Abstract. This work analyzes the spontaneous emission of a single emitter placed near the graphene waveguide formed by two parallel graphene monolayers, with an insulator spacer layer. In this case, the eigenmodes supported by the structure, such as surface plasmon and wave guided modes, provide decay channels for the electric dipole placed close to the waveguide. We calculated the contribution to the decay rate of symmetric and antisymmetric eigenmodes as a function of frequency and the orientation of the emitter. Our results show that the modification of the spontaneous emission due to excitation of guided modes is much lower than the corresponding decays through the excitation of symmetric and antisymmetric surface plasmons, for which, the spontaneous emission is dramatically enhanced. As a consequence of the high confinement of surface plasmons in the graphene waveguide, we found that the decay rate of the emitter with vertical orientation (with respect to graphene sheets) is twice the corresponding decay of the same emitter with parallel orientation in the whole frequency range where surface plasmon modes exist. Differently from metallo–dielectric structures, where structural parameters determine the range and magnitude of this emission, our work shows that, by dynamically tuning the chemical potential of graphene, the spectral region where the decay rate is enhanced can be chosen over a wide range.

Keywords: graphene, surface plasmons, quantum electrodynamics, plasmonics
1. Introduction

A property of materials that exhibit a real negative electric permittivity—such as metals—is their capacity to guide surface plasmons (SPs) along their boundary [1, 2]. SPs propagate along the surface with a periodicity lower than the wavelength of same frequency electromagnetic radiation, which is a suitable feature for the miniaturization of photonic devices. In bounded geometries, these modes, called localized surface plasmons, are characterized by discrete frequencies that depend on the size and shape of the object to which they are confined. The localization provided by SPs is quite adequate for many applications such as data storage, microscopy, light generation, biochemical sensing, antennas working at nanoscale [3, 4] and control applications like light trapping [5].

Apart from the well known SPs supported by an insulator–metal interface, long lived SPs can be supported by graphene—a 2D sheet of carbon atoms arranged in a honeycomb lattice [6]—from terahertz up to mid–infrared frequencies [7, 8]. High confinement, relative low loss, and good tunability of surface plasmon spectrum through electrical or chemical modification of the carrier density [7, 9, 10, 11, 12], are three characteristics that make graphene a promising plasmonic alternative material to noble metals.

This paper deals with the modification of the spontaneous emission of a single optical emitter by interaction with its local environment [13], a process that plays a key role in the realization of current light control devices, such as photonic band gaps [14], high efficient single photon sources [15] or single–photon transistors [16]. Since SPs are non radiative modes trapped on the surface, an emitter close to a plane surface can be regarded as an element of surface roughness that serves to couple photons to SPs [17]. Experiments concerning this coupling have proved the non radiative energy transfer to SPs on a planar metallic interface [18, 19].

Rigorous classical theoretical approach, using Hertz–vector representation of electromagnetic fields [20, 21] or Green’s tensor approach [22] have been applied to determine the contribution of the radiating and evanescent modes to the power emitted by a source close to the reflecting surface. The coupling between a single emitter and metals surface states was also studied in the framework of quantum electrodynamics, as emission stimulated by zero–point fluctuations of the electromagnetic field [17, 23, 24 25]. In the limit of weak coupling, results of quantum mechanical calculations have been found to be similar to those derived by classical electromagnetic theory [17, 23, 27, 26]. Both classical and quantum formalisms have been applied to study the spontaneous emission of a single emitter near a planar microcavity characterized by more than two interfaces. In these structures, wave guided modes (WG) are resonant optical modes that, like SPs, provide new channels for the spontaneous decay rate of a single emitter [28, 29, 31, 30]. Enhanced emission rate due to excitation of p and s polarized SPs or WG modes on negative index material multilayers has been reported [32, 33, 34]. A variety of structures such as uniform planar microcavities [35], periodically patterned metallic or dielectric membranes (2–D photonic crystal) [36, 37], cylindrical nanowires
Spontaneous emission – graphene waveguides – surface plasmon polaritons

and gratings have been the object of intensive research over the last few years due to the possibility to engineer the WG or SP mode density of states and consequently modify the emission into a particular mode.

Interactions between single optical emitters and SPs on graphene have been investigated in different structures, such as infinite graphene monolayers, ribbons or nanometer sized disks. Double–layer graphene waveguides have also become the focus of particular attention. For example, a thin glass film coated with graphene and with a dipole emitter embedded at the center of the glass has been recently proposed. On the other hand, coupling between a single emitter and SPs in paired graphene layers has recently been examined. To efficiently couple the fundamental SP mode, the emitter is set to be vertically polarized to graphene layers and positioned at the center of the gap between them. However, there is no reference in the literature about a comprehensive examination of the role played by each of the waveguide SPs in modifying the spontaneous emission rate for an arbitrary polarization of the emitter.

In this paper we analytically study the spontaneous emission rate of a dipole located above a waveguide formed by two parallel graphene sheets with an insulator spacer layer, and we present results showing the role of the eigenmodes of the structure (SPs or WG modes) in modifying the spontaneous emission rate with respect to the rate in absence of the waveguide. One of the interesting differences with a single graphene monolayer structure is that the graphene waveguide studied here has two graphene interfaces, each of which may carry SP modes, and the fields of these modes can overlap through the gap dielectric layer, leading SPs into separated branches. By exploiting the separation between the two graphene sheets as a degree of freedom, it is possible to modify these branches and consequently their influence on the spontaneous emission rate. In this context, several works focused on the role that the eigenmodes play on metallic waveguides or on metamaterial waveguides. In addition, when graphene is included, by exploiting the chemical potential on graphene monolayers as another degree of freedom, one can shift these properties to other frequency regions.

The plan of the paper is as follows. In section 2 we sketch the classical electromagnetic formalism based on the calculation of the electric vector potential. By virtue of the translational invariance of the system along a plane parallel to graphene sheets (x − y plane), we reduce the solution of the original vectorial problem to the treatment of two scalar problems corresponding to the basic modes of polarization (magnetic field parallel to the x − y plane) and (electric field parallel to the x − y plane). In section 3 we provide a general expression for the spontaneous decay rate of an oscillating emitter with an arbitrary orientation of its dipole moment. Assuming that the graphene surface conductivity follows the Kubo model, we determine the eigenmode dispersion curves – that is, the real and the imaginary parts of the eigenmode propagation constant as functions of the frequency – and we present approximated analytic expressions for the spontaneous decay rate into these eigenmodes. By applying the residues method, in section 4 we calculate the contribution of each eigenmode to the total decay rate. We find that, the decay rate near the interface through SPs is
much larger (by over five orders of magnitude) than the decay rate through guided modes. Within the framework of quantum electrodynamics, results are discussed in terms of both the surface plasmon density of states and the effective mode length. Concluding remarks are provided in Section 5. The Gaussian system of units is used and an \( \exp(-i\omega t) \) time-dependence is implicit throughout the paper, with \( \omega \) as the angular frequency, \( t \) as the time, and \( i = \sqrt{-1} \). The symbols Re and Im are used for denoting the real and imaginary parts of a complex quantity, respectively.

2. Electromagnetic field of a radiating dipole

Let us consider a structure made up of three linear, isotropic and homogeneous media arranged as shown in Figure 1. The interfaces of the layers are parallel to the \( x-y \) plane. It is assumed that the graphene monolayers are embedded between adjacent dielectric layers, at \( z = 0 \) and \( z = d \). An electric dipole is located at \( \vec{x} = z' \hat{z} \), at a distance \( z' > d \) from the plane interface \( z = 0 \). The current density of the electric dipole with moment \( \vec{p} \) placed at \( \vec{x} = x' \) is

\[
\vec{j}_e(x) = -i\omega \vec{p} \delta(\vec{x} - \vec{x}').
\]

Since the decay rate can be related to the electric field induced by a dipole itself, the

\[\textbf{Figure 1. Schematic illustration of the system. Two graphene sheets, characterized by surface conductivity } \sigma, \text{ are embedded between adjacent dielectric layers at } z = 0 \text{ and } z = d. \text{ The electric dipole is located at } \vec{x} = z' \hat{z}.\]
of the polarization mode \( \tau \) where functions \( f \) derived according to potentials \([21, 27]\), \( \vec{x} \) potentials \( \vec{E} \) The electric field \( \vec{E} = \vec{E}_p(\vec{x}) + \vec{E}_s(\vec{x}) \) and the magnetic field \( \vec{H} = \vec{H}_p(\vec{x}) + \vec{H}_s(\vec{x}) \) can be derived according to

\[
\vec{E}_p(\vec{x}) = ik_0 \mu \left[ \begin{array}{c} \frac{1}{k^2} \frac{\partial \alpha_p}{\partial y} \\ \frac{1}{k^2} \frac{\partial \alpha_p}{\partial z} \\ (1 + \frac{\beta^2}{\partial \alpha^2})a_p \end{array} \right], \quad \vec{H}_p(\vec{x}) = \left[ \begin{array}{c} \frac{\partial \alpha_p}{\partial y} \\ -\frac{\partial \alpha_p}{\partial x} \\ 0 \end{array} \right],
\]

\[
\vec{E}_s(\vec{x}) = \left[ \begin{array}{c} -\frac{\partial \alpha_s}{\partial y} \\ \frac{\partial \alpha_s}{\partial x} \\ 0 \end{array} \right], \quad \vec{H}_s(\vec{x}) = ik_0 \varepsilon \left[ \begin{array}{c} \frac{1}{k^2} \frac{\partial \alpha_s}{\partial y} \\ \frac{1}{k^2} \frac{\partial \alpha_s}{\partial z} \\ (1 + \frac{\beta^2}{\partial \alpha^2})a_s \end{array} \right].
\]

The direct field emitted by the dipole placed at \( \vec{x} = \vec{x}' \) is written as \([21, 27, 49]\)

\[
a_\tau(\vec{x}) = \frac{k_0}{2\pi} \int_{-\infty}^{\infty} \frac{1}{\gamma^{(1)}} d\gamma(\alpha, \beta) e^{i\gamma^{(1)}|\vec{x} - \vec{x}'|} e^{i\alpha x + \beta y} d\alpha d\beta,
\]

where \( \tau = p, s \) indicates the polarization mode, \( \gamma^{(1)} = \sqrt{k_1^2 - \alpha^2 - \beta^2}, \ k_1^2 = k_0^2 \varepsilon_1 \mu_1, \ k_0 = \omega/c \) is the modulus of the photon wave vector in vacuum, \( \omega \) is the angular frequency, \( c \) is the vacuum speed of light, \( \varepsilon_1 \) and \( \mu_1 \) are the electric permittivity and magnetic permeability, respectively, and the spectral functions \( d_\gamma \) are given by \([21, 27]\)

\[
d_\gamma = \frac{k_0^2}{\gamma^{(1)}} \left[ -\frac{\beta}{\alpha^2 + \beta^2} p_x + \frac{\alpha}{\alpha^2 + \beta^2} p_y \right],
\]

\[
d_p^\pm = \mp \frac{\gamma^{(1)}}{\alpha^2 + \beta^2} p_x \mp \frac{\beta^{(1)}}{\alpha^2 + \beta^2} p_y + p_z.
\]

Note that in lossless media the quantities \( \gamma^{(1)} \) are real or purely imaginary. In the first case, which occurs in the so-called radiative zone \( \sqrt{\alpha^2 + \beta^2} < (\omega/c)\sqrt{\varepsilon_1 \mu_1} \), the integrand in Eq. (7) represents plane waves propagating away from the dipole along a direction that forms an angle \( \theta \) (\( \sin \theta = c/(\omega \sqrt{\varepsilon_1 \mu_1}) \)) with the \( \pm z \) axis. In the second case, which occurs in the so-called non radiative zone \( \sqrt{\alpha^2 + \beta^2} > (\omega/c)\sqrt{\varepsilon_1 \mu_1} \), these fields represent evanescent waves that attenuate for \( z \to \pm \infty \).

The infinitesimal translational invariance in \( x \) and \( y \) directions of the system for which the scalar potentials are being searched, allows us to write the Fourier representation of scalar potentials \( a_p(\vec{x}) \) and \( a_s(\vec{x}) \) like

\[
a^{(m)}_\tau(\vec{x}) = \frac{k_0}{2\pi} \int_{-\infty}^{\infty} d\gamma f^{(m)}_\tau(\alpha, \beta, z, z') e^{i\alpha x + \beta y}
\]

where functions \( f^{(m)}_\tau(\alpha, \beta, z, z') \) \( (m = 1, 2, 3) \) depend on the location of the source and of the polarization mode \( \tau = p, s \).

The integrand in (7) is written as

\[
f^{(1)}_\tau(\alpha, \beta, z, z') = \frac{1}{\gamma^{(1)}} d_\gamma e^{i\gamma^{(1)}|\vec{x} - \vec{x}'|} + A^{(1)}_\tau e^{i\gamma^{(1)} z},
\]

\[
f^{(2)}_\tau(\alpha, \beta, z, z') = A^{(2)}_\tau e^{i\gamma^{(2)} z} + B^{(2)}_\tau e^{-i\gamma^{(2)} z},
\]
where the superscript \( m = 1, 2, 3 \) denotes medium 1 \((z > d)\), medium 2 \((0 < z < d)\) or medium 3 \((z < 0)\), and \( \gamma^{(m)} = \sqrt{k_m^2 - (\alpha^2 + \beta^2)} \), with \( k_m^2 = k_0^2 \varepsilon_m \mu_m \), is the normal component of the wave vector in each homogeneous region. The complex coefficients \( A^{(m)} \) and \( B^{(m)} \) in Eqs. (8) to (10) correspond to the amplitude of upgoing \((+z \text{ propagation direction})\) and downgoing \((-z \text{ propagation direction})\) plane waves, respectively, and they are solutions of Helmholtz equation, whereas the former term in Eq. (8) is associated to the primary dipole emission of the source. There are two types of boundary conditions which must fulfill the solutions given by Eqs. (7) to (10), boundary conditions at \( z = \pm \infty \) and boundary conditions at interfaces \( z = 0 \) and \( z = d \). The former requires either outgoing waves at infinity or exponentially decaying waves at infinity, depending on the values of \( \alpha, \beta \) and \( \omega \).

The boundary conditions on interfaces \( z = 0 \) and \( z = d \) impose that
\[
\hat{z} \times [\vec{E}^{(m)} - \vec{E}^{(m+1)}]|_{z=d_m} = 0,
\]
\[
\hat{z} \times [\vec{H}^{(m)} - \vec{H}^{(m+1)}]|_{z=d_m} = \frac{4\pi \sigma}{c} \hat{z} \times \vec{E}|_{z=d_m}
\]
where \( \sigma \) is the graphene conductivity, \( d_1 = d \) and \( d_2 = 0 \). Inserting the expressions for \( \vec{E}_p \) and \( \vec{H}_p \) given by Eq. (3) into Eqs. (11) we obtain the following conditions on the scalar potential \( a_p(x) \),
\[
\frac{1}{\varepsilon_m} \frac{\partial a_p^{(m)}}{\partial z}|_{z=d_m} = \frac{1}{\varepsilon_{m+1}} \frac{\partial a_p^{(m+1)}}{\partial z}|_{z=d_m},
\]
\[
a_p^{(m)}|_{z=d_m} - a_p^{(m+1)}|_{z=d_m} = \frac{4\pi \sigma}{c} i \frac{\partial a_p^{(m)}}{\partial z}|_{z=d_m}.
\]
Similarly, by using Eqs. (4) and (11) we obtain following conditions on the scalar potential \( a_s(x) \),
\[
\frac{1}{\mu_m} \frac{\partial a_s^{(m)}}{\partial z}|_{z=d_m} = \frac{1}{\mu_{m+1}} \frac{\partial a_s^{(m+1)}}{\partial z}|_{z=d_m},
\]
\[
a_s^{(m)}|_{z=d_m} - a_s^{(m+1)}|_{z=d_m} = -\frac{4\pi}{c} i k_0 a_s^{(m)}|_{z=d_m}.
\]
To obtain the complex amplitudes \( A^{(m)}_p \) and \( B^{(m)}_p \) we must combine Eq. (7), with \( f^{(m)}_p \) given by Eqs. (8) to (10), with conditions (12) and (13) for \( \tau = p \) and \( \tau = s \) polarization, respectively. Here, we write the amplitude corresponding to region \( m = 1 \), where the dipole is placed,
\[
A^{(1)}_p = \frac{1}{\gamma_1} r^{(1,3)} e^{i\gamma^{(1)}(z'-2d)} d_{r},
\]
where
\[
r^{(1,3)} = \frac{r^{(1,2)} + r^{(2,3)} F e^{i\gamma^{(2)}2d}}{1 - r^{(2,1)} r^{(2,3)} e^{i\gamma^{(2)}2d}},
\]
and
\[
F = t^{(1,2)} t^{(2,1)} - r^{(1,2)} r^{(2,1)}.
\]
The complex amplitudes

\[ r_p^{(i,j)} = \frac{\gamma^{(i)}_{\parallel}}{\varepsilon_i} - \frac{\gamma^{(j)}_{\parallel}}{\varepsilon_j} + \frac{4\pi\gamma^{(i)}_{\perp} \gamma^{(j)}_{\perp}}{ck_0 \varepsilon_i \varepsilon_j}, \]  
(17)

\[ t_p^{(i,j)} = \frac{2\gamma^{(i)}_{\parallel}}{\varepsilon_i} + \frac{2\gamma^{(j)}_{\parallel}}{\varepsilon_j} + \frac{4\pi\gamma^{(i)}_{\perp} \gamma^{(j)}_{\perp}}{ck_0 \varepsilon_i \varepsilon_j}, \]  
(18)

are the Fresnel reflection and transmission coefficients, respectively, for \( p \) polarization, whereas

\[ r_s^{(i,j)} = \frac{\gamma^{(i)}_{\parallel}}{\mu_i} - \frac{\gamma^{(j)}_{\parallel}}{\mu_j} - \frac{4\pi k_{0\alpha}}{c}, \]  
(19)

\[ t_s^{(i,j)} = \frac{2\gamma^{(i)}_{\parallel}}{\mu_i} + \frac{2\gamma^{(j)}_{\parallel}}{\mu_j} + \frac{4\pi k_{0\alpha}}{c}, \]  
(20)

are the Fresnel reflection and transmission coefficients, respectively, for \( s \) polarization. Note that, in the case of \( \sigma = 0 \), i.e., in the absence of current density induced in each graphene sheet, \( F_\tau \) given by Eq. (16) is equal to unity and then the coefficient (15) converges to the well known reflection coefficient of three–layer medium without graphene [49].

The potential of the scattered field in the medium \( m = 1 \) can be obtained subtracting the first term in Eq. (8) corresponding to the primary dipole field,

\[ f_\tau^{(1)}(\alpha, \beta, z, z')|_{\text{scatt}} = f_\tau^{(1)}(\alpha, \beta, z, z') - \frac{1}{\gamma^{(1)}} d_\tau e^{i\gamma^{(1)}|z-z'|}. \]  
(21)

Introducing Eq. (21) into Eq. (7), and using Eqs. (3) and (4) we obtain an expression for the scattered electric field on region \( z > d \)

\[ \widetilde{E}(\vec{x})|_{\text{scatt}} = \frac{ik_0}{2\pi} \int_{-\infty}^{+\infty} \left\{ \left[ \frac{k_0\mu}{k_1^2} \alpha \gamma^{(1)} \hat{x} - \frac{k_0\mu}{k_1^2} \beta \gamma^{(1)} \hat{y} + \frac{k_0\mu}{k_1^2} (\alpha^2 + \beta^2) \hat{z} \right] A_p^{(1)} + [-\beta \hat{x} + \alpha \hat{y}] A_s^{(1)} \right\} e^{i\gamma^{(1)}z} e^{i(\alpha x + \beta y)} d\alpha d\beta, \]  
(22)

where \( A_p^{(1)} \) and \( A_s^{(1)} \) are given by Eq. (14).

3. Spontaneous emission on a graphene waveguide

The aim of this section is to derive a general formula of the spontaneous decay rate of an oscillating dipole placed above a graphene waveguide, paying special attention to the decay rate into the eigenmodes of the structure. All of the materials are non magnetic \((\mu_m = 1, m = 1, 2, 3)\). The waveguide is embedded in a transparent medium with an electric permittivity \( \varepsilon_1 = \varepsilon_3 \) and the region of space between graphene sheets is filled with a transparent material with an electric permittivity \( \varepsilon_2 \).
Spontaneous emission – graphene waveguides – surface plasmon polaritons

The graphene layer is considered as an infinitesimally thin, local and isotropic two-sided layer with frequency-dependent surface conductivity \( \sigma(\omega) \) given by the Kubo formula [50, 51], which can be read as 
\[
\sigma(\omega) = \sigma_{\text{intra}} + \sigma_{\text{inter}},
\]
with the intraband and interband contributions being
\[
\sigma_{\text{intra}}(\omega) = \frac{2ie^2\mu_c k_B T}{\pi \hbar (\omega + i\gamma_c)} \ln \left[ 2\cosh(\frac{\mu_c}{2k_B T}) \right],
\]
\[
\sigma_{\text{inter}}(\omega) = \frac{e^2}{\hbar} \left\{ \frac{1}{2} + \frac{1}{\pi} \arctan \left[ (\omega - 2\mu_c)/2k_B T \right] - \frac{i}{2\pi} \ln \left[ \frac{(\omega + 2\mu_c)^2}{(\omega - 2\mu_c)^2 + (2k_B T)^2} \right] \right\},
\]
where \( \mu_c \) is the chemical potential (controlled with the help of a gate voltage), \( \gamma_c \) the carriers scattering rate, \( e \) the electron charge, \( k_B \) the Boltzmann constant and \( \hbar \) the reduced Planck constant.

3.1. Radiated power

According to Poynting theorem, the time-averaged radiated power \( P \) by a dipole with a harmonic time dependence is given by [52]
\[
P = -\frac{1}{2} \int_V \Re \left\{ \tilde{j}^* \cdot \tilde{E} \right\} \, dV
\]
where \( V \) encloses the source and \( \tilde{j} \) represents the source density current. Introducing the value of the current in Eq. (1), we obtain
\[
P = \frac{\omega}{2} \Im \left\{ \tilde{p}^* \cdot \tilde{E}(\vec{x}') \right\}
\]
where the field \( \tilde{E} \) is evaluated at the dipole position \( \vec{x}' \). For an electric dipole above the plane waveguide interface we have
\[
\tilde{E}(\vec{x}) = \tilde{E}_0(\vec{x}) + \tilde{E}(\vec{x})|_{\text{scatt}}
\]
where \( \tilde{E}_0(\vec{x}) \) and \( \tilde{E}(\vec{x})|_{\text{scatt}} \) are the primary dipole field and the scattered field, respectively. Inserting Eq. (27) into Eq. (26) we obtain the radiated power normalized with respect to the rate in absence of the waveguide [21, 27]
\[
\frac{P}{P_0} = 1 + \frac{\Im \left\{ \tilde{p}^* \cdot \tilde{E}(\vec{x})|_{\text{scatt}} \right\}}{\Im \left\{ \tilde{p}^* \cdot \tilde{E}_0(\vec{x}) \right\}} = 1 + \frac{3\epsilon_1}{2\mu^2 k_1^3} \Im \left\{ \tilde{p}^* \cdot \tilde{E}(\vec{x})|_{\text{scatt}} \right\}.
\]
where \( P_0 = \omega \mu^2 k_1^3/(3\epsilon_1) \) is the total power radiated by an electric dipole in the unbounded medium 1 [27]. Introducing the value of the electric field (22), we obtain
\[
\frac{P}{P_0} = \cos^2 \theta \left[ \frac{P}{P_0} \right]_{\perp} + \sin^2 \theta \left[ \frac{P}{P_0} \right]_{\parallel},
\]
(29)
where subscripts $\perp$ and $||$ indicate the normal and parallel orientation of the dipole with respect to the $x-y$ plane, respectively, and

$$
\left[ \frac{P}{P_0} \right]_{\perp} = 1 + \frac{3}{2k_1^3} \text{Re} \int_{0}^{+\infty} dk_{||} \frac{k_{||}^3}{\gamma(1)} r_{p}^{(1,3)}(k_{||}) e^{i2\gamma(1)[z'-d]}, \\
\left[ \frac{P}{P_0} \right]_{||} = 1 + \frac{3}{4k_1^3} \text{Re} \int_{0}^{+\infty} dk_{||} \frac{k_{||}}{\gamma(1)} \left[ k_1^2 r_{s}^{(1,3)}(k_{||}) - \gamma(1)^2 r_{p}^{(1,3)}(k_{||}) \right] e^{i2\gamma(1)[z'-d]},
$$

(30)

(31)

where the substitutions $\alpha = k_{||} \cos \phi_k$ and $\beta = k_{||} \sin \phi_k$ have been made, and $r_{r}^{(1,3)}$ is the reflection coefficient of three-layer medium given by Eq. (15), with $\varepsilon_1 = \varepsilon_3$.

The first term in expressions (30) and (31), equal to unity, corresponds to the direct dipole radiation in the homogeneous medium 1. The integration range $[0, +\infty]$ can be divided into the two ranges $[0, k_1]$ and $[k_1, +\infty]$. In the first range, the $z$-component of the propagation wave vector $\gamma(1)$ is real, which means the waves in medium 1 are propagating. This integral yields the contribution of multiple reflections on the graphene waveguide of all the plane waves emitted by the dipole at $\vec{x} = \vec{z}' \hat{z}$ and arriving at this position. In the second range of integration $[0, +\infty]$, the $z$-component of the propagation wave vector $\gamma(1)$ is imaginary, which means the waves in medium 1 are exponentially decaying in the normal direction. This integral yields the contribution of the evanescent field radiated by the dipole, and thus it has a noticeable effect when the dipole is close enough to the interface 1–2.

**3.2. Decay through graphene eigenmodes**

Eigenmodes, like WG modes or SPs, may provide decay channels for the electric dipole placed close to the waveguide [28]. The WG modes refer to modes which are evanescent waves in the two semi-infinite regions (regions 1 and 3) and standing waves in the insulator spacer layer (region 2), and SPs refer to modes which propagate along the waveguide with their electric and magnetic fields decaying exponentially away from the graphene sheets in all three regions.

As in any resonance phenomenon, the full characteristics of the electromagnetic eigenmodes supported by the graphene waveguide can be obtained by studying the singularities of the analytic continuation of the field (22). Pole singularities occur at generally complex locations ($k_{||}$ is a complex magnitude) and they represent the propagation constant of the eigenmodes supported by the graphene waveguide. In the present case of the symmetric waveguide ($\varepsilon_1 = \varepsilon_3$ and both graphene sheets with the same value of the conductivity $\sigma$), the dispersion equation of $p$-polarized surface plasmons splits into two branches [54]. The possibility of tuning the electronic properties of graphene by adjusting the bias voltage leads to unprecedented control over the location of plasmon resonances, for which this system has been suggested as an efficient
Spontaneous emission – graphene waveguides – surface plasmon polaritons

plasmonic modulator [55]. Apart from these plasmon modes, \( p \) and \( s \) polarized guided modes can also be supported by the symmetric waveguide [56].

In order to obtain all the propagation characteristics of these eigenmodes, the propagation constants are obtained by requiring the denominator in Eq. (15) to be zero,

\[
1 - \left[ r_r^{(2,1)} \right]^2 e^{i\gamma(2)2d} = 0,
\]

where we have taken into account the equality \( \varepsilon_1 = \varepsilon_3 \). Physically, resonant condition (32) implies that a self-consistent field is established by means of a wave bouncing between the two boundaries of the layer at \( z = 0 \) and \( z = d \). This mean that the wave, after reflecting from the top and the bottom interfaces, together with a phase shift through the layer, should become in phase with itself again [49]. Because the expression for the field [22] are derived from Maxwell’s equations and boundary conditions, the resonant condition (32) holds for both homogeneous and inhomogeneous plane wave [57]. As a consequence of the waveguide symmetry, the modal fields are either odd or even with respect to the mirror symmetry plane at \( z = d/2 \). Following the same procedure developed in [54, 56], we can see that, for \( p \) polarization Eq. (32) splits into two branches, one with a symmetric and the other with an antisymmetric magnetic field across the gap dielectric layer

\[
\begin{align*}
    i \tan(\eta(2)/2) &= \frac{\gamma(1)\varepsilon_2}{\gamma(1)\varepsilon_2 + 1} \quad H\text{–symmetric}, \\
    i \tan(\eta(2)/2) &= \frac{\gamma(1)\varepsilon_2}{1 + \frac{4\pi\varepsilon_2}{\gamma(1)}} \quad H\text{–antisymmetric}.
\end{align*}
\]

Similarly, for \( s \) polarization Eq. (32) splits into two branches, one with a symmetric and the other with an antisymmetric electric field across the gap dielectric layer

\[
\begin{align*}
    i \tan(\eta(2)/2) &= \frac{\gamma(1)\varepsilon_2}{\gamma(1)\varepsilon_2 + 1} \quad E\text{–symmetric}, \\
    i \tan(\eta(2)/2) &= \frac{\gamma(1)\varepsilon_2}{1 + \frac{4\pi\varepsilon_2}{\gamma(1)}} \quad E\text{–antisymmetric}.
\end{align*}
\]

Complex roots of equations (33) and (34) have been found by adapting a numerical code based on Newton-Raphson method to complex values. Figures 2a and 2b show the real and the imaginary parts of the nondimensional propagation constant \( ck || \omega \) of SPs as a function of \( \omega/c \) obtained by solving Eqs. (33) for \( \varepsilon_1 = \varepsilon_3 = 1, \varepsilon_2 = 3.9 \) and for two different waveguide thicknesses, \( d = 0.2 \mu m \) and \( d = 0.02 \mu m \). The graphene parameters are \( \mu_c = 0.2eV, \gamma_c = 0.1meV \) and \( T = 300K \). These figures also show the curves corresponding to the propagation constant of eigenmodes supported by a single graphene sheet interface (dashed line), i.e., a system with the flat graphene sandwiched between two dielectric half space with permittivities \( \varepsilon_1 \) and \( \varepsilon_2 \). Since \( \text{Im} \sigma \) changes sign from positive to negative, due to the presence of the interband term in the conductivity \( \sigma \), at \( \hbar\omega/\mu_c \approx 1.667 \mu m^{-1} \) Eqs. (33) predicts \( p \) polarized surface plasmons restricted to the range below this frequency. Moreover, the dispersion curves plotted in figure 2a exhibit backbending in the vicinity of \( \omega/c \approx 1.667 \mu m^{-1} \). This behavior has also been observed in the dispersion curves of metallic SPs when damping is taken into
Figure 2. Dispersion curves for SSP and ASP modes, calculated for $\mu = 0.2eV$, $T = 300 K$, $\gamma_c = 0.1meV$, $\varepsilon_1 = 1$ and $\varepsilon_2 = 3.9$. (a) $\text{Re} ck_{||}/\omega$ and (b) $\text{Im} ck_{||}/\omega$ as a function of $\omega/c$. Plots also show the SP dispersion curve for a single graphene sheet sandwiched between two dielectric half space with permittivities $\varepsilon_1$ and $\varepsilon_2$. 

account. At high frequencies, $\omega/c > 0.25\mu m^{-1}$ for $d = 0.2\mu m$ or $\omega/c > 1\mu m^{-1}$ for $d = 0.02\mu m$, the layer between the two graphene sheets is thick relative to the decay length of SP in medium 2. Therefore, SPs of the two graphene sheets are essentially uncoupled from each other and their dispersion curves are practically unchanged from the single interface case. On the contrary, at lower frequencies, the fields of these modes strongly overlap through the thin layer (medium 2), leading to solutions into well separated branches. The upper branch corresponds to the antisymmetric surface plasmon (ASP) mode and the lower branch corresponds to the symmetric surface plasmon (SSP) mode.

Figure 3 shows the real part of the dimensionless propagation constant $ck_{||}/\omega$ of WG modes as a function of $\omega/c$ obtained by solving the Eqs. (33) and (34) for $p$ and $s$ polarization, respectively, and for three different waveguide thicknesses, $d = 1\mu m$ (figure 3a) and $d = 0.2$ and $0.02\mu m$ (figure 3b). It has been verified [not shown in figure 3] that the imaginary part of the dimensionless propagation constant of these modes is less than $10^{-4}$. From this figure, it can be seen that the dimensionless propagation constant lies between $n_1 = 1$ and $n_2 = \sqrt{\varepsilon_2} \approx 1.97$ ($n_1 < \text{Re} ck_{||}/\omega < n_2$), thus in the upper (medium 1) and the lower (medium 3) claddings $\gamma^{(m)} (m = 1, 3)$ is almost
Spontaneous emission – graphene waveguides – surface plasmon polaritons

Figure 3. Real part of the dispersion curves for $s$ and $p$-polarized WG modes calculated for $\mu = 0.2\,\text{eV}$, $T = 300\,\text{K}$, $\gamma_c = 0.1\,\text{meV}$ as a function of $\omega/c$. (a) $d = 1\,\mu\text{m}$ and (b) $d = 0.2, 0.02\,\mu\text{m}$.

purely imaginary, $\gamma^{(m)} = i\gamma_{wg}$ where $\gamma_{wg} = \sqrt{k_{||}^2 - \left(\frac{\omega}{c}\right)^2}$, and hence, the field mode exponentially decays along the $z$ axis. In the core (medium 2) $\gamma^{(2)}$ is real and hence the field mode is propagating along the $z$ axis resulting in a standing wave in this medium. This analysis confirms the guided wave nature of these modes, which also exists for a waveguide without graphene, provided that the core has a higher index of refraction than the cladding, $\varepsilon_2 > \varepsilon_1$. Moreover, $\text{Re} k_{||}/\omega$ decreases with decreasing values of $d$, thus the WG mode is less tightly bound as the spacing between the two graphene sheets decreases. This fact highlights the small degree of localization of WG modes for very small thicknesses.

Once the zeros of Eqs. (33) and (34) are determined, the contribution of each pole to the total decay rate has been calculated by the residues method [58]. These contributions dominate the behavior of the spontaneous emission on frequency regions where the eigenmodes are well defined.

In order to obtain an approximated analytic expression for the normal decay rate into each of the eigenmodes, each pole contribution is extracted of Eq. (30) in the small losses limit for which the imaginary part of the eigenmode propagation constant can be neglected,

$$\left[ \frac{P}{P_0} \right]_{\perp,\text{mod}} = \frac{3}{2} \pi \left( \frac{k_{\text{mod}}}{k_1} \right)^3 e^{-\gamma_{\text{mod}}^2(\varepsilon' - d)} \gamma_{\text{mod}} \text{Res} r_p^{(1,3)}, \quad (35)$$

where $k_{\text{mod}}$ is the real part of the propagation constant of a particular eigenmode, $k_{\text{spp}}$. 
Spontaneous emission – graphene waveguides – surface plasmon polaritons

for SP or $k_{wg}$ for WG modes (both quantities higher than the modulus of the photon wave vector in vacuum $k_0 = \omega / c$), $\gamma_{\text{mod}} = \gamma^{(1)} / i = \sqrt{k_{\text{mod}}^2 - (\omega / c)^2}$ is the $z$ component of the wave vector in medium 1, and $\text{Res}$ is the residue of the integrand in (30) at the pole $k_\parallel = k_{\text{mod}}$, \[ \text{Res}_{r_p^{(1,3)}} = \lim_{k_\parallel \to k_{\text{mod}}} (k_\parallel - k_{\text{mod}}) r_p^{(1,3)}. \] (36)

Similarly, the contribution of each eigenmodes to the parallel decay rate can be approximated by evaluating each pole contribution, in the small losses limit, in Eq. (31), \[ \left[ \frac{P}{P_0} \right]_{||,\text{mod}} = \frac{3}{4} \pi \left( \frac{k_{\text{mod}}}{k_1} \right) \frac{e^{\gamma_{\text{mod}} 2(z' - d)}}{\gamma_{\text{mod}}} \times \text{Res}_{r_s^{(1,3)}} \]
\[ + \frac{3}{4} \pi \left( \frac{k_{\text{mod}}}{k_1} \right) \frac{\gamma_{\text{mod}} e^{\gamma_{\text{mod}} 2(z' - d)}}{k_1^2} \times \text{Res}_{r_p^{(1,3)}}, \] (37)

where \[ \text{Res}_{r_s^{(1,3)}} = \lim_{k_\parallel \to k_{\text{mod}}} (k_\parallel - k_{\text{mod}}) r_s^{(1,3)}. \] (38)

Note that, for a horizontal dipole, there are $s$ and $p$ polarized decay channels involved in the first and in the second term in Eq. (37), respectively. Since only $p$ polarized SPs exist, only the second term corresponds to the decay rates into SPs.

From figure 2a, it is clear that the modulus of the photon wave vector is negligible compared with the propagation constant of SPs ($n_m \omega / c << k_{\text{spp}}$, where $m = 1, 2, 3$ and $k_{\text{spp}}$ denotes either the symmetric or the antisymmetric SP propagation constant). As a consequence, $\gamma_{\text{spp}} \approx k_{\text{spp}}$ and hence, the pole contribution in Eq. (37) corresponding to the plasmonic contribution (SSP or ASP) can be approximated as follows \[ \left[ \frac{P}{P_0} \right]_{||,\text{spp}} = \frac{3}{4} \pi \left( \frac{k_{\text{spp}}}{k_1} \right) \gamma_{\text{spp}} e^{\gamma_{\text{spp}} 2(z' - d)} \times \]
\[ \text{Res}_{r_p^{(1,3)}} \approx \frac{3}{4} \pi \left( \frac{k_{\text{spp}}}{k_1} \right) \frac{e^{\gamma_{\text{spp}} 2(z' - d)}}{\gamma_{\text{spp}}} \times \]
\[ \text{Res}_{r_p^{(1,3)}} = \frac{1}{2} \left[ \frac{P}{P_0} \right]_{\perp,\text{spp}}, \] (39)

where in the last equality Eq. (35) has been used. From Eq. (39) we see that the spontaneous decay rate into SPs of a single emitter whose dipole moment is perpendicular to the graphene monolayers is twice the corresponding value to the same emitter but with the dipole moment in the parallel direction to the graphene monolayers.

4. Results and discussion

Initially, we analyze the contribution of eigenmodes to the total decay rate of a dipole located at distance $l = z' - d = 0.01 \mu m$ from the surface of the graphene waveguide.
Thickness $d = 1\mu m$, constitutive parameters of the dielectric slab and graphene sheets are $\varepsilon_1 = 1$, $\varepsilon_2 = 3.9$, and $\mu_c = 0.2eV$, $\gamma_c = 0.1meV$, $T = 300K$, respectively.

Figure 4 and figure 5 show the normal and the parallel decay rates as a function of $\omega/c$ frequency, respectively. The total decay rate is the numerical result of Eqs. (30) and (31) for perpendicular and parallel dipole orientation, respectively. In the former case only $p$ polarized eigenmodes can be excited, while in the second case $p$ and $s$ polarized eigenmodes can be excited. These figures also show the different contributions to the spontaneous emission rate obtained by using Eqs. (35) and (37). The acronym SWG refers to symmetric WG modes, i.e., to solutions of the first Eq. (33) or to solutions of the first Eq. (34). Similarly, the acronym AWG refers to antisymmetric WG modes, i.e., to solutions of the second Eq. (33) or to solutions of the second Eq. (34). From these figures, it is clear that the decay rates through the WG modes is much lower (by a factor $10^5$) than the corresponding decays through the excitation of SSP and ASP modes. This is true because the field of SPs concentrates near the surface much more strongly than the field of the WG modes. As Figures 4a and 5a show, the total decay rate and the sum of the contributions from SP modes overlap. These figures also shows the curve corresponding to the same emitter placed at a distance $l = 0.01\mu m$ above a single graphene sheet separating medium 1 (where the dipole is placed) from medium 2. We see that the contribution of both SSP and ASP modes coincide in the whole frequency range, in agreement with the fact that, for sufficiently large $d$, both the symmetric and the antisymmetric branches merge into the dispersion curve of the single SP mode supported by a graphene monolayer (dashed line in fig. 2). Moreover, the total contribution to the decay rate of SPs (ASP + SSP) agree with the corresponding contribution to the decay rate of SPs on a single graphene monolayer, according to the fact that for large enough $d$ values and for low values of $l$ ($l << d$) the system formed by the source and the graphene waveguide resembles a system formed by the source and a single graphene sheet. As the thickness $d$ is decreased, a splitting of the dispersion curves into the symmetric and the antisymmetric mode curves occurs (figure 2a) and, as a consequence different contributions to the decay rate by the symmetric and the antisymmetric SPs are expected. This fact can be seen in figure 6a, where we have plotted the integrand of Eq. (30), $(c/\omega) dP_\perp/dk_\parallel (k_\parallel -$ space power spectrum), as a function of the dimensionless parallel wave vector $ck_\parallel/\omega$ for a vertical dipole placed at distance $l = 0.01\mu m$ from the waveguide and for several $\omega/c = 0.3$, $0.5$, and $0.8\mu m^{-1}$ frequency values. All curves show two prominent peaks due to excitation of antisymmetric (low wavenumber) and symmetric (high wavenumber) SPs. The correspondence between these peaks and the SP resonances of the graphene waveguide is evidenced in figure 6b, where we have plotted the real part of the dispersion curves for symmetric and antisymmetric SP modes. Moreover, as the frequency increases both peaks are widened in accordance with the fact that, in this frequency range, the imaginary part of the dimensionless propagation constant of both symmetric and antisymmetric SPs increases as the frequency increases (figure 2b). Similar behavior has been observed [not shown in fig. 6] in the case for which the dipole is placed parallel to the graphene waveguide. From figure 6a, we
observe that most of the contribution to the power spectrum is given by SP peaks, and observing this figure allows us to assert that each of these peaks contributes with a different value to the spontaneous decay rate. This fact can be viewed in figure 7 in which the frequency dependence of the total decay rate and the SP contributions are plotted for the same parameters as in figure 6 except now for distances $l = 0.008$, $0.02$, and $0.03\mu m$. From this figure, it can be seen that the differences between the total decay rate and the sum of the contributions from SP modes are small. On the other hand, for small values of $l$, the level of the total decay rate for graphene waveguide is larger than the corresponding level reached for a single graphene sheet (figs. 7a and 7d). As the distance $l$ is increased, the level of the total decay rate for graphene waveguide

Figure 4. (a) Total decay rate and SP contributions to the decay rate of a vertical dipole placed at a distance $l = 0.01\mu m$ above a graphene waveguide as a function of $\omega/c$. (b) WG mode contributions to the decay rate as a function of $\omega/c$. The waveguide parameters are $\mu_c = 0.2eV$, $\gamma_c = 0.1meV$, $\varepsilon_1 = \varepsilon_3 = 1$, $\varepsilon_2 = 3.9$, $d = 1\mu m$ and $T = 300K$. Plot (a) also shows a curve corresponding to the SP contribution of a vertical dipole placed at a distance $l = 0.01\mu m$ above a single graphene sheet.
Figure 5. (a) Total decay rate and SP contributions to the decay rate of a parallel dipole placed at a distance $l = 0.01\mu m$ above a graphene waveguide as a function of $\omega/c$. $s$ polarized (b) and $p$ polarized (c) WG mode contributions to the decay rate as a function of $\omega/c$. The waveguide parameters are the same as in figure 4.

is equal or even lower than for a single graphene sheet (figs. 7b, 7c and 7e, 7f).

It is worth noting that the shape of the spontaneous emission spectrum is strongly influenced by the SP branches. For instance, when the distance $l$ is small, the coupling strength between the near field emitted by the source and SPs with large wave vectors is high, leading to an increase of the decay rate in the corresponding high frequency range. In this range, the dispersion of the ASP and SSP modes are similar to that of the SP mode on a single graphene interface (figure 2a) and, thus, the frequency of the peak in the total decay rate curve for graphene waveguide coincides with the frequency of the peak corresponding to a single graphene sheet (figures 7a and 7d). As $l$ distance is increased, the strength in this range of frequency falls because the near
Figure 6. (a) $k_\parallel$ space power spectrum for a vertical dipole placed a distance $l = 0.01\mu m$ above a graphene waveguide and for frequencies $\omega/c = 0.3, 0.5$ and $0.8\mu m^{-1}$. (b) Dispersion curves for $p$ polarized SPs. The waveguide parameters are $\mu_c = 0.2eV, \gamma_c = 0.1meV, \varepsilon_1 = \varepsilon_3 = 1, \varepsilon_2 = 3.9, d = 0.02\mu m$ and $T = 300K$.

field can only excite SPs with increasingly smaller wave vectors. In this range, the fields of the ASP and SSP modes strongly overlap through the thin layer, leading to well separated branches (figure 2a), where the upper branch corresponds to the ASP mode and the lower branch corresponds to the SSP mode. As a consequence, the frequency of the peak in the ASP decay rate curve is larger than that corresponding to decay rate through the excitation of SSP modes, explaining the separation between the peaks in the decay rate curves for graphene waveguide and for a single graphene sheet observed in figures 7b, 7c, 7e, and 7f. Moreover, as $l$ is increased, the peak of the curves shifts to lower frequencies and, for large enough $l$ values the total decay rate for graphene waveguide exhibits a double peak structure, as can be seen in figures 7c and 7f. Note that, according to Eq. (39), the values of the decay rates plotted in figures 7a, 7b and 7c are approximately twice the values of the decay rates plotted in figures 7d, 7e and 7f, respectively.

It is well established nowadays that the phenomenon of the spontaneous emission can be understood in the framework of quantum electrodynamics. In the weak coupling regime, within the dipole approximation, the decay constant for a radiating dipole located at $\vec{x}' = z'\hat{z}$ is given by Fermi’s golden rule (see Refs [23, 59]),

$$\frac{1}{\tau} = \frac{2\pi}{\hbar^2} |\vec{p} \cdot \alpha \vec{E}(z',\omega)|^2 D_{2D}(\omega), \quad (40)$$
Spontaneous emission – graphene waveguides – surface plasmon polaritons

Figure 7. Total decay rate and different contributions to the decay rate as a function of $\omega/c$ of a dipole placed above a graphene waveguide for the same parameters as in figure 6. Plots also show a curve corresponding to total decay rate of a same dipole placed above a single graphene sheet. The orientation of the dipole is vertical for the three panels on the top row and it is horizontal for the three panels on the bottom row. The distance $l = 0.008\mu m$ (a) and (d), $l = 0.02\mu m$ (b) and (e), and $l = 0.03\mu m$ (c) and (f).

where $\bar{p}$ is the dipole moment matrix element, $D_{2D}$ is the surface plasmon density of states and $\alpha$ is a normalization factor related to the vacuum fluctuation energy,

$$|\alpha|^2 = \frac{\hbar \omega / 2}{\frac{S}{8\pi} \int_{-\infty}^{\infty} \left\{ \varepsilon(z)|E(z', \omega)|^2 + |H(z', \omega)|^2 \right\} dz},$$

(41)

If the dipole lies in the $x-y$ plane ($\bar{p} = p_x \hat{x} + p_y \hat{y}$), so that $p_x^2 = p_y^2 = p^2/2$, then the decay rate (40) can be written as

$$\frac{1}{\tau_{||}} = \frac{\pi^2 \omega |\bar{p}|^2}{\hbar V_{\text{eff}}(z', \omega)},$$

(42)

where $S$ is the in–plane quantization area, $V_{\text{eff}} = SL_{\text{eff},||}$ is the effective mode volume, and $L_{\text{eff},||}$ is the effective mode length in $z$–axis direction for a dipole oriented parallel to the $x-y$ plane

$$L_{\text{eff},||}(z', \omega) = \frac{1}{2} \int_{-\infty}^{\infty} \left\{ \varepsilon(z)|E(z', \omega)|^2 + |H(z', \omega)|^2 \right\} dz \frac{1}{|\vec{E}_{||}(z', \omega)|^2}$$

(43)
Spontaneous emission – graphene waveguides – surface plasmon polaritons

with $E_{||}$ being the parallel component of the plasmon field. The surface plasmon density of states is obtained calculating the number of corresponding modes in the two–dimensional $k$ space,

$$D_{2D} = \frac{S}{2\pi} \int \frac{dk}{d\omega} = \frac{S}{2\pi v_p(\omega)v_g(\omega)},$$

(44)

with $v_p$ and $v_g$ representing the phase and group velocities of the SP mode calculated at the dipole emission frequency, respectively. Inserting Eq. (44) into Eq. (12), using Eq. (43), we find the normalized emission lifetime to be

$$\frac{\tau_0}{\tau_{||}} = \frac{3}{8} \frac{c^2 \lambda}{v_p v_g L_{eff}(z',\omega)}$$

(45)

where $\lambda = \frac{2\pi c}{\omega}$ is the wavelength of the source, $\tau_0^{-1} = 4|\vec{p}|^2 \omega^3/(3\hbar c^3)$ is the spontaneous emission decay constant for vacuum derived from cavity quantum electrodynamics considerations [60].

On the other hand, if the dipole is oriented in the $z$ axis, $\vec{p} = p\hat{z}$, following the same procedure as used to deduce Eq. (45), the decay rate (40) can be written as

$$\frac{\tau_0}{\tau_{\perp}} = \frac{3}{4} \frac{c^2 \lambda}{v_p v_g L_{eff}(z',\omega)}$$

(46)

where

$$L_{eff,\perp}(z',\omega) = \frac{1}{2} \int_{-\infty}^{\infty} \left\{ \varepsilon(z)|E(z',\omega)|^2 + |H(z',\omega)|^2 \right\} dz$$

(47)

$|E_{\perp}(z',\omega)|^2$ is the effective mode length when the dipole is oriented in $z$–axis direction and $E_{\perp}$ is the perpendicular component of the plasmon field.

It is known that [27] if we identify the dipole matrix element $\vec{p}$ in Eqs. (45) and (46) with the classical dipole in Eqs. (30) and (31), then the normalized decay constant is equal to the normalized classical radiation power, i.e., $\tau_0/\tau = P/P_0$ for both dipole orientations, parallel and perpendicular to the $x$–$y$ plane. In this framework, the enhancement of the spontaneous emission rate can be quantified by the reduction of effective mode length and the group velocity of surface plasmons, i.e., $L_{eff} v_g$.

To illustrate, we explore the tunability of the spontaneous emission by varying the chemical potential $\mu_c$ on graphene sheets. As in the classical treatment, from the quantum point of view the decay rate of a dipole with parallel orientation is close to half of the corresponding decay of the same dipole with perpendicular orientation in the whole frequency range where SP modes exist. This fact can be viewed as follows. Due to the fact that the modulus of the photon wave vector is negligible compared with the propagation constant of SPs, $\omega/c \ll k_{spp}$, the modulus of both components of SP electric fields, $|E_{||}|$ and $|E_{\perp}|$, are approximately equal. Therefore, from Eqs. (45) and (46) it follows that $[P/P_0]_{||} \approx [P/P_0]_{\perp}/2$. We have numerically verified this assertion. Thus, we only show examples corresponding to an emitter whose dipole moment is perpendicular to graphene monolayers. The waveguide parameters chosen are the same as in figure 7.
Figure 8. Decay rate of a vertical dipole located at $l = 0.01\mu m$ from the graphene waveguide into (a) ASP and (c) SSP for different values of the chemical potential $\mu_c$ (0.2, 0.3, 0.4 and 0.5eV). Dispersion curves for (b) ASPs and (d) SSPs calculated for the same chemical potential values of (a) and (c). The waveguide parameters are $\gamma_c = 0.1\text{meV}$, $\varepsilon_1 = \varepsilon_3 = 1$, $\varepsilon_2 = 3.9$, $d = 0.02\mu m$ and $T = 300\text{K}$.

Figure 8a and 8c show the normalized decay rate of a vertical dipole placed at a distance $l = 0.01\mu m$ above the graphene waveguide into the symmetric and the antisymmetric SPs, respectively, calculated by using Eq. (46). The drop in these curves occur at the frequency where $\sigma$ changes sign from positive to negative, $\hbar\omega \approx 1.667\mu_c$. At this frequency the slope of the dispersion curves tends to zero, as can be seen in Figures 8b and 8d where these curves have been plotted for symmetric and antisymmetric SPs, respectively. Unlike section 3.2, the dispersion curves shown in figures 8b and 8d have been calculated neglecting losses in graphene sheets, a basic approach to derive Eqs. (45) and (46) from the quantization scheme of SP field [26]. We have verified that results obtained from Eq. (46) are in agreement with those obtained from classical formalism.
by using Eq. (35).

Figure 9. Normalized mode length for (a) ASP and (b) SSP. Normalized group velocity for (c) ASPs and (d) SSPs. The curves have been calculated for different values of the chemical potential \( \mu_c \) (0.2, 0.3, 0.4 and 0.5eV). The vertical dipole is located at \( l = 0.01\mu m \) from the graphene waveguide. The waveguide parameters are \( \gamma_c = 0.1\text{meV} \), \( \varepsilon_1 = \varepsilon_3 = 1 \), \( \varepsilon_2 = 3.9 \), \( d = 0.02\mu m \) and \( T = 300K \).

Figure 8a and figure 8c show that the decay rate peak shifts to blue, as the value of \( \mu_c \) increases. This behavior can be understood with the help of figure 9, where both the effective mode length \( L_{\text{eff}} \) and the group velocity of surface plasmons as a function of \( \omega/c \) have been plotted. From figures 9a and 9b, it can be seen that the curves of \( L_{\text{eff}} \) exhibit a minimum at a frequency value slightly lower than the frequency where the curves corresponding to spontaneous decay rates shown in figures 8a and 8b exhibit a maximum. The reduction of the group velocity with the frequency, shown in figures 9c and 9d, moves the minimum of the denominator in Eq. (46) \( (L_{\text{eff}} v_g) \) toward the position of the spontaneous decay rate peak.
5. Conclusions

We have presented an exhaustive study of the spontaneous emission rate of a single emitter (atom or molecule) in a planar graphene waveguide formed by two parallel graphene monolayers with an insulator spacer layer. We developed an analytical classical method and obtained a rigorous solution in a closed integral form. This solution has the functional form corresponding to a dielectric or a metallic slab, although the current density induced in the graphene sheets leads to a marked difference between the reflection coefficient corresponding to a graphene waveguide and a waveguide without graphene monolayers (bare waveguide).

We separately calculated the contribution of symmetric and antisymmetric eigenmodes – SPs and WG modes– to the total decay rate. In the presented examples, we have varied the location of the emitter for both dipole moment orientations, parallel and perpendicular to the graphene monolayers. The dipole moment perpendicular to the graphene monolayers cannot couple to $s$-polarized eigenmodes, whereas the dipole moment parallel to the graphene monolayers couples to both $s$ and $p$ eigenmodes. The emphasis has been centered around the plasmonic channels, since their contributions play a prominent role in the spontaneous emission rate of single emitters placed near the graphene waveguide. An interesting result revealed in this study is related with a redistribution of the emitted power by a dipole located near a waveguide structure, i.e., the influence of the SP branches on the shape of the emission spectrum. We have shown that by increasing the distance between the emitter and the graphene waveguide, one can obtain spectral behaviors ranging from a single peak curve similar to that of a single graphene sheet to a double peak curve.

The coupling efficiency between the emitter and SP modes was also studied from an equation based on Fermi golden rule. Our examples show that the reduction of both the effective mode length and the group velocity of surface plasmons lead to an enhancement of the spontaneous emission rate. We have shown that, by tuning of the chemical potential of graphene, it is possible to modify the density of states as well as the effective mode volume of SPs leading to unprecedented control over the location and magnitude of the spontaneous emission rate.

The possibility to vary the chemical potential of one of the graphene sheets with respect to the other one fixed, allows another degree of freedom to modify SP branches, with fields no longer symmetric or antisymmetric across the gap dielectric layer, and their influence on the spontaneous emission rate. Although we are planning to report the results of such study in a future paper, as a first step, here we have restricted ourselves to performing an analysis of the symmetric waveguide in which the two conductivities of the graphene sheets are equal.
