Abstract
AIM: To explore dysregulation of c-fos in several human malignancies, and to further investigate the role of c-fos in Helicobacter pylori (H. pylori)-induced gastric precancerosis.

METHODS: Four-week-old male Mongolian gerbils were employed in the study. 0.5 mL 1x10⁶ cfu L⁻¹ suspension of H. pylori NCTC 11 637 in Brucella broth were inoculated orally into 20 Mongolian gerbils. Another 20 gerbils were inoculated with Brucella broth as controls. 10 of the infected gerbils and 10 of the non-infected control gerbils were sacrificed at 25 and 45 weeks after infection. The stomach of each gerbil was removed and opened for macroscopic observation. The expression of c-fos was analyzed by RT-PCR and immunohistochemistry in the stomach samples of infected and control-animals. The level of c-fos was analyzed by RT-PCR and immunohistochemistry in the stomach samples of infected and control-animals. The level of c-fos was significantly higher in infected animals (6/10) than those in control-animals (0.74±0.22, P<0.01). C-fos mRNA levels were increased 2.5-fold by 25th week (P<0.01) and 2.1-fold by 45th week (P<0.01) in precancerosis induced by H. pylori, when compared with normal gastric epithelium of Mongolian gerbil. Immunohistochemical staining revealed exclusive nuclear staining of c-fos. Furthermore, there was a sequential increase in c-fos positive cells from normal epithelium to precancerosis.

RESULTS: The study suggested that overexpression of c-fos occurs relatively early in gastric tumorigenesis in this precancerosis model induced by H. pylori.

CONCLUSION: The study suggested that overexpression of c-fos occurs relatively early in gastric tumorigenesis in this precancerosis model induced by H. pylori.

INTRODUCTION
H. pylori, a gram-negative spiral bacterium first isolated in 1982 from a patient with chronic active gastritis, is responsible for a large portion of chronic gastritis and nearly all duodenal ulcers, most gastric ulcers, and probably an increased risk of gastric adenocarcinoma[1-9]. More than 50 % of the adult population are infected with H. pylori in developing countries as well as in developed countries. Gastric cancer is a major health problem[10] and remains the second most common cancer in the world[11]. Although epidemiological studies have indicated that H. pylori infection plays a crucial role in human gastric carcinogenesis[12-25], there is no direct proof that H. pylori is actually associated with gastric carcinogenesis[26]. The purpose of this study was to elucidate the relationship between H. pylori infection and gastric carcinogenesis by using an animal model of long-term H. pylori infection, and to explore the role played by c-fos in gastric tumorigenesis.

MATERIALS AND METHODS

Animals treatment
Four-week-old specific pathogen-free male Mongolian gerbils weighing 20±5 g were employed in this study. They were housed in individual metabolic cages in a temperature conditioned room 23±2 °C with a 12 h light-dark cycle, allowed to access to standard rat chow (provided by Experimental Animal Center, First Military Medical University) and water ad libitum, and acclimated to the surrounding for 7 days prior to the experiments. H. pylori (NCTC 11 637) was obtained from American Type Culture Collection and cultured on Brucella agar plates containing 70 mL L⁻¹ goat blood in a microaerobic condition (volume fraction, N₂: 85 %, O₂: 5 %, CO₂: 10 %, in aerobic globe box) at 37 °C for 3 days. The strain was identified by morphology, Gram’s stain, urease production and so on.

Experimental protocol
0.5 mL 1x10⁶ cfu L⁻¹ suspension of H. pylori NCTC 11 637 in Brucella broth were inoculated orally into 20 Mongolian gerbils for 14 days continuously which had been fasted overnight. Another 20 gerbils were inoculated with Brucella broth as controls. 10 of the infected gerbils and 10 of the non-infected control gerbils were sacrificed after infection for 25 and 45 weeks, respectively. The stomach of each animal was removed and opened for macroscopic observation. Half of each gastric antrum mucosa were dissected for RNA isolation. The rest of the stomach samples were used for histological examination,
which were fixed with neutral-buffered 100 mL \textsuperscript{1}L\textsuperscript{-1} formalin and processed by standard methods that embedded in paraffin, sectioned and attained with haematoxylin for analyzing histological changes. Giemsa stain for detecting for 	extit{H. pylori} and Alcian blue (AB)/PAS stain for examining intestinal metaplasia.

**RNA isolation and RT-PCR analysis**

Using Tripure isolation reagent (Boehringer Mannheim, Germany), total cellular RNA was isolated from previously frozen tissues according to the manufacturer’s instruction. All RNA samples were analyzed for integrity of 18s and 28s rRNA by ethidium bromide staining of 0.5 µg RNA resolved by electrophoresis on 12 g \textsuperscript{-1} agarose-formaldehyde gels. RT-PCR analysis was performed as follows. RNA was incubated at 60 °C for 10 min and chilled to 4 °C immediately before being reverse transcribed. 1 µg of total RNA was reversely transcribed using antisense primers in a volume of 20 µl for 40 min at 50 °C, containing 200 U MMLV reverse transcriptase, 1xbuffer RT, 1 MU L\textsuperscript{-1} Rnasin, 0.5 mmol \textsuperscript{-1} L\textsuperscript{-1} dNTPs of dATP, dGTP, dCTP and dTTP and each antisense primers including 	extit{c-fos} and β-actin at 0.2 µmol \textsuperscript{-1} L\textsuperscript{-1}. The samples were heated to 99 °C for 5 min to terminate the reverse transcription reaction. By using a Perkin-Elmer DNA Thermocycler 4 800 (Perkin-Elmer, Norwalk, CT), 5 µl cDNA mixture obtained from the reverse transcription reaction was then amplified for 	extit{c-fos} and β-actin. β-actin was used as the housekeeping gene and amplified with 	extit{c-fos} as control. The amplification reaction mixture consisted of 10xbuffer 5 µl, 0.2 mmol \textsuperscript{-1} L\textsuperscript{-1} dNTPs of dATP, dGTP, dCTP and dTTP, 2.5 U Taq DNA polymerase, and sense and antisense primers at 0.2 µmol \textsuperscript{-1} L\textsuperscript{-1} in a final volume of 50 µl. The reaction mixture was first heated at 94 °C for 2 min and amplification was carried out for 29 cycles at 94 °C for 0.5 min, 58 °C for 1 min, 70 °C for 1.5 min, followed by an incubation for 7 min at 70 °C. The amplification cycles was previously determined to keep amplification in the linear range to avoid the “plateau effect” associated with increased PCR cycles. The PCR primers were as following: c-fos, sense 5’-CAC GAC CAT GAT GTT CTC GG-3’ and antisense 5’-AGT AGA TTG GCA ATC TCG GT-3’; β-actin, sense 5’-CCA AGG CCA ACC GCC AGA AGA TGA C-3’ and antisense 5’-AGG GTA CAT GTG GGT GCC GCC AGA C-3’. PCR products of 	extit{c-fos} and β-actin had 348 bp and 587 bp, respectively. PCR products were run on a 15 g \textsuperscript{-1} agarose gel in 0.5×TBE buffer and then analyzed by gel image analysis system. The level of 	extit{c-fos} was reflected with the ratio of c-fos/β-actin.

**Immunohistochemical staining**

Four micrometers paraffin-embedded tissue sections were deparaffinized and rehydrated. Endogenous peroxidase activity was ablated with 10 mL \textsuperscript{1}L\textsuperscript{-1} hydrogen peroxide in methanol. The immunostaining for 	extit{c-fos} was conducted using the StreptAvidin-Biotin-enzyme Complex kit (Boster, Wuhan). Immunostaining by replacing primary antibody with PBS was also conducted as a negative control. The staining was evaluated semiquantitatively on the basis of the percentage of positive cells, and classified as follows\textsuperscript{[27]}: diffusely positive (+++) when positive cells accounted for more than 70 % of the total cells, partially positive (++) when positive cells were 35-70 %, partially positive (+) when positive cells accounted for 5-35 %, and negative (-) when positive cells accounted for less than 5 %.

**Statistical analysis**

Experimental results were analyzed with Chi-square Tests and K-Related Samples Test by SPSS software. Statistical significance was determined at \textit{P}<0.05.

**RESULTS**

**Histopathological findings**

	extit{H. pylori} was detected in gastric antrum and gastric body of all infected animals in this study, and more in gastric antrum than that in gastric body. After infection of 	extit{H. pylori} for 25 weeks, ulcers were observed in the gastric antrum and gastric body in 60 % infected animals (6/10). Histological examination showed that all infected animals developed severe inflammation, especially in the area close to ulcers; multifocal lymphoid follicles appeared in the lamina propria and submucosa; and there were mild atrophic gastritis in all infected animals. After infection of 	extit{H. pylori} for 45 weeks, severe atrophic gastritis in all infected animals, intestinal metaplasia in 80 % infected animals (8/10) and dysplasia in 60 % infected animals (6/10) could be observed. Those metaplastic glands appeared more atypical than the surrounding nonmetaplastic and hyperplastic glands. Severe atrophic gastritis, intestinal metaplasia and dysplasia were gastric precancerosis. In the uninfected animals, there were no significant changes throughout the study.

**Analysis of c-fos mRNA expression**

There was c-fos mRNA expression in gastric antrum mucosa of control-animals. C-fos mRNA levels were significantly higher after infection of 	extit{H. pylori} for 25 weeks (1.84±0.79), and for 45 weeks (1.59±0.37) than that in control-animals (0.74±0.22, \textit{P}<0.01); C-fos mRNA levels were increased 2.5-fold in 25 weeks (\textit{P}<0.01) and 2.1-fold in 45 weeks (\textit{P}<0.01) in precancerosis induced by 	extit{H. pylori}, when compared with control gastric epithelium of Mongolian gerbil (Figure 1-4).

**Figure 1** RT-PCR products. Lane 1 PCR marker; Lane 2 c-fos; Lane 3 β-actin.

**Figure 2** RT-PCR analysis of c-fos mRNA levels using β-actin as internal control. Total RNA was first reverse transcribed into cDNA and then amplified by PCR in control.

of the models studied mimics human *H. pylori* infection and subsequent pathology. Recently, two expreriments were conducted in Japan that demonstrated that chronic *H. pylori*-infection models of Mongolian gerbils would develop gastric carcinoma. These results will be extremely helpful to elucidate the mechanism of gastric carcinogenesis due to *H. pylori* infection\(^{27-28}\). Apoptosis, a programmed cell death, was ignored, just like *H. pylori*, only to reappear recently. However, the number of current publications dealing with apoptosis of *H. pylori* has increased exponentially. Although gastric epithelial apoptosis is a programmed physiological event in the superficial aspect of the mucosa and is important for healthy cell turnover, *H. pylori* infection reportedly promotes such a cell death sequence\(^{27-28}\). Because apoptosis regulates the cycle of cell turnover in balance with proliferation, dysregulation of apoptosis or proliferation evoked by *H. pylori* colonization would be linked to the gastric carcinogenesis\(^{29-31}\).

*C-fos* is an immediate early response gene, and *c-fos* protein is an important transcription-factor of nucleus\(^{32-38}\). Oncogene *c-fos* is also a kind of effect protein of the karyomitosis signal, which can trigger and regulate the transcription of the genes related with proliferation. Besides, *c-fos* can also regulate its own gene expression with a positive feedback and promote the mitosis and proliferation of the cells. Because *c-fos* can regulate cell proliferation and cell apoptosis, its abnormal expression might induce cell turnover and carcinogenesis\(^{39-46}\). Previous studies have showed that the expression of oncogene *c-fos* is closely related to cellular multiplication and differentiation. The amplification and over-expression of *c-fos* gene are associated with malignancy and tumorigeneity of cells. Recently, some studies suggested that oncogene *c-fos* was amplified in the primary tumor DNA\(^{47-49}\). Shirin et al tested the hypothess that *H. pylori* might inhibit cell growth and cell cycle progression by inhibiting signaling pathways that mediate the transactivation of the serum-response element in the *c-fos* promoter\(^{57}\).

In this study, mRNA level of *c-fos* was measured by quantitative RT-PCR analysis in Mongolian gerbil gastric antrum mucosa to explore dysregulation of *c-fos* in malignancies and to further investigate the role of *c-fos* in *H. pylori*-induced gastric precancerosis. In addition, the expression and localization of its protein product was analyzed by immunohistochemical staining. *C-fos* mRNA levels were significantly increased in precancerosis induced by *H. pylori*, when compared with normal gastric epithelium of Mongolian gerbil. Immunohistochemical staining revealed exclusive nuclear staining of *c-fos*. Furthermore, there was a sequential increase in *c-fos* positive cells from normal epithelium to precancerosis. This study indicates that the expression of *c-fos* mRNA and protein is increased from normal epithelium to precancerosis. The dysregulation of *c-fos* expression occurre relatively early in gastric tumorigenesis in this model and may participate in tumor progression. These findings suggeste that *H. pylori*- induced gastric precancerosis is associated with dysregulation of gastric epithelial cell cycle. Further studies are needed to delineate the mechanism of those alterations.
