to produce good label sizes. The pruned landmark scheme PLL in [7] builds labels for an unweighted graph by a breadth first search (BFS) from vertices ordered in non-increasing degrees. The search frontiers of BFS are halted at vertices where the label entries are pruned by previously entered entries as described in the above. Note that such pruning has also been proposed in [4]. This ordering by degree is found to be highly effective for many real graphs. In the next subsection, we will derive reasons behind this effectiveness for scale-free graphs. We make use of the definition of hitting sets and a concept similar to the highway dimension introduced in [5, 2] for road networks. However, we should point out that the characteristics of a scale-free graph is very much different from that of a road network.

2.2 Hitting Sets in Scale-free Graphs

A function $f(x)$ is said to be scale-free if $f(ba) = C(b)f(x)$, where $C(b)$ is some constant dependent only on $b$. It is common to call a graph scale-free if the distribution of vertex degrees of the graph follows a power law: \( \text{Prob} (a \text{ vertex has degree } k) \propto k^{-a} \), where $a$ is a positive real number. This is scale-free since if $f(x) = cx^{-a}$, then $f(ba) = c(ba)^{-a} = b^{-a}f(x)$. Typically, $2 \leq a \leq 3$ [13, 11, 17]. Existing works [10, 17, 1, 25] have shown that many real world graphs do follow such power law distributions. Based on the BA model [8] of scale-free graphs, Bollbarus et al. [10] proved that the diameter $D$ of a scale-free random graph is asymptotically

\[
D = \log |V|/\log \log |V|
\]

(1)

Although this is an asymptotic analysis, it gives very accurate prediction for many real world scale-free graphs [1, 32].

Newman et al. [25] studied the properties of scale-free graphs by means of generating functions for the probability distribution of vertex degrees. Let $z_i$ be the average number of vertices that are $i$ hops away from a randomly chosen vertex $v$. It is shown that with very high probability, $z_m = (z_2/z_1)^{m-1}z_1$. Hence, $z_m = (z_2/z_1)z_{m-1}$. Thus, the expansion factor $R$ can be determined by the average number of vertices that are 1 or 2 hops from $v$, respectively, i.e., $R = z_2/z_1$. With an expansion factor of $R$, the diameter of the graph can be estimated to be $D = \log_R |V| = \log |V|/\log R$. From Equation (1), the expansion factor is given by

\[
R = \log |V|
\]

(2)

For a graph $G = (V, E)$ that follows a power law distribution, Faloutsos et al. [17] derived the following relationship between the degree $deg_v$ of a vertex $v$ in $G$ and its rank in terms of the degree. For a vertex $v \in V$, $v$ has the $r(v)$-th highest degree in $G$.

Lemma 1. [17] The degree, $deg_v$, of a vertex $v$, is a function of the rank of the vertex, $r(v)$, and the rank exponent, $\gamma$, as follows:

\[
deg_v = \frac{1}{|V|^\gamma} (r(v)^\gamma)
\]

(3)

In the above, $\gamma$ is a small real number found to be between $-0.8$ and $-0.7$ for many real-world graphs [17]. According to Equation (3), taking $\gamma = -0.8$ for a scale-free graph $G_1 = (V_1, E_1)$, if $|V_1| = 10M$, then less than 500 vertices have degree above 500, and the top-degree vertex $v_0$ has a degree of 63095. From Equation (2), the expansion factor is given by $R = \log |V| \approx 20$. Since $63095 \times 20 > 1M$, $v_0$ is expected to reach all vertices within 2 hops.

Let us call the number of hops (edges) on a path its hop length. Given a set of paths $P$, a hitting set for $P$ is a set of vertices $S$ such that each path $p$ in $P$ contains at least one vertex $v$ in $S$ (we say that $p$ is hit by $v$). For the above graph $G_1$, a single highest degree vertex is expected to hit all shortest paths with length $\geq 4$. In general, we make an assumption of a small hitting set for long shortest paths as follows.

Assumption 1. Given an unweighted scale-free graph $G = (V, E)$, there exist small integers $d_0$ and $h$, and a set $H$ of the highest degree vertices in $V$, such that $v \in V$, if there exist shortest paths $u \leadsto v$ with hop length $\geq d_0$, then one such path is hit by one of $H$ vertices in $V$.

In Assumption 1, $|H| \geq h$. Given Equations (1) to (3), we can show that Assumption 1 holds with $d_0 = 4$ and $h = 1$ for any undirected unweighted scale-free graph $G = (V, E)$ with $|V| \geq 3$, and rank exponent $-0.8 \leq \gamma \leq -0.7$ (typical values in real world graphs [17]). The analysis goes as follows. From Lemma 1, the degree of $v_0$ is given by $|V|^{-\gamma}$ since $r(v_0) = 1$. With an expansion factor of $R$, if $(deg_{v_0} \times R) \geq |V|$, then $v_0$ reaches all vertices in 2 hops. This is the case where $(|V|^{-\gamma} \cdot R) \geq |V|$, and from Equation 2, $R = \log |V|$; hence the inequality becomes $(|V|^{-\gamma} \cdot \log |V|) \geq 1$, and this holds for all values of $|V| \geq 3$ for $-0.8 \leq \gamma \leq -0.7$. Therefore, when $|V| \geq 3$, the highest degree vertex will reach all other vertices in 2 hops, which means that each vertex can reach any other vertex within 4 hops. Hence, $d_0 = 4$ and $h = 1$.

The above analysis is based on undirected unweighted graphs. However, the power law distribution is commonly found in directed graphs by examining the in-degree and out-degree distribution separately [22, 26]. The study in [25] also considers directed graph, and by focusing on the vertices that can be reached from a random vertex, it is found that many results follow as in undirected graphs. Hence, Assumption 1 is also for directed graphs.

Based on $d_0$, we have two types of shortest paths: long ones (i.e., those of hop length at least $d_0$) and short ones (i.e., those of hop length below $d_0$). We have identified hitting sets for covering the long shortest paths based on Assumption 1. Next, we will examine how the shortest paths of hop length shorter than $d_0$ can be handled.

Let $P_a$ be the set of all shortest paths $p$ such that $|p| < d_0$, and $P_b$ be the set of all shortest paths $p$ such that $|p| \geq d_0$. The $d_0$-inner-circle of a vertex $v$ is defined to be $N_{\leq d_0}(v) = \{ p \mid p \in P_\leq d_0 \land v \in p \}$. We can visualize $N_{\leq d_0}(v)$ as the set of all shortest paths passing through $v$ within a ball with radius $d_0$ centered at $v$, where each path has length less than $d_0$. Similarly, the $d_0$-outer-circle of $v$ is defined as $N_{> d_0}(v) = \{ p \mid p \in P_{> d_0} \land v \in p \}$.

We define a neighborhood for vertex $v$ to be used as a hitting set for short shortest paths through $v$. Let $N(v) = \{ u \mid \text{dist}_{\leq d_0}(v, u) < d_0 \land \text{dist}_{\leq d_0}(u, v) < d_0 \}$, then $N(v) = N(v) \cap H$ and $N''(v) \subseteq N(v)$ be vertices connected to $N(v)$ so that for any vertex $u \in N''(v)$, there is a shortest path from $v$ to $u$ or from $u$ to $v$ which contains a vertex in $N_H(v)$. Then, the set of vertices of $N(v) = \{ (N(v) \setminus N''(v)) \cup N_H(v) \}$ is called the $H$-excluded neighborhood of $v$. If there exists a shortest path $p = v \leadsto u$ with hop length $< d_0$, then $p$ is hit by a vertex $w$, where $w \in N(v)$ and $w \in N_H(v)$.

If we include entries for all vertices in $N_H(v)$ in the label for each vertex $v$, such a shortest path will be found from the labels of the 2
endpoint vertices of the path. We make an assumption that $N_r(v)$ is small.

**Assumption 2.** In an unweighted scale-free graph $G = (V, E)$, for a vertex $v$, the $\text{II}$-excluded neighborhood of $v$, $N_r(v)$, contains at most $h$ vertices.

Given an expansion factor of $R$, for a scale free graph $G = (V, E)$, $|N_r(v)|$ for $v \in V$ is bounded by $R^{d_0 - 3}$. If $|V| = 1M$, then $R \approx 20$, and if $-0.8 \leq \gamma \leq -0.7$, $d_0 = 4$. Then, $|N_r(v)| < 20^3 = 8000$. The actual size of $|N_r(v)|$ is much smaller than this bound since high degree vertices cover a large number of edges in $G$ and their expansions are excluded in $N_r(v)$.

The small $h$ value assumption is substantiated by our experimental results on a large number of real graphs. We say that a graph has hub dimension $h$ if $\forall u \in V$, $\exists$ a hitting set $H_<$ for $N_u(u)$ such that $|H_<_| = O(h)$ and $\exists$ a hitting set $H_\geq$ for $N_u(u)$ such that $|H_\geq| = O(h)$. Intuitively, given hub dimension $h$, there exists for each vertex $u$ a set of at most $O(h)$ vertices hitting all shortest paths passing through $u$, which bounds the optimal label size of $u$ by $O(h)$. We state our assumption of small hub dimension.

**Assumption 3.** An unweighted scale-free graph has a small hub dimension $h$.

In summary, we provide realistic assumptions for unweighted directed/undirected scale-free graphs. Based on Assumption 3, the optimal label size is bounded by $O(h)$ for each vertex. Our empirical study in Section 7 shows that for all the scale-free real-world and synthetic graphs that we have tested, the label sizes resulting from our algorithm are very small compared to the graph size. Thus, the assumptions above are strongly supported by experimental results. The remaining question is how to attain this size bound.

### 2.3 Existing Algorithms with Vertex Ordering

As discussed in Section 2.1, ranking of vertices by their degrees has been adopted in PLL [7], and less explicitly in IS-Label [18]. However, as noted in Section 1, both of these methods are not scalable. For PLL, the in-memory label construction involves many iterations of breadth first search (BFS), and BFS does not yield to an efficient external algorithm to date [24]. More importantly, to be efficient, the label pruning in PLL requires a main memory that can hold the labeling index, which is typically much bigger than the given graph. Hence, it is an open problem to derive an algorithm with scalable bounds on memory and computation consumption and that produces bounded index sizes. We will focus on this problem for scale-free graphs.

In [13], it is shown that high-degree vertices in power-law graphs are useful for finding approximate shortest paths by a compact routing scheme. A routing table is built for each vertex $v$, which keeps track of shortest paths to high-degree vertices called landmarks and to vertices closer to $v$. However, the query evaluation in [13] does not return exact answers. In the next sections, we shall make use of vertex degree ordering to derive an I/O efficient algorithm for index construction for exact querying on a large scale-free graph. Our algorithm does not require the knowledge of $h$ but will seamlessly attain the label size bound of $O(h|V|)$ and scalable complexities.

### 3. PROPOSED SOLUTION

Our proposed solution is made up of the three major components of algorithmic designs. We first give an outline of each component.

1. The basic framework of our label index construction is an iterative process with two steps in each iteration: (i) label entry generation based on a set of rules; and (ii) label pruning to reduce the label size.

2. The second design component is an I/O efficient algorithm for implementing the iterative process (see Section 4).

3. The third algorithmic design is an enhancement on the performance based on the idea of hop-stepping (see Section 5).

In this section we describe the iterative process of label generation and pruning. Based on the discussion in Section 2.2, we design our labeling algorithm with the assumption that the hitting set of the majority of paths of longer lengths passing through a vertex $v$ is a small set of $h$ high degree vertices in $\mathbb{H}$. Since each label entry should correspond to a shortest path, if we place the entries $(v_h, d)$ for vertices $v_h$ in $\mathbb{H}$ in the relevant vertex labels, they would serve most querying. Analogously, we should try to avoid creating label entries for shortest paths $p = v \sim u$ where $v_h$ is in $p$ for some vertex $v_h \in \mathbb{H}$, and $v_h \notin \{u, v\}$. From our assumptions, there are many such paths, and hence many possible label entries, which will lead to large label sizes. We will introduce the notion of trough paths for these purposes.

Our strategy is to rank all vertices uniquely according to non-increasing degrees, with the highest rank given to the highest degree vertex. Next, our algorithm generates label entries to cover shortest paths with increasing number of hops. There are several reasons for this strategy. Firstly, we need to search the neighborhood of each vertex for the coverage of short shortest paths. Secondly, we need short shortest paths involving $\mathbb{H}$ for pruning other paths. Hence, we traverse from short to long paths. Thirdly, the iterative approach can be realized by I/O efficient algorithms with scalable I/O complexities, as we will show in Section 5. We will explain these points in the following discussion.

### 3.1 Iterative Labeling Algorithm

Given a directed unweighted graph $G = (V, E)$, let $\{v_1, v_2, ..., v_n\}$ be a ranking of the vertices in $V$ so that the rank of $v_i$, denoted by $r(v_i)$, is equal to $i$. We rank the vertices in non-increasing order of their vertex degrees. Thus, vertex $v_1$ has the highest degree. We break ties arbitrarily for vertices with the same degree. Next we introduce the notion of a trough shortest path.

**Definition 1 (Trough Shortest Path).** A trough path from $v$ to $u$ is a path passing through only vertices with ranks smaller than $\max\{r(u), r(v)\}$. A trough shortest path is a trough path that is also a shortest path.

For example, in the graph $G$ in Figure 3 (a), if we rank vertices by non-increasing degrees, then vertex 0 has the highest rank, the path $(3, 7, 2)$ is a trough shortest path, while $(5, 3, 7)$ is not. We create labels for each vertex $v$ with the following labeling objectives:

1. **[O1]** if there is a trough shortest path from $v$ to $u$, where $r(u) > r(v)$, then $(u, dist_G(v, u)) \in L_{out}(v)$;

2. **[O2]** if there is a trough shortest path from $u$ to $v$, where $r(u) > r(v)$, then $(u, dist_G(u, v)) \in L_{in}(v)$.

**Notations:** Given a label entry $e_1 = (u, d_1) \in L_{out}(v)$, it implies that $r(u) > r(v)$ and there is a trough path $p_1$ from $u$ to $v$ of length $d_1$. $e_1$ is called an in-label entry. We also denote $e_1$ by $(u \rightarrow v, d_1)$. If there is a label entry $e_2 = (v, d_2) \in L_{out}(u)$, then $r(v) > r(u)$ and there is a trough path $p_2$ from $u$ to $v$ of length $d_2$. $e_2$ is called an out-label entry, and is also denoted by $(u \rightarrow v, d_2)$.

In each case, we say that $e_1$ covers the path $p_1$, Conversely, given a label entry $(u \rightarrow v, d)$, then $(u, d) \in L_{out}(v)$; given $(u \rightarrow v, d)$, then $(v, d) \in L_{out}(u)$. When the ranking is immaterial, we write $(u \rightarrow v, d)$, which implies $r(u) > r(v)$ or $r(u) < r(v)$.
In our labeling algorithm, initially each vertex v is assigned two labels \( \mathcal{L}_in(v) = \{v, 0\} \) and \( \mathcal{L}_out(v) = \{v, 0\} \). In the initialization process, for each edge \((u, v) \in E\), if \( r(u) < r(v) \), we add label entry \( e = (v, dist_2(u, v)) \) to \( \mathcal{L}_out(u) \); if \( r(u) > r(v) \), we add \( e = (u, dist_2(u, v)) \) to \( \mathcal{L}_out(v) \).

Our algorithm iteratively generates label entries for all vertices until no more label entries can be formed. The first iteration is the initialization process. In each remaining iteration, we have a set of new label entries which have been generated in the previous iteration, which we denote by \( prevLabel \). Also we have a set of all label entries generated from all previous iterations, we refer to this set as \( allLabel \). In each iteration, we adopt 6 rules repeatedly to generate all the possible label entries for the iteration. The rules are encoded in Table 5. The first rule is derived from the first row in the table as follows: \( \forall (u \rightarrow v, d) \in prevLabel \), \( \forall (u_1 \rightarrow w, d_1) \in allLabel \), generate \( (u_1 \rightarrow v, d_1 + d) \). Similarly, the other 5 rules can be derived from the table. The rules are illustrated in Figure 4, where each solid or dotted arrow indicates a label entry.

### Algorithm 1: Hop-Doubling Labeling

**Input:** \( G = (V, E) \)  
**Output:** \( (\mathcal{L}_in, \mathcal{L}_out) \)

1. **Initialization**
   - rank the vertices by non-increasing degrees;  
   - \( allLabel = prevLabel = \) set of labels covering all edges \( e \in E \).  
2. **Iterative Construction**
   - while \( prevLabel \neq \emptyset \) do
     1. Update \( prevLabel, allLabel \) using the set of label entry generation rules;
   - build index of \( (\mathcal{L}_in, \mathcal{L}_out) \) from \( allLabel \);

Next, we show that distance querying based on the labels constructed by the algorithm is correct. First, we need a lemma.

**Lemma 2. Hop-Doubling labeling achieves the labeling objectives of \([O1] \) and \([O2] \) given in Section 3.1.**

**Proof:** Consider a trough shortest path \( p \) from \( v \) to \( u \). Let the path be \( p = (v = w_1, w_2, ..., w_k = u) \). We show by induction on the hop length of \( P \). The base case is trivial since we always include \((v, 0), (0, 0)\) in \( \mathcal{L}_in(v) \) and \( \mathcal{L}_out(v) \). Next, assume the statements in \([O1] \) and \([O2] \) true for all paths of hop length \( k \) and \( j \neq 1 \). Consider the path \( p = (v = w_1, w_2, ..., w_k = u) \). There are two possible cases. Case A: \( r(w_k) > r(w_i) \); Case B: \( r(w_k) > r(w_i) \). Let use first consider Case A. Let \( w_i \). Since \( p \) is a shortest path from \( v \) to \( u \), the sub-path \( p_1 = (w_1, ..., w_i) \) must be a shortest path from \( w_1 \) to \( w_i \). Similarly, the sub-path \( p_2 = (w_i, ..., w_k) \) is a shortest path from \( w_i \) to \( w_k \). Clearly, \( dist_2(w_i, w_k) = dist_2(w_i, w_k) + dist_2(w_i, w_k) \). Since \( r(w_i) \) is the second highest rank in \( p \), both \( p_1 \) and \( p_2 \) are trough shortest paths. There are two subcases:

- Case A1: \( r(w_k) < r(w_i) \) or \( r(w_i) \). By the induction hypothesis, \( e_1 = (w_i, dist_2(w_i, w_i)) \) will be inserted into \( \mathcal{L}_out(w_i) \), and \( e_2 = (w_i, dist_2(w_i, w_k)) \) will be inserted into \( \mathcal{L}_in(w_i) \). Note that \( e_1 = (w_i, dist_2(w_i, w_i)) \) and \( e_2 = (w_i, dist_2(w_i, w_k)) \) will be inserted at the same iteration or at different iterations. If \( e_1 \) is inserted in a later round than \( e_2 \), then by Rule 1, \( e_3 = (w_i, dist_2(w_i, w_i) + dist_2(w_i, w_i)) \) for \( \mathcal{L}_out(w_i) \) will be generated. If \( e_2 \) is inserted in a later round, then by Rule 4, \( e_3 \) will be generated for \( \mathcal{L}_out(w_i) \).
Figure 6: 4 sufficient rules for label entry generation

Case A2: \( r(w_1) < r(w_i) < r(w_j) \). By the induction hypothesis, \( e_1 = (w_i, dist_G(w_i, w_j)) \) will be inserted into \( \mathcal{L}_{out}(w_i) \), and \( e_2 = (w_i, dist_G(w_i, w_j)) \) will be inserted into \( \mathcal{L}_{out}(w_j) \). Note that \( e_1 = (w_i, dist_G(w_i, w_j)) \) and \( e_2 = (w_i, dist_G(w_i, w_j)) \). If \( e_1 \) is inserted before \( e_2 \), then when \( e_2 \) is newly added, by Rule 3, \( e_3 = (w_i, dist_G(w_i, w_j) + dist_G(u, w_i)) \) will be added to \( \mathcal{L}_{out}(w_i) \). If \( e_2 \) is inserted before \( e_1 \), then \( e_3 \) will be added to \( \mathcal{L}_{out}(w_j) \) by Rule 2.

Similar arguments hold for Case B with subcase B1, where Rules 1 and 4 apply, and subcase B2, where Rules 5 and 6 apply.

**Theorem 1.** The labels constructed by Hop-Doubling Labeling return correct answers for point-to-point distance queries.

**Proof:** By construction, each label entry \((u, d)\) in \( \mathcal{L}_{in}(v)\) covers a path \( w \leadsto v \) in the graph with length \( d \). Given a distance query from \( u \) to \( v \), consider a shortest path \( p \) from \( u \) to \( v \). Let \( w \) be the vertex with the highest rank in \( p \). Note that \( w \) can be \( u \) or \( v \). Then the sub-paths \( u \leadsto w \) and \( w \leadsto v \) of \( p \) are trough shortest paths. From Lemma 2 we have an entry \((w, dist_G(u, w))\) in \( \mathcal{L}_{out}(u) \) and also an entry \((w, dist_G(v, w))\) in \( \mathcal{L}_{in}(v) \). Hence we get the correct distance value of \( dist_G(u, v) = dist_G(u, w) + dist_G(v, w) \) when we look up the labels for \( u \) and \( v \).

### 3.2 Minimizing the Rules for Labeling

As illustrated by Figure 4, we use 6 rules for generating new label entries. In this subsection, we show how to minimize the set of rules to accelerate the generation of new entries. For simplicity, here we refer to a label \((u \rightarrow v, d)\) as \((u \rightarrow v)\).

**Lemma 3.** Rules 1,2,4,5 generate the same results as Rules 1,2,3,4,5,6.

**Proof:** We first prove by induction that label entries generated by Rule 3 can be generated by Rule 1 and Rule 2. Assume the lemma holds for all iterations up to the \( i \)-th iteration. At the \((i+1)\)-th iteration, suppose Rule 3 can generate \((y \rightarrow u)\) from \((y \rightarrow v)\) and \((u \rightarrow u)\) where \((u \rightarrow v)\) is generated in the \( i \)-th iteration and \((u \rightarrow u)\) is in \( allLabel \), then there are two cases of how \((u \rightarrow v)\) is generated in the \( i \)-th iteration. (See Figure 7.)

**Case 1:** \((y \rightarrow v)\) is generated by \((y \rightarrow w)\) and \((w \rightarrow v)\) where \( r(u) < r(w) < r(v) \). Hence in the \( i \)-th iteration, we have \((y \rightarrow w)\), \((w \rightarrow v)\) and \((u \rightarrow u)\). By Rule 2 we have \((w \rightarrow u)\) before the \((i+1)\)-th iteration. Hence, by Rule 2 we can generate \((u \rightarrow u)\) from \((u \rightarrow w)\) and \((u \rightarrow u)\).

**Case 2:** \((y \rightarrow v)\) is generated by \((u \rightarrow w)\) and \((w \rightarrow v)\). Hence in the \( i \)-th iteration, we have \((u \rightarrow w)\), \((w \rightarrow v)\) and \((u \rightarrow u)\). Thus we also have \((u \rightarrow u)\) before the \((i+1)\)-th iteration, and by Rule 1 we can generate \((u \rightarrow u)\) from \((u \rightarrow w)\) and \((u \rightarrow u)\).

Thus, \((u \rightarrow u)\) can be generated in another way with Rule 1 or Rule 2 in the same iteration. Similarly, we can prove that Rule 6 is covered by Rule 4 and Rule 5.

Other than removing Rules 3 and 6, next, we show that Rules 1 and 4 can be further simplified as follows.

Figure 7: Eliminating Rule 3

1. \( \forall (u \rightarrow v, d) \in prevLabel, \forall (u_1 \rightarrow w, d_1) \in allLabel \), where \( r(v) > r(u_1) > r(u) \), generate \((u_1 \rightarrow v, d_1 + d)\)

2. \( \forall (u \rightarrow v, d) \in prevLabel, \forall (u_2 \rightarrow u_4, d_4) \in allLabel \), where \( r(u) > r(u_4) > r(v) \), generate \((u_2 \rightarrow u_4, d_4 + d)\)

Previously, Rule 1 may also generate \((u_1 \rightarrow v)\), now it only generates \((u_1 \rightarrow v)\). Similar change applies for Rule 4. The 4 simplified rules are illustrated in Figure 6.

**Lemma 4.** The simplified Rules 1,2,4,5 generate the same results as the original Rules 1,2,4,5.

**Proof:** Consider Rule 1. Originally, we generate \((u_1 \rightarrow v)\) from an old label entry \((u_1 \rightarrow w)\) and a label entry \((y \rightarrow v)\) from the previous iteration. (1) If \( r(u_1) < r(v) \), then \((u_1 \rightarrow v)\) is also generated by the simplified Rule 1. (2) If \( r(u_1) > r(v) \), then the label \((u_1 \rightarrow v)\) must have been generated by either Rule 1 or 2 or \((u \rightarrow w)\) and \((w \rightarrow v)\) for some \( w \). In the previous iteration or earlier, we have \((u_1 \rightarrow w)\), \((u \rightarrow w)\), and \((w \rightarrow v)\), by which we also generate \((u_1 \rightarrow w)\). Then, the simplified Rule 4 will generate \((u_1 \rightarrow v)\). The arguments for Rule 4 are similar.

With the above results, the set of rules in Algorithm 1 now consists of the 4 simplified rules. We will show that after every 2 iterations, we double the maximum hop length of paths covered by labeling. Let \( D_H \) be the maximum number of edges among all the pairwise shortest paths. We shall refer to \( D_H \) as the hop diameter of the graph. \( D_H \) is the diameter of the graph for an unweighted graph. We call a path with \( k \) hops or edges a \( k \)-length path.

**Theorem 2.** For all \( 0 \leq i \leq \lceil \log(D_H) \rceil \), after the \( 2i \)-th iteration, for each positive integer \( k \leq 2^i \), the label entries covering all \( k \)-length trough paths are generated.

**Proof:** We say that a path \( p \) is processed if the label entry covering \( p \) is generated in the label sets. We prove by induction. The base case where \( i = 0 \) is straightforward. Assume the statement true for \( i \leq j \). We want to show that in the \((2j + 2)\)-th iteration, the label entries for all \( k \)-length trough paths are generated where \( k \leq 2^{j+1} \).

Consider a \( k \)-length trough path \( p = (v_1, v_2, \ldots, v_k) \), \( k = 2^{j+1} \). Without loss of generality, assume \( r(v_1) < r(v_{k+1}) \). Let \( v_\ell \) be the midpoint of \( p \), so that \( p \) is divided into 2 paths \( p_1 = (v_1, \ldots, v_\ell) \) and \( p_2 = (v_{\ell + 1}, \ldots, v_k) \). Obviously, \( p_2 \) is a trough path and it has a hop length of \( 2^j \), and by induction, its label entry has been generated latest in the \( 2j \)-th iteration. Let \( v_\ell \) be the vertex of highest rank among \( v_1, \ldots, v_j \). Then, from \( p_1 \), we have two trough paths \( p_{11} = (v_1, \ldots, v_\ell) \) and \( p_{12} = (v_{\ell + 1}, \ldots, v_j) \). The hop lengths of \( p_{11} \) and \( p_{12} \) are bounded by \( 2^j \), and hence both of them are processed latest in the \( 2j \)-th iteration. Hence latest at the \((2j + 1)\)-th iteration, the label entries for the trough path linking \( p_{12} \) and \( p_{12} \), i.e. \( (v_\ell, \ldots, v_{k+1}) \) will be created. Therefore latest at the \((2j + 2)\)-th iteration, the path \( p \) which concatenates \( p_{11}, p_{12} \) and \( p_{22} \) will be found and processed. The same argument applies for \( k = 2^{j+1} \).

### 3.3 Reducing Index Size by Label Pruning

While the iterative process generates new label entries for trough shortest paths of increasing hop lengths, such a shortest path \( p \) =
u \sim v$ may be hit by a higher degree vertex $v_h$. We can discover such a case if we find label entries $(u \rightarrow w, d_1)$ and $(w \rightarrow v, d_2)$, since $w$ is a higher degree vertex. We add a pruning step in order to remove such generated label entries. This step is applied to all generated label entries at each iteration after the label generation step at Line 4 of Algorithm 1.

**Label Pruning:** A label entry $(u \rightarrow v, d)$ is pruned if there exist label entries $(u \rightarrow w, d_1)$ and $(w \rightarrow v, d_2)$ where $d_1 + d_2 \leq d$.

**Example 2.** For our example in Figure 3, in the first iteration, $(2 \rightarrow 1, 2)$ is generated from $(3 \rightarrow 2, 1)$ and $(3 \rightarrow 1, 1)$, however, there exist label entries $(2 \rightarrow 0, 1)$ and $(0 \rightarrow 1, 1)$ before this iteration. By the above pruning step, $(2 \rightarrow 1, 2)$ will be pruned.

We want to show that with the pruning steps, the labeling result is still correct. A similar pruning step is used in PLL [7], but PLL creates label entries by decreasing rank order of the pivots, and thus, the correctness follows from canonical labeling. It is not obvious in our case since we do not create label entries in rank order. To show the correctness, we need some definitions. For the labeling without pruning, let $L(k)$ be the set of labels at the end of iteration $k$, and $L$ be the set of labels in the final index. For the labeling with pruning, let $L'(k)$ be the set of labels at the end of iteration $k$, and $L'$ be the set of labels in the final index.

**Theorem 3 (Correctness).** Distance querying by the index built by Hop-Doubling labeling with pruning is correct.

**Proof:** Given a distance query from $s$ to $t$ in $G$, consider the set $P$ of all shortest paths from $s$ to $t$. Let $p \in P$ contain the highest ranked vertex $v_m$ in all paths in $P$. Note that $v_m$ can be $s$ or $t$. Then, subpaths $(s \rightarrow v_m)$ and $(v_m \rightarrow t)$ in $p$ are true shortest paths. By Lemma 2, $e_1 = (s \rightarrow v_m, dist_G(s, v_m))$ and $e_2 = (v_m \rightarrow t, dist_G(v_m, t))$ are generated in $L$. We want to show that $e_1$ and $e_2$ are also in $L'$. We prove by contradiction. Suppose $e_1 \not\in L'$, then it has been pruned at some iteration $k$, so that $e_1 \in L(k) \subseteq L'(k)$. By the pruning mechanism, at iteration $k$, there exist label entries $(s \rightarrow w, d_1)$ and $(w \rightarrow v_m, d_2)$ from previous iterations, and $d_1 + d_2 = dist_G(s, v_m)$. Therefore, there exists a path $(s, u, v, v_m, t, w)$ with a length of $d_1 + d_2 + dist_G(v_m, t) = dist_G(s, v_m) + dist_G(v_m, t)$, and it is a shortest path from $s$ to $t$. However, $r(w) > r(v_m)$, which contradicts our assumption that $v_m$ is the highest ranked vertex in all shortest paths from $s$ to $t$. The argument for the case where $e_2 \not\in L'$ is similar. Hence, we conclude that $e_1$ and $e_2$ exist in $L'$ and the answer to the query is correct.

**Corollary 1.** Latest at iteration $k = 2[\log D_H]$, for any shortest path $u \sim v$, there exist the label entries $(u \rightarrow v_m, d_1)$ and $(v_m \rightarrow v, d_2)$ in $L'(k)$ such that $d_1 + d_2 = dist_G(u, v)$.

The corollary follows from the above proof and Theorem 2, considering that $v_m$ is the highest ranked vertex among all shortest paths $u \sim v$. Now, we are ready to bound the number of iterations of our algorithm.

**Theorem 4.** The number of iterations of Hop-Doubling with pruning is upper bounded by $2[\log D_H]$.

**Proof:** Consider iteration $k = 2[\log D_H] + 1$, if a label covering a path $p$, $(u \rightarrow v, d)$, is generated by one of the rules, then there exists a trough path $u \sim v$, and therefore a shortest path from $u$ to $v$. From Corollary 1, there exist in $L'(k-1)$ the label entries $e_1 = (u \rightarrow v_m, d_1)$ and $e_2 = (v_m \rightarrow v, d_2)$ such that $d_1 + d_2 = dist_G(u, v)$, and these entries will not be pruned in $L'(k)$. If $v_m = v$, then $(u \rightarrow v, d_1) \in L'(k-1)$, and $(u \rightarrow v, d)$ will not be generated as a new label. Similarly, if $v_m \neq v$ and $v_m \neq u$, the label $(u \rightarrow v, d)$ will be pruned by $e_1$ and $e_2$, and will not survive as a new label. We conclude that no new label will be generated after $2[\log D_H]$ iterations.

As we shall see in our empirical studies, the above bound is very helpful for some datasets which deviate from the small diameter property of scale-free graphs.

## 4 I/O Efficient Algorithms

In this section, we describe the implementation of Hop-Doubling with pruning and analyze the time complexity and I/O complexity. There are two steps in each iteration: (1) label generation, which we call candidate generation here, and (2) label pruning. For the analysis of I/O complexity, we adopt the following conventions from [6]. Let $\text{scan}(N) = \Theta(N/B)$, where $N$ is the amount of data being read or written from or to disk, $M$ is the main memory size, and $B$ is the block disk size ($1 < B \leq M/2$).

### 4.1 Candidate Generation

We assume that main memory may not be able to hold the label index or even the input graph. Hence we devise an I/O efficient mechanism that resembles a nested loop join for candidate generation. In the following, for clarity, we refer to a label entry $(u \rightarrow v, d)$ as $(u, v)$ in each iteration. We have three types of label entries: *prev entries* are generated in the previous iteration and survived pruning, *candidates* are generated in the current iteration, and *old entries* are all label entries that survived pruning before the current iteration. Hence, the set of *old entries* includes the *prev entries*.

The pseudo code for candidate generation by Rules 1 and 2 is shown in Algorithm 2. We load *prev* label entries $(u \rightarrow v)$ and *old* label entries $(u_1 \rightarrow u)$ into memory in the outer loop, which are sorted by $u$ in the corresponding files. We make sure that for each $u$ where there is a *prev* out-label entry $(u \rightarrow v)$, we load the

---

### Algorithm 2: Candidate Generation (Rules 1 and 2)

- **Input**: preve, old (label entries)
- **Output**: candidate label entries

```plaintext
2 foreach (u \rightarrow v, d) in preve do
3    allocate buffer B_L to load next batch of prev (u \rightarrow v), (u \rightarrow v'), ...
4    allocate buffer B_R to load old (u_1 \rightarrow u), (u_1 \rightarrow u'), ...
5    sort the (u_1 \rightarrow u) entries in B_L by u_1;
6    sort the (u_1 \rightarrow u) entries in B_R by u_1;
7    foreach u in B_L do
8        generate candidate (u_1 \rightarrow v) = (u = u_1 \rightarrow u \rightarrow v);
9    foreach u in B_R do
10       generate candidate (u_1 \rightarrow v) = (u = u_1 \rightarrow u \rightarrow v);
```

- **Generation by Rule 1**

```plaintext
foreach (u \rightarrow v, d) in B_L do
    if (u \rightarrow v) \not\in B_R, then
        generate candidate (u \rightarrow v) = (u \rightarrow v);
```

- **Generation by Rule 2**

```plaintext
foreach (u_1 \rightarrow u) in B_R do
    if (u_1 \rightarrow u) \not\in B_L, then
        generate candidate (u_1 \rightarrow u) = (u = u_1 \rightarrow u);
```

---
Finally, and candidate label entries once. The total I/O cost is thus given by
\(|v| \log |V| + \log M + |\text{label}|| / (\log (|\text{cand}| + |\text{old}|)/M) \times \text{scan}(|\text{cand}| + |\text{old}|))\) I/Os.

5. ENHANCEMENT BY HOP-STEPPING

For Hop-Doubling labeling, the I/O complexity is given by \(O(D_H(|\text{old}| + |\text{cand}|)/M) \times (|\text{old}| + |\text{cand}|)/B\). Let us consider \(|\text{cand}|| \text{cand}|| in the previous round of execution. From Equation (2), the expansion factor is \(R = \log |V|\). In each iteration, from Theorem 4, the path hop length can expand by at most \(D_H/2\), where \(D_H\) is the hop diameter of the graph. Hence, \(|\text{cand}| = O(\log |V| / (\log |V|)^{D_H/2})\). The factor of \(\log |V| / (\log |V|)^{D_H/2}\) can greatly affect the I/O cost. It is caused by the hop doubling property, where in each iteration we may cover paths with hop lengths up to double that in the previous round. To deal with this issue, we consider an alternative strategy whereby we increase the number of hops by one in each iteration. We show that after each iteration, the label size is bounded by \(O(h(V))\). Since \(R = \log |V|\), the value of \(|\text{cand}||\text{cand}||\text{cand}|| in the complexity analysis becomes \(O(h(V)/\log |V|)\). We call this method Hop-Stepping.

5.1 Hop Length \(i + 1\) from \(i\) and 1

Hop-Stepping retains all the steps of the Hop-Doubling labeling method. However, the 4 rules as illustrated in Figure 6 for generating labels are refined as follows: at iteration \(i + 1\), hop length of the path covered by \(u \rightarrow v\) is \(i\); while we have unit hop length for the paths covered by the following labels: \(u_1 \rightarrow u\) in Rule 1; \(u_2 \rightarrow u\) in Rule 2; \(u \rightarrow u_4\) in Rule 4; and \(u \rightarrow u_5\) in Rule 5. Only edges in \(E\) have unit hop lengths. E.g., Rule \(\overline{1}\) becomes \(V(v \rightarrow v, i) \in \text{prevLabel}, \forall(v_1 \rightarrow u, 1) \in \text{allLabel}, where (u_1, u) \in E\) and \(r(v) > r(u_1) > r(u)\), generate \((u_1 \rightarrow v, i + 1)\).

EXAMPLE 3. For the graph \(G\) in Figure 3, in the second iteration of Hop-Stepping, (4 \(\rightarrow\) 2.4) will not be generated, since the hop lengths of both \((4 \rightarrow 3, 2)\) and \((3 \rightarrow 2, 2)\) are 2. (4 \(\rightarrow\) 2.4) is generated in the next iteration from (4 \(\rightarrow\) 5, 1) and (5 \(\rightarrow\) 2, 3).

Let us consider the correctness and other properties of Hop-Stepping. First, we show that it generates label entries for paths of unit increasing hop-lengths in subsequent iterations. In the following, we refer to a path with \(i\) hops as an \(i\)-length path.

LEMMA 5. For \(1 \leq i \leq D_H\), at the \(i\)-th iteration, the label entries covering all \(i\)-length trough shortest paths are generated.

PROOF: We prove by induction. The base case where \(i = 1\) is straightforward. Assume the statement true for \(1 \leq i \leq j\). Consider a \((j + 1)\)-length trough shortest path \(p = (v_1, v_2, ..., v_{j+2})\).

Suppose \(r(v_1) < r(v_{j+2})\). \(p\) is made up of two sub-paths \(p_1 = (v_1, v_2)\) and \(p_2 = (v_{j+2}, v_{j+2})\). Obviously \(p_2\) is a trough shortest path and it has a hop length of \(j\), by induction, the label entry covering \(p_2\) has been generated at the \(j\)-th iteration. \(p_1 = (v_1, v_2)\) is also a trough shortest path with a hop length of 1, so the covering entry has also been generated. By the Hop-Stepping algorithm, \(p\) will be generated at the \((j + 1)\)-th iteration by either Rule 1 or Rule 2. Similar arguments hold for \(r(v_1) > r(v_{j+2})\) by using Rule 4 and Rule 5.

Next, we add the pruning steps to each iteration. We show that the resulting labeling is correct for distance querying.
Theorem 5 (Correctness). Distance querying by the index built by Hop-Doubling labeling with pruning is correct.

The proof is similar to that for Hop-Doubling. From Lemma 5, we also have the following bound on the number of iterations.

Theorem 6. The number of iterations of Hop-Stepping labeling with pruning is upper bounded by $D_H$.

5.2 A Bound on the Label Size

In this section we derive a bound on the label size. First we show that after $d_0$ iterations, only label entries involving vertices in $\mathbb{H}$ (see Assumption 1) will be added to the labels of each vertex.

Lemma 6. Let $l(p) = (u \rightarrow v, d)$ be a label entry which covers trough shortest path $p$, where the hop length of $p$ is $k$ and $k \geq d_0$. Then, $l(p)$ is pruned at iteration $k$ unless $u \in \mathbb{H}$ or $v \in \mathbb{H}$.

Proof: From Lemma 5, $l(p)$ is generated at iteration $k$. Since $p$ has a hop length of $k \geq d_0$, by Assumption 1, $p$ is hit by some vertex in $\mathbb{H}$. Consider the set $P$ of all shortest paths from $u$ to $v$ with hop length $k$, let $w$ be a vertex in $\mathbb{H}$ with the highest rank in $P$. Let $h_1$ be the hop length of the shortest path from $u$ to $w$ and let $h_2$ be the hop length of the shortest path from $w$ to $v$. So, $h_1 + h_2 = k$. Hence, $h_1 \leq k$ and $h_2 \leq k$. Let us define label sets $L(i)$ and $L(i)$ as in Section 3.3. From Lemma 5, $e_1 = (u \rightarrow w, dist_{C}(u, w))$ and $e_2 = (w \rightarrow v, dist_{C}(w, v))$ are generated at or before iteration $k$. We prove by contradiction that $e_1$ and $e_2$ are in $L(k)$. Suppose $e_1 \notin L(k)$, then since it is in $L(k)$, it has been pruned. By the pruning condition, there exists a higher ranked vertex $x$, with $r(x) > r(w)$, such that $p_2 = (u, ..., x, ..., w)$ has a length of $dist_{C}(u, w)$. Thus, $x$ is a higher ranked vertex that is on a shortest path from $u$ to $v$. Compared to $u$ and $w$, a contradiction to the fact that $w$ has the highest rank. Similarly, we prove that $e_2$ is not in the label of $v$ in $L(k)$. Thus, $l(p)$ is pruned at iteration $k$, except when $w = u$ or $v = w$. \hfill $\square$

Assumption 2 in Section 2.2 states that paths of distance below $d_0$ are hit by a small set of at most $h$ vertices in the close neighborhood if $\mathbb{H}$ is excluded. Thus, we derive the following.

Lemma 7. For each label for each vertex $v$ in the label index $L$, the number of entries $(u, d)$ where $u \notin \mathbb{H}$ is bounded by $h$.

Proof: We need only consider $v \notin \mathbb{H}$ since otherwise $(u, d)$ cannot be in its labels. $\mathcal{L}_{out}(v)$ initially contains the entries involving out-neighbors of $v$, then expanding to the close neighborhood with increasing hop lengths. If no high degree vertex is expanded, this neighborhood is kept small. Consider a vertex $w \in \mathbb{H}$ in the neighborhood at $k$ hops from $v$. Thus, $r(w) > r(v)$. Let the path $p$ from $v$ to $w$ via $k$ hops be a shortest path of distance $d_1$. Consider an out-neighbor $u$ of $w$, where $r(u) < r(w)$, and $u$ is $k + 1$ hops from $v$. Let the path from $v$ to $u$ via $p$ and $w$ be a shortest path of distance $d_1 + d_2$. The candidate entry $(u, d)$ will be generated from $p$ and $w$ with $d = d_1 + d_2$ at the $(k + 1)$-th iteration. From Lemma 5, the entries $(v \rightarrow w, d_1)$ and $(w \rightarrow u, d_2)$ have been generated in previous iterations since their corresponding hop lengths are less than $k + 1$. Candidate $(u, d)$ will be pruned by $(v \rightarrow w, d_1)$ and $(w \rightarrow u, d_2)$ since $d_1 + d_2 = d$, and will not be added to $\mathcal{L}_{out}(v)$. Similar arguments hold for $\mathcal{L}_{in}(v)$. The lemma then follows from Assumption 2 and Lemma 6. \hfill $\square$

Theorem 7. Given an unweighted scale-free graph $G$, the label size of any vertex at any iteration of Hop-Stepping with Pruning is $O(h)$.

Theorem 7 follows from Lemmas 6 and 7, and Assumptions 1 to 3. Note that this is an optimal label size if the value of $h$ is a tight bound on the hitting set size. It is easy to show that Hop-Doubling generates all the label entries that are generated in Hop-Stepping, and by exhaustive pruning, the label size is the same as that of Hop-Stepping and is bounded by $O(h)$.

5.3 Complexity Analysis

The detailed algorithm for Hop-Stepping with Pruning is similar to that for Hop-Doubling, except that we only consider the old label entries with only one hop. Thus, the analysis is similar to that described in Section 4, except that we have $D_H$ iterations. From Theorem 7, $|old| = |prev| = O(h|V|)$. Since $| cand| = |prev| \times R$, where $R = \log |V|$, $| cand| = O(h|V| \log |V|)$. Therefore, label generation requires $O(D_H h|V|/M \times h \log h |V| \times (\log M + h))$ CPU time and $O(D_H h|V|/M \times scan(h|V| \log |V|))$ I/Os. Also, in total label pruning takes $O(D_H h|V|/M \log |V|)(\log M + h)$ CPU time and $O(D_H \times h|V|/M \log |V| \times scan(h|V|))$ I/Os.

Theorem 8. With the assumptions of small $D_H$ and $h$, the total CPU time for Hop-Stepping with pruning is given by $O(V|\log M||V|M + \log |V|)$, and the I/O complexity is $O(V|\log V|M/M + |V|/B)$.

5.4 Hop-Stepping and Hop-Doubling

It is possible to combine the strengths of Hop-Doubling with that of Hop-Stepping. Hop-Stepping can trim the fast growth of the lengths of paths covered by label entries at the earlier iterations, when the hop lengths are small. For graphs where the hop diameter is not very small, a small fraction of the shortest paths will have long hop lengths. In such a case, to avoid the larger number of iterations, we can continue the growth by Hop-Doubling.

Lemma 8. If we begin the label construction with Hop-Stepping and switch to Hop-Doubling after a number of iterations, with the pruning step applied to all iterations, distance querying based on the resulting labeling is correct.

6. UNDIRECTED, WEIGHTED, AND GENERAL GRAPHS

Our algorithms can be easily extended to handle undirected graphs. Instead of having two labels $\mathcal{L}_{in}(v)$ and $\mathcal{L}_{out}(v)$ for each vertex $v$, we need only one label $\mathcal{L}(v)$. To cover an undirected path of length $d$ between $u$ and $v$, where $r(u) < r(v)$, we use the label entry $(v, d)$ in $\mathcal{L}(v)$. It is simpler than the directed case, since Rule 1(2) will be identical to Rule 4(5), when the directions of paths are removed. Hence we only need Rules 1 and 2. For instance, Rule 1 says that: from $(u_1 \rightarrow u_2, d_1)$ and $(v_2 \rightarrow v, d)$, where $r(v) > r(u_1) > r(u)$, generate $(u_1 \rightarrow v, d_1 + d)$. For undirected graphs, this rule becomes: from $(u_1, d_1) \in \mathcal{L}(u)$ and $(v, d) \in \mathcal{L}(v)$, where $r(v) > r(u_1)$, generate $(v, d_1 + d) \in \mathcal{L}(u_1)$. Rules 2 is similarly converted. For distance querying, the labels $\mathcal{L}(s)$ and $\mathcal{L}(t)$ are looked up for a given query of $dist(s, t)$.

While our discussions so far have focused on unweighted graphs, all our mechanisms also apply to weighted directed/undirected graphs with positive edge weights. Though our complexity analysis is based on unweighted scale-free graphs, our experiments on real weighted graphs show highly promising results.

For graphs that are not scale-free, the ranking by degree may not be effective. For example, road networks do not have high degree vertices. However, our algorithms are still relevant for the general graphs since they work with any total ranking of vertices. As discussed in Section 2, higher ranked vertices should hit a large
7. EXPERIMENTAL RESULTS

We implemented our algorithms in C++, and tested the performance of our algorithms using a Linux machine with an Intel 3.3 GHz CPU, 4GB RAM and 7200 RPM SATA hard disk. We compared with three state-of-the-art algorithms, IS-Label [18], PLL [7], and HCL [20], with coding provided by their authors. We conducted experiments on various real-world networks. We used a 32-bit integer for each vertex in the vertex set and an 8-bit integer for each edge. We also compared with baseline bi-Dijkstra search for in memory querying.

We rank vertices by non-increasing product of in-degree and out-degree due to its better performance. We have also considered synthetic scale-free networks generated based on the GLP (Generalized Linear Preference) model [11]. The GLP model is based on the BA model [8] but allows more flexibility. The required parameters $m$ and $m_0$ are set to 1.13 and 10, respectively, as in [11], which gives a power law exponent of 2.155. Unweighted undirected graphs of varying vertex set sizes and densities are generated, syn1 to syn6 are six such datasets.

**Performance Comparison:** We compared our algorithm with the only external algorithm IS-Label [18] which is capable of building full indices. We also compared our algorithm with the two best existing main memory based indexing methods, namely PLL [7] and HCL [20]. We examined the index size, indexing time, disk based querying time and memory based querying time (with index in memory). We measured the performance of IS-Label when building the complete index. We also compared with baseline bi-Dijkstra search for in-memory querying.

The PLL coding provided by the authors of [7] only handles undirected unweighted graphs and it incorporated a bit-parallel mechanism for efficient querying, which is applicable to any 2-hop index on undirected unweighted graphs. Hence, we have also added an enhanced bit-parallel component in HopDb for handling the graphs that can be handled by PLL. The idea of bit-parallel is to select a small set of vertices as roots, e.g. 50 by default in PLL’s assumptions based on scale-free graphs are adopted.

Table 6: Performance comparison of BIDIJ, IS-Label, PLL and HopDb on complete 2-hop indexing for different graphs $G$. 

| $G = (V, E)$ | $|V|$ | $|E|$ | Index size (MB) | Indexing time (sec) | Memory query time (ms) | Disk query time (ms) |

Users. Epinions is a who-trust-who network. EuAll is a European email network. AmazonRatings and EpinionsRatings are customer-product rating networks. MovRatings and BookRatings are networks of movie rating and book rating, respectively. For directed graphs, we rank vertices by non-increasing product of in-degree and out-degree due to its better performance. We have also considered synthetic scale-free networks generated based on the GLP (Generalized Linear Preference) model [11]. The GLP model is based on the BA model [8] but allows more flexibility. The required parameters $m$ and $m_0$ are set to 1.13 and 10, respectively, as in [11], which gives a power law exponent of 2.155. Unweighted undirected graphs of varying vertex set sizes and densities are generated, syn1 to syn6 are six such datasets.
From the results as shown in Table 6, HopDb outperformed the other methods in nearly all aspects. HCL could not finish all the datasets after running for 24 hours, except for Enron, for which all the costs are 3 orders of magnitude higher than HopDb, so the results are not included in Table 6. PLL has a smaller indexing time since it is a main memory based algorithm, while HopDb is a disk based algorithm. However, PLL could not handle most of the datasets because of the large main memory requirement for the index construction. IS-Label could not finish the medium or large sized datasets after running for 24 hours. With the dataset Flickr, the intermediate graph $G_i$ has grown to become bigger than the original graph in the second iteration, and continued to grow. This is because the pruning strategy of IS-Label is much less effective compared with our pruning method.

For the smaller datasets, PLL, IS-Label and HopDb built the complete 2-hop index successfully, but the index sizes of our algorithm are significantly smaller than those of IS-Label and always smaller than PLL, and hence the querying efficiency of HopDb is also substantially better than IS-Label and better than PLL.

We have also conducted experiments on weighted graphs. While we assume small hitting sets for unweighted graphs only, the results on weighted real graphs also indicate small hitting sets for weighted graphs. This is a promising evidence that the assumptions may also hold for many weighted scale-free graphs.

Results on Small Hitting Set: We verify the concept of small hitting set in the real life datasets by showing small average number of label entries ($|\text{label}|$) per vertex and high coverage of label entries by top vertices in Table 7. A label entry $(v, d)$ is said to be covered by $v$. From our discussion in Section 5.2, the size of the final label set can be bounded by $O(h|V|)$ with a small $h$, which is consistent with the small average $|\text{label}|$ values listed in the table, and is the guarantee for the high efficiency of our query processing. Moreover, from the label coverage by top vertices, we know that an extremely small amount of top vertices, given by the percentages in the last three columns of Table 7, can cover most label entries, like 70%, 80%, and 90% listed in the table. The top 1% of vertices often cover close to 100% of the label entries, as shown in Figure 8. These top vertices formed the set $H$ for the small hitting sets.

### Table 7: Results supporting the assumptions of small hub dimension $h$ and small hitting sets ($|\text{label}| = |\text{label}|$ per vertex)

### Results on Synthetic Scale-free Data: We have generated scale-free networks with different densities in GLP to show the scalability of HopDb. In our first experiment, the number of vertices of the graphs is fixed to 10 million, and the densities $|E|/|V|$ are varied from 2 to 70. The number of iterations varies from 7 to 5, which confirms our assumption of a small diameter for scale-free graph. The graph sizes and the average number of label entries in a vertex are reported in Figure 9. As the graph size increases linearly, the average label size remains very small and approaches a flat value below 200. The results strongly support our assumptions of small hitting sets and small hub dimension for scale-free graphs.

Similarly, we tested the scalability of HopDb in scale-free networks with growing number of vertices by the GLP model. We set the density $|E|/|V|$ to 20, and varied the number of vertices from 2 millions to 30 millions. The greatest average label size is around 200, which is very small compared to $|V|$. This indicates that our assumption of small hub dimension holds for all graph sizes.

### Effects of Hop-Stepping and Pruning: To show the effectiveness of the hop-stepping and pruning strategies, we compared the efficiency of adopting different strategies in Table 8 and Figure 10. We considered the three alternatives: only hop-doubling, only hop-stepping, and our default hybrid approach. The hybrid approach achieved the best performance as listed in the column hybrid. Only adopting doubling strategy may lead to too many candidates in the beginning, so it took a long time to finish the large datasets. In the first 10 iterations, hybrid utilized the hop-stepping strategy to limit the growth of candidates and label size. From the 11-th iteration, the hybrid approach switched to hop-doubling to accelerate the process of candidate growing and limit the number of iterations. In datasets with large diameters, the hybrid approach could limit the number of iterations and finish the whole process earlier.

We analyze the running process of a large dataset, wiki-Eng, to show the power of the pruning strategy and hop-stepping in Figure 10. We introduce two numbers, i.e., growing factor and pruning factor, to show the effectiveness. For each iteration, the growing
factor is the ratio of \((\text{number of candidates generated in this iteration}) / (\text{number of label entries generated in the previous iteration})\). The pruning factor is the percentage of pruned label entries in one iteration, i.e. it is the ratio of \((\text{number of pruned candidate}) / (\text{total number of candidates})\). The pruning strategy was powerful throughout the whole process. In the first 10 iterations when adopting hop-stepping, the growing factor was successfully limited at about 3 to 4, this is in line with the small expansion factor described in Section 2.2. After switching to hop-doubling, the growing factor increased to around 25. Thus, hop-doubling accelerated the label generation and led to earlier termination. In this phase, the effectiveness of the pruning strategy is also shown by the pruning factor, with up to about 90% of the candidates pruned. The runtime of these iterations is short since very few candidates are generated. Figure 10 also shows that the size of the candidate set did not exceed 1.5 times the size of the final index size. Hence, the growth in candidates was well under control.

8. CONCLUSION

We introduce a new disk-based indexing algorithm for distance querying on a large scale-free graph. With scalable indexing complexities, our method performs well on different types of scale-free networks and can handle graphs many times larger than existing methods. The consistently small label sizes resulting from our label indexing with all our tested graphs strongly support our assumption of small hub dimension. The experimental result also verifies the scalability of our algorithm and the small label sizes give rise to highly efficient query evaluation both in-memory and on-disk.

ACKNOWLEDGEMENTS: We thank the authors of [7] for the PLL coding, and the authors of [20] for the HCL coding. We are grateful for the data collections from SNAP and KONECT. We thank James Cheng for suggestions on the presentation and review responses to another conference. This work was supported by the Hong Kong RGC GRF grant 412313 and grant FSGRF12EG50.
