Abstract

In the large dimension ($D$) limit, the Einstein’s equation reduces to the effective theory on the horizon surface, drastically simplifying the black hole analysis. Especially, the effective theory on the black brane was successful in describing the non-linear dynamics not only on the black brane, but also on compact black objects which are encoded as solitary Gaussian-shaped lumps, blobs. In the rigidly rotating ansatz, in addition to axisymmetric deformed branches, various non-axisymmetric solutions as black bars are found by using this blob approximation, which only stay stationary at the large $D$ limit.

In this article, we demonstrate the blob approximation has a wider range of applicability by formulating the interaction between blobs and subsequent dynamics. We identify that this interaction occurs via thin necks connecting blobs. Especially, black strings are captured quite well by this approximation sufficiently away from the perturbative regime. Highly deformed black dumbbells and ripples are also found to be tractable in the approximation. By defining the local quantities, the effective force acting on distant blobs are evaluated as well. These results reveal a new aspect of the large $D$ effective theory as the dynamics of interactive blobs — brane blobology.

1 Introduction

Black holes in higher dimensions exhibit colorful dynamics, in which horizons are stretched, bended and even pinched off [1]. Remarkably, elongated horizons are generally endowed with a long wave length instability, the Gregory-Laflamme (GL) type instability [2, 3], which can evolve to the horizon pinch-off accompanied by the curvature singularity illustrating the generic violation of the strong cosmic censorship [4–6]. On the other hand, the same dynamics produces numerous stationary deformed solution branches coming out from the onset of the instability.

The large spacetime dimension limit, or the large $D$ limit [7, 8] is a keen approach to cut out such distinctive features of the higher dimensional gravity. In the large $D$ limit, black hole dynamics splits to two sectors with separate scales about the horizon scale $r_0$:

**Decoupled sector** ‘Slow’ dynamics with the gradient of $O(1/r_0)$, which is confined within the thin layer of the near horizon, and contains GL-like self-gravitational deformations.

**Non-decoupled sector** ‘Fast’ dynamics with the gradient of $O(D/r_0)$, which corresponds to the radiative degrees of freedom in the time domain, as well as the radical horizon deformation in the space domain.

Due to its non-perturbative-in-1/$D$ nature, the common framework has not been established for the fast dynamics.\(^1\) On the other hand, the slow dynamics is successfully reformulated into an effective theory of collective degrees of freedom on the horizon surface which is perturbative in 1/$D$ [11–15]. So far, the large $D$ effective theory approach has been applied to solve various black hole problems with or without the Maxwell charge, cosmological constant, and even Gauss-Bonnet correction [16–30].

The large $D$ effective theory of black branes also admits Gaussian-shaped solitary lumps\(^2\), or blobs, which encode compact black objects within the planer setup [31]. In the blob solution, the Gaussian tail in the asymptotic region is expected to be matched with the equatorial part of black objects. In the rigidly rotating setup, this blob approximation enabled to find a large variety of stationary deformed black holes bifurcating from Myers-Perry as black bars, ripples, dumbbells and flowers [31–33]. Having the multiple blobs, each blob travels almost independently until they collide to merge or split [34–36]. One should bear in mind that, in the multiple configuration, the leading order theory does not resolve whether or not the horizon is actually joined or split, since the thickness between blobs can be arbitrary thin. Only with 1/$D$ correction, the thin region leads to the breakdown of 1/$D$ expansion indicating disconnected horizons.

In the large $D$ limit, the gravity from black holes are suppressed non-perturbatively in 1/$D$ except the thin near horizon region, and hence the interaction between black holes

\(^1\)Though, recent studies [9, 10] shed some light on this sector.

\(^2\)Blobs are almost solitons except that the collision does not preserve the number of blobs due to the thermalization by the viscosity.
are usually negligible in the $1/D$-expansion. The blobs, nevertheless, can weakly interact each other. For example, in the blob-blob collision, it is observed that the large impact parameter leads two blobs to orbit several rounds before they collide or split away, as if they are attracted to each [36]. At highly deformed regime, black dumbbells form a multiple binary of separate blobs, and black ripples multiple concentric ring-shaped blobs [33], in which blobs are connected by thin neck regions. In both cases, the centrifugal forces should be sustained by a certain attraction between blobs. These interactions can be understood by encoding multiple blobs as either of black holes whose horizons are almost touching (so that near horizons have some overlap) or large lumps on a single black object thinly connected to each other, which are undistinguishable at the leading order.

In this article, we establish analytical descriptions for the blob-blob interaction by resolving thin neck regions between blobs. The resulting formula is written by the trans-series with respect to the distance between blobs.

This article is organized as follows. In section 3, we revisit the non-uniform black string analysis in highly deformed regime by expanding in small tension. In sections 4 and 5, highly deformed black dumbbells and ripples are studied by using the same technique in the limit $\Omega \to 0$. In section 6, we formulate the effective kinematics of blobs by defining the localized variables for each blob. The approximate equation of motion for blobs are derived. We summarize and discuss the possible extension of the result in section 7.

Brane blobology

The term ‘brane blobology’ was introduced in [36], as a pun on the brain blobology in the neuroscience. Though, we do not claim any scientific relation.

2 Large $D$ effective theory

In this section, the large $D$ effective theory on the black brane is briefly reviewed [11–15, 37,38]. The effective theory of the $p$-brane is embedded in $D = p + 3 + n$ background

$$ds^2 = -dt^2 + dr^2 + \frac{1}{n} dx^i dx_i + r^2 d\Omega^2_{n+1}$$

where $i = 1, \ldots, p$ and $d\Omega^2_{n+1}$ is $S^{n+1}$-metric. Here, we set the physical horizon scale $r_0 = 1$. Assuming $n \approx D$, it is convenient to expand by $1/n$ instead of $1/D$. The $1/n$ scaling for $x$ coordinates is introduced to capture the nonlinear dynamics along those directions. In the large $D$ limit, the entire spacetime geometry is written only by the collective degrees of freedom : the mass density $m(t,x)$ and momentum density $p_i(t,x)$. By introducing the velocity field $p_i = mv_i + \partial_t m$, the effective equation take the form of

---

3Throughout this article, we focus on the vacuum, asymptotically-flat spacetime. The extension to the Einstein-Maxwell theory and inclusion of the cosmological constant will be discussed in section 7.
a fluid equation,
\[ \partial_t m + \nabla_i (mv^i) = 0, \quad \partial_t (mv^i) + \nabla_j (mv^i v^j + \tau^{ij}) = 0, \quad (2.2) \]
\[ \tau_{ij} := -m \delta_{ij} - 2m \nabla_i (v^j) - m \nabla_i \nabla_j \log m \]

where the indices are raised by \( \delta_{ij} \) and \( \nabla_i \) is the covariant derivative for \( \delta_{ij} \).

**Gaussian blobs** Besides ordinary brane solutions, this equation exhibits stable Gaussian solutions, or blobs. For \( p = 2 \), the general rotating blob solution is given by
\[ m(t, z) = m_0 \exp \left( -\frac{(x - ut - b)^2}{2(1 + a^2)} \right), \quad v^i(t, z) = u^i + \frac{a}{1 + a^2} \varepsilon_{ij}(x^i - u^i t). \quad (2.3) \]
where \( a \) corresponds to the spin parameter of the singly spinning Myers-Perry, \( u^i \) and \( b^i \) are arbitrary constants reflecting the boost invariance and Galilean symmetry of the system.

**Rigidly rotating solutions** With the rigidly rotating ansatz
\[ (\partial_t + v^i \partial_i)m = 0, \quad \partial_t v^i = 0, \quad \nabla_i (v^i) = 0, \quad (2.4) \]
the effective equation is integrated to the soap bubble equation [31]
\[ \nabla^2 \mathcal{R} + \frac{1}{2} (\nabla \mathcal{R})^2 + \mathcal{R} + \frac{1}{2} v^2 = C, \quad (2.5) \]
where \( C \) is an integral constant fixing the mass scale and \( \mathcal{R} = \log m \) denotes the horizon radius as
\[ r_H \simeq m^{\frac{1}{D}} \simeq 1 + \frac{1}{D} \mathcal{R}. \quad (2.6) \]

## 3 Highly deformed non-uniform black strings

Let us start from revisiting the black string analysis in the 1 + 1 effective theory [11, 12, 16, 22]. The effective equation for the static black string is given by
\[ \mathcal{R}_0''(z) + \frac{1}{2} \mathcal{R}_0'(z)^2 + \mathcal{R}(z) = C, \quad (3.1) \]
where the constant \( C \) determines the mass scale. Multiplying by \( e^{\mathcal{R}(z)} \mathcal{R}'(z) \), this can be integrated to
\[ \left( \frac{1}{2} \mathcal{R}^2 + \mathcal{R} - 1 - C \right) e^{\mathcal{R}} = -\tau, \quad (3.2) \]
where \( \tau \) is the string tension. Without loss of generality, we fix \( C = 0 \) in the following analysis, in which the non-uniform black strings are obtained for \( 0 < \tau < 1 \), and the

---

4The event horizon and apparent horizon are degenerately equal to \( m^{\frac{1}{D}} \) in the leading order.
uniform string at the bifurcation point for $\tau = 1$. Once the solution $(\mathcal{R}(z; \tau), \tau)$ is obtained, the mass scale is easily recovered by

$$\mathcal{R}(z; \tau) \to \mathcal{R}_C(z; \tau_C) = \mathcal{R}(z; e^{-C \tau_C}) + C, \quad \tau \to \tau_C = e^{C \tau}.$$  \hspace{1cm} (3.3)

At the zero tension limit $\tau \to 0$, the non-uniform solution goes to the non-periodic Gaussian distribution.

### 3.1 Gaussian blob with small tension

Assuming $\tau \ll 1$, the leading order solution is given by the zero tension Gaussian solution

$$\mathcal{R}(z) = 1 - \frac{1}{2} z^2 + \mathcal{O}(\tau).$$  \hspace{1cm} (3.4)

The small tension gives a linear correction to the Gaussian by $\delta \mathcal{R}(z) = -e^{-1+\frac{1}{2} \tau} + e^{-1} \sqrt{\frac{\pi}{2}} z \text{erfi}(z/\sqrt{2})$.

$$\delta \mathcal{R}(z) = -e^{-1+\frac{1}{2} \tau} + e^{-1} \sqrt{\frac{\pi}{2}} z \text{erfi}(z/\sqrt{2}).$$  \hspace{1cm} (3.5)

In the mass profile, this correction breaks the Gaussian fall off at large $z$,

$$m(z) = e^{\mathcal{R}(z)} \approx e^{1-\frac{1}{2} \tau} + \frac{\tau z^2}{\sqrt{2}}.$$  \hspace{1cm} (3.6)

This seems a pathological behavior. However, we will see the solution is smoothly continued to the neck waist solution where these two terms become comparable.

### 3.2 Short waist

According to the numerical solution, the long Gaussian tail is smoothly connected to the short waist (figure 1). The amplitude of the waist is estimated by eq. (3.4) as $\mathcal{R} \approx -L^2/8$.

From this observation, we introduce another scaling on the neck waist

$$\mathcal{R} = -\frac{1}{8} L^2 + \bar{\mathcal{R}}(\xi), \quad z = \pm \frac{L}{2} + \frac{2\xi}{L}.$$  \hspace{1cm} (3.7)
Plugging this into the effective equation (3.1), we obtain
\[ R''(\xi) + \frac{1}{2} R'(\xi)^2 - \frac{1}{2} = -\frac{4}{L} R(\xi). \] (3.8)

This equation can be solved by expanding \( \tilde{R}(\xi) \) with \( 1/L^2 \),
\[ \tilde{R}(\xi) = \sum_{i=0}^{\infty} L^{-2i} \tilde{R}_i(\xi). \] (3.9)

Since eq. (3.8) only includes the derivative terms in the leading order, we always have a translation degree of freedom at each order, which is used to set the minimum at \( \xi = 0 \). This also sets the solution to be symmetric in \( \xi \to -\xi \). In the leading order, the solution becomes
\[ \tilde{R}_0(\xi) = \tilde{r}_0 + 2 \log \cosh(\xi/2), \] (3.10)
where \( \tilde{r}_0 \) is an integration constant which contributes to the minimum value at the neck. The leading order solution has the following asymptotic behavior at \( \xi \to \pm \infty \),
\[ \tilde{R}_0(\xi) \simeq \pm \xi + \tilde{r}_0 - 2 \log 2 + 2e^{-|\xi|}. \] (3.11)

This gives the match with the Gaussian blobs (3.4) at both sides \( z = \pm L/2 \),
\[- \frac{L^2}{8} + \tilde{R}_0(\xi) + \mathcal{O}(L^{-2}) \simeq -\frac{1}{2} \left( \frac{L}{2} + \frac{2\xi}{L} \right)^2 + \tilde{r}_0 - 2 \log 2 + \mathcal{O} \left( e^{-|\xi|}, L^{-2} \right), \] (3.12)
where the matching region is given by \( 1 \ll \xi \ll L \). The match with the Gaussian solution (3.4) determines the integration constant
\[ \tilde{r}_0 = 1 + 2 \log 2, \] (3.13)
which gives the neck minimum up to \( \mathcal{O}(L^0) \),
\[ R_{\text{min}} = -\frac{L^2}{8} + 1 + 2 \log 2 + \mathcal{O}(L^{-2}). \] (3.14)
Since the tension is given by the minimum value, we can express the tension in terms of the compactification length,
\[ \tau = (1 - R_{\text{min}}) e^{R_{\text{min}}} \simeq \frac{1}{2} L^2 e^{1 - \frac{L^2}{4\tau}}. \] (3.15)

Inversely, the scale \( L \) is expressed by the tension
\[ L \simeq 2\sqrt{-2W_{-1}(-\tau/(4e))}, \] (3.16)
where \( W_{-1}(x) \) is the lower branch of the Lambert W function. At the limit \( \tau \to 0 \), the scale \( L \) admits a logarithmic dependence to the tension,
\[ L \simeq 2\sqrt{-2\log \tau}. \] (3.17)
**Match with $O(\tau)$-correction**  Given the relation between the tension and compactification scale, we can evaluate the behavior of the correction to the Gaussian blob (3.5) in the matching region. For $z \to \infty$, eq. (3.5) has the asymptotic behavior

$$
\delta R(z) = e^{-1} \sqrt{\frac{\pi}{2}} z \text{erfi}(z/\sqrt{2}) - e^{-1+\frac{z^2}{2}} \simeq \frac{1}{z^2} e^{-1+\frac{z^2}{2}} (1 + O(z^{-2})). \tag{3.18}
$$

Expanding at $z = \pm L/2 + \xi/L$ with eq. (3.15), the correction term is shown to be $O(L^0)$,

$$
\tau \delta R \simeq 2 e^{-|\xi|} + O(\tau, L^{-2}) \tag{3.19}
$$

This gives a consistent match with eq. (3.11) at $O(e^{-|\xi|})$. Here, we should note that $O(\tau k)$-correction gives $\tau k \delta^k R \sim \tau k e^{k z^2/2} \sim e^{-k |\xi|}$, resulting in the similar consistent match up to the relevant order in $1/L^2$.

**Higher order in $1/L^2$**  The next-to-leading order solution is obtained straightforwardly,

$$
\bar{R}_1(\xi) = \bar{r}_1 + 16 \log \cosh(\xi/2) - 2 \left[ \xi^2 + 4 \xi + \pi^2/3 + 4 \text{Li}_2 \left( -e^{-\xi} \right) \right] \tanh(\xi/2), \tag{3.20}
$$

where we used the matching result (3.13). Again the integration constant $\bar{r}_1$ is set for the neck minimum at $\xi = 0$, which is determined by the asymptotic behavior

$$
\bar{R}_1(\xi) \simeq -2\xi^2 + \bar{r}_1 - \frac{2\pi^2}{3} - 16 \log 2 + O(e^{-|\xi|}). \tag{3.21}
$$

The match with the Gaussian blob (3.4) gives

$$
\bar{r}_1 = \frac{2\pi^2}{3} + 16 \log 2. \tag{3.22}
$$

The next-to-next-to-leading order solution $\bar{R}_2(\xi)$ is obtained in the similar way. The result is put in the appendix A. Here, we only show the matching result for the neck minimum,

$$
\bar{r}_2 = \frac{64\pi^2}{3} + 96\zeta(3) + 128(\log^2 2 + \log 2). \tag{3.23}
$$

This improves the relation between $R_{\text{min}}$, $\tau$ and $L$,

$$
R_{\text{min}} = -\frac{L^2}{8} + 1 + 2 \log 2 + \frac{1}{L^2} \left( \frac{2\pi^2}{3} + 16 \log 2 \right)
+ \frac{1}{L^4} \left( \frac{64\pi^2}{3} + 96\zeta(3) + 128(\log^2 2 + \log 2) \right) + O(L^{-6}), \tag{3.24}
$$

$$
\tau = \frac{L^2}{2} e^{-L^2/8} \left( 1 + \frac{2\pi^2}{3L^2} + \frac{16\pi^2/9 + 96\zeta(3)}{L^4} + O(L^{-6}) \right). \tag{3.25}
$$

In figure 2, we compare the tension with the numerical calculation, together with the perturbatively constructed result from the uniform solution.
Figure 2: The tension for given period $L$. The gray curve represents the numerical result. The red curve is given by the perturbative expansion in the small non-uniformity up to 8-th order. The blue dotted, dashed and solid curves correspond the blob approximation up to LO, NLO and NNLO in eq. (3.25), respectively.

### 3.3 Phase diagram

Finally, we evaluate the total mass for a period

$$M := \int_{-\frac{L}{2}}^{\frac{L}{2}} e^{R(z)} dz. \quad (3.26)$$

The total mass is obtained by summing the both contributions from the blob and neck parts,

$$M = M_{\text{blob}} + M_{\text{neck}}. \quad (3.27)$$

After the summation, the actual matching position should not appear in the result. The contribution from the blob part is given by

$$M_{\text{blob}} = 2 \int_0^{z_c} dz \left[ e^{1 - \frac{z^2}{2}} + \tau \left( \sqrt{\frac{1}{2}} z \text{erfi}(z/\sqrt{2}) - 1 \right) \right]$$

$$= \sqrt{2\pi} e - \sqrt{2\pi} e \text{erfc}(z_c/\sqrt{2}) - \sqrt{2\pi} \tau e^{-\frac{z_c^2}{2}} \text{erfi}(z_c/\sqrt{2}), \quad (3.28)$$

where $z_c$ is a cut off of the integral. We set $z = z_c$ at some point in the matching region

$$z_c = \frac{L}{2} - \frac{2\xi_c}{L}, \quad (1 \ll \xi_c \ll L). \quad (3.29)$$

The asymptotic expansion at large $L$ leads to

$$M_{\text{blob}} = \sqrt{2\pi} e - 2Le^{1 - \frac{L^2}{2}} \left[ 1 + \frac{2}{L^2} \left( \frac{\pi^2}{3} + 2 + 2\xi_c + \xi_c e^{2\xi_c} + \frac{4}{L^4} \left( 24\zeta(3) + 12 + \frac{14\pi^2}{3} + \frac{\pi^4}{18} \right) + \frac{2}{3} (18 + \pi^2) \xi_c + 4\xi_c^2 - e^{\xi_c} \left( \xi_c^2 - 2\xi_c + 2 \right) \right] + O \left( \tau, e^{-\xi_c}, L^{-6} \right), \quad (3.30)$$

where eq. (3.25) is used. It turns out that $O(\tau^k)$-correction also has the contribution of $O(\tau^k e^{\frac{(k-1)\xi^2}{2}}) = O \left( \tau e^{(1-k)\xi_c} \right)$, which should cancel out with the neck terms. Here, we
Figure 3: The mass and the mass-normalized, scale-invariant entropy of the nonuniform black string for given period $L$. The gray, red curve correspond to the numerical result and perturbative expansion in the small non-uniformity up to 8-th order. The blue dotted, dashed and solid curves are the blob approximation up to LO, NLO and NNLO, respectively. The black dotted curve in the right panel is the scale-invariant entropy of the uniform string given by $S_1 = \log(2\pi/L)$.

simply neglect $\mathcal{O}(e^{-\xi_c})$-terms, so that we do not have to care $\mathcal{O}(\tau^k)$-corrections for $k > 1$. For the neck part, we take the solution up to NLO in $1/L^2$,

$$M_{\text{neck}} = 2 \int_{\tilde{z}_c}^{L/2} dz e^{\mathcal{R}(z)} = e^{-1-L^2/8} \int_0^{\xi_c} d\xi \cosh^2(\xi/2) \left( 1 + \frac{1}{L^2} \tilde{R}_1(\xi) + \mathcal{O}(L^{-4}) \right)$$

$$= 4 e^{-1-L^2/8} \left( 2\xi_c + e^{\xi_c} + \frac{2}{L^2} \left( 16 + \frac{4\pi^2}{3} + \frac{2}{3}(18 + \pi^2)\xi_c + 4\xi_c^2 - e^{\xi_c}(\xi_c^2 - 2\xi_c + 2) \right) \right) + \mathcal{O}(e^{-\xi_c}, L^{-4})$$

(3.31)

We should note that the neck part also gives the finite contribution in the sub-leading order. Therefore, the effect of the cut off cancels out in the total mass,

$$M = \sqrt{2\pi} e^{-1-L^2/8} \left[ 1 + \frac{4}{L^2} \left( \frac{\pi^2}{6} + 1 \right) + \frac{2(432\zeta(3) + \pi^4 + 60\pi^2 - 72)}{9L^4} \right] + \mathcal{O}(L^{-6})$$

(3.32)

Using the effective equation, the mass-normalized, scale-invariant entropy [36] is given by the total mass

$$S_1 = -\log M + \log(2\pi).$$

(3.33)

where the scaling is fixed so that the uniform black string with $L = 2\pi$ gives zero entropy. These results well-approximate the numerical result in the highly deformed regime (figure 3).

Up to now, we only considered in the linear order correction of the tension. Including higher orders of the tension will result in the trans-series of $1/L^2$ and $e^{-L^2/8}$, which will require the knowledge of the trans-series expansion of error functions. One can notice that, although the convergence of the $1/L^2$-expansion is not bad close to $L = 2\pi$, the
formula starts to disagree with the numerical result. This would also imply the presence of the correction terms in the trans-series expansion. Lastly, we consider the limit \( L \sim \sqrt{D} \), which gives the neck amplitude \( \mathcal{R} \sim -D \) and \( 1/D \) expansion breaks down there. In this regime, the physical compactification length reaches \( \mathcal{O}(1) \), in which one can observe the smooth topology-changing transition by taking the proper scaling on the neck [10]. On the other hand, eq. (3.32) reduces to the trans-series expansion in \( 1/D \) and \( e^{-\alpha D} \), that is consistent with the large \( D \) conifold analysis in which the back reaction from the pinching region becomes non-perturbative in \( 1/D \). This implies the trans-series expansion in the blob approximation captures the smooth transition from the decoupled to the non-decoupled sector in the topology-changing phase. In ref. [23], trans-series in the perturbative and non-perturbative expansion in \( 1/D \) was also obtained for non-decoupled quasinormal modes.

4 Highly deformed black dumbbells

The same analysis can be applied to the black dumbbells found in the 2+1 rigidly rotating system [33]. Dumbbells are deformed branches bifurcating from the onsets of the instability on the black bar. In ref. [33], dumbbells end up with the array of multiple Gaussian blobs almost separate from each other at the highly deformed phase. The blobs are aligned in almost equal distances logarithmically growing in \( \Omega \), which would imply the pinch-off transition to the multiple spherical black holes. We show that these behaviors are actually described by the interaction between the blobs and necks.

4.1 Setup

The effective equation for 2+1 rigidly rotating black brane is given by [31]

\[
\partial_t^2 \mathcal{R} + \frac{1}{r} \partial_r \mathcal{R} + \frac{1}{r^2} \partial_\phi^2 \mathcal{R} + \frac{1}{2} \left( \left( \partial_r \mathcal{R} \right)^2 + \frac{1}{r^2} \left( \partial_\phi \mathcal{R} \right)^2 \right) + \mathcal{R} + \frac{1}{2} \Omega^2 r^2 = 0, \tag{4.1}
\]

where the solution is rigidly rotating as \( \mathcal{R}(t, r, \phi) = \mathcal{R}(r, \phi - \Omega t) \). Black bars and dumbbells are solved by introducing the co-rotating Cartesian coordinate,

\[
x := r \cos(\phi - \Omega t), \quad y := r \sin(\phi - \Omega t). \tag{4.2}
\]

The dumbbell branch is solved further assuming the separation of the variables \( \mathcal{R}(x, y) = \ell_{\perp}^{-2} (1 - x^2/2) + \mathcal{R}(y) \), in which the equation reduces to

\[
\mathcal{R}''(y) + \frac{1}{2} \mathcal{R}'(y)^2 + \mathcal{R}(y) + \frac{1}{2} \Omega^2 y^2 = 0 \tag{4.3}
\]

where

\[
\ell_{\perp}^2 := \frac{2}{1 + \sqrt{1 - 4\Omega^2}}. \tag{4.4}
\]

The dumbbells bifurcate from the onsets of the instability on the black bar at \( \ell_{\perp}^{-2} \Omega^{-2} = 2N \), where \( N \) is a positive integer. Since dumbbells produce \( N \) bumps which develop to \( N \) separate blobs, we call each branch as \( N \)-dumbbells.
4.2 Blobs and necks

In the limit of $\Omega \to 0$, eq. (4.3) reduces to the black string effective equation (3.1) and the solution is locally approximated by the Gaussian blob:

$$e^{\mathcal{R}(y)} = e^{1 - \frac{1}{2}(y - L_i)^2} + O(\Omega^2)$$

(4.5)

where $L_i$ is the peak position of each blob. In the highly deformed phase, we assume a dumbbell consists of $N$ separate Gaussian blobs and the blobs are labeled by $k = -k_{\text{max}}, \ldots, k_{\text{max}} := \lfloor N/2 \rfloor$ from the negative end to the positive end. The index includes $k = 0$ for odd $N$.

Now, we see the distance between blobs is determined by the balance between the neck tension and rotation. By integrating eq. (4.3) multiplied by $\mathcal{R}'(z)e^{\mathcal{R}(z)}$ from a neck waist $y_{\text{neck}}$, we obtain

$$\left[\left(\frac{1}{2}\mathcal{R}'(y)^2 + \mathcal{R}(y) - 1\right)e^{\mathcal{R}(y)}\right]_{y_{\text{neck}}}^\infty = -\frac{\Omega^2}{2} \int_{y_{\text{neck}}}^\infty y^2 e^{\mathcal{R}(y)}\mathcal{R}'(y)dy. \quad (4.6)$$

Assuming the mass density falls off at $|y| \to \infty$, the right hand side reproduces the black string equation (3.2) near the neck, given the other part becomes constant. On the left hand side, the integral picks up the blob part and each blob integrals can be approximated by the full Gaussian integral, which gives the constant tension of $O(\Omega^2)$. As seen in the black string analysis, the effect of the tails will be the order of the tension which is now approximated to be $O(\Omega^2)$. Therefore, the cut-off tail part contributes to only $O(\Omega^4)$ in eq. (4.6), and hence are safely negligible.

The approximated tension $\tau_k$ between $k - 1$-th and $k$-th blob is given by the sum of the integrals over Gaussian blobs at $y = L_k, \ldots, L_{k_{\text{max}}}^-$,

$$-\left(\frac{1}{2}\mathcal{R}'^2 + \mathcal{R} - 1\right)e^{\mathcal{R}} = \tau_k =: \sqrt{2\pi e}\Omega^2 \sum_{i=k}^{k_{\text{max}}} L_i. \quad (4.7)$$

This can be interpreted as the balance condition between the brane tension and centrifugal forces on the outer blobs. By taking the difference, one can actually see the force balance on a single blob ring is given by the centrifugal force and tensions on both sides,

$$\tau_k = \tau_{k+1} + \sqrt{2\pi e}\Omega^2 L_k. \quad (4.8)$$

By using the result of the black string analysis (3.25), the local tension determines the interval $\Delta_k := L_k - L_{k-1}$,

$$\tau_k = \frac{\Delta_k^2}{2}e^{1 - \frac{\Delta_k^2}{8}\left(1 + \frac{2\pi^2}{3\Delta_k^2}\right)}, \quad (4.9)$$

5In the higher order of $\Omega$, eq. (4.6) will give the coordinate dependence on the tension term due to the broken mirror symmetry, in which the neck analysis should be changed from that of the black string.
where we include the correction up to $O(\Delta_1^{-2})$. We should note that $\Delta_1$ for even dumbbell is defined by $\Delta_1 = L_1 - L_{-1} = 2L_1$. Eliminating the tension, we obtain a coupled equation for intervals,

$$\sqrt{2\pi e} \Omega^2 \sum_{i=k}^{k_{\max}} L_i = \frac{\Delta_1^2}{2} e^{1/\Delta_1^2} \left( 1 + \frac{2\pi^2}{3\Delta_1^2} \right), \quad (4.10)$$

where

$$L_k = \left\{ \begin{array}{ll} \sum_{i=1}^{k} \Delta_i & (N: \text{odd}) \\ -\frac{\Delta_1}{2} + \sum_{i=1}^{k} \Delta_i & (N: \text{even}) \end{array} \right.. \quad (4.11)$$

### 4.2.1 2-dumbbells

Let us start from the easiest case, $N = 2$. Since we only have a single interval $\Delta_1 = 2L_1$, eq. (4.10) is no longer coupled,

$$\sqrt{2\pi e} \Omega^2 \Delta_1 = \frac{\Delta_1^2}{2} e^{1/\Delta_1^2} \left( 1 + \frac{2\pi^2}{3\Delta_1^2} \right). \quad (4.12)$$

Ignoring the correction term in the left hand side, we obtain

$$\Delta_1 = 2\sqrt{-W_1(-\pi \Omega^4/2)} \simeq 4\sqrt{-\log \Omega}. \quad (4.13)$$

This reproduces the logarithmic dependence of $\Omega$ in the separation found in the numerical solution [33]. Including $O(\Delta_1^{-2})$ term, we can improve the approximation,

$$\Delta_1 = 2\sqrt{-W_1(-\pi \Omega^4/2)} \left( 1 + \frac{2\pi^2}{3W_1(-\pi \Omega^4/2)^2} \right). \quad (4.14)$$

### 4.2.2 Even dumbbells

Now, we proceed to more general cases. First, we consider even dumbbells with $N = 2s$. Since all the intervals are highly coupled in eq. (4.10), it is no longer directly solvable. Instead, hinted by the numerical solution, we assume the intervals are almost the same at $\Delta_k \to \infty$,

$$\Delta_k = \Delta + O(\Delta^{-1}). \quad (4.15)$$

Then, each position is given by

$$L_k \simeq \left( k - \frac{1}{2} \right) \Delta. \quad (4.16)$$

Eq. (4.10) now reduces to the single equation,

$$\sqrt{2\pi \Omega^2} (s^2 - (k - 1)^2) \Delta = \Delta_2 e^{\Delta_2^2/\Delta}. \quad (4.17)$$
where $\Delta_k$ is kept in the exponent because the correction contributes to the factor. This
is solved by

$$\Delta_k = \Delta - \frac{4c_k}{\Delta}, \quad \Delta := 2\sqrt{-W_{-1}(-\pi\Omega^4/2)}, \quad (4.18)$$

where

$$c_k = \log(s^2 - (k - 1)^2). \quad (4.19)$$

Since $\Delta \sim \sqrt{-\log \Omega}$, this determines the blob position up to $O\left(1/\sqrt{-\log \Omega}\right)$.

For one higher order in $1/\Delta$, we need to take into account the contribution from the
$k$-dependent correction. The blob positions are corrected by

$$L_k = \left(k - \frac{1}{2}\right)\Delta - \frac{4}{\Delta} \log \left(\frac{\Gamma(s + k)}{\Gamma(s - k + 1)}\right). \quad (4.20)$$

By the summation, we obtain

$$\sum_{\ell=k}^{n} L_\ell = \frac{1}{2} e^{c_k} \Delta - \frac{4}{\Delta} \log \left(\frac{G(2s + 1)}{G(s + k)G(s - k + 1)}\right), \quad (4.21)$$

where $G(n)$ is the Barnes G function defined by the superfactorial

$$G(n) := \prod_{k=1}^{n-1} \Gamma(k). \quad (4.22)$$

Plugging this into eq. (4.10), we obtain $O\left(\Delta^{-3}\right)$ correction as

$$\Delta_k = \Delta - \frac{4c_k}{\Delta} + \frac{16d_k}{\Delta^3}, \quad (4.23a)$$

where

$$c_k = \log(s^2 - (k - 1)^2), \quad (4.23b)$$

$$d_k = \frac{\pi^2}{6} - 2c_k - \frac{1}{2} c_k^2 + 2e^{-c_k} \log \left(\frac{G(2s + 1)}{G(s + k)G(s - k + 1)}\right). \quad (4.23c)$$

### 4.2.3 Odd dumbbells

In the similar way, odd dumbbells with $N = 2s + 1$ are studied. The interval is given by

$$\Delta_k = \Delta - \frac{4c_k}{\Delta} + \frac{16d_k}{\Delta^3}, \quad (4.24a)$$

where $\Delta = 2\sqrt{-W_{-1}(-\pi\Omega^4/2)}$ and

$$c_k = \log(s(s + 1) - k(k - 1)), \quad (4.24b)$$

$$d_k = \frac{\pi^2}{6} - 2c_k - \frac{1}{2} c_k^2 + 2e^{-c_k} \log \left(\frac{G(2s + 2)}{G(s + k + 1)G(s - k + 2)}\right). \quad (4.24c)$$

In figure 4, we compared the result for several branches.

---

6Due to the logarithmic property, there is an ambiguity in the leading order solution that multiply $\Omega$ by
a factor, which changes the next-to-leading order. One can also include $k$-dependence in the next-to-leading
order within the leading order solution as $\Delta_k = 2\sqrt{-W_{-1}([s^2 - (k - 1)^2]^{4}\Omega^4)/2]}$. 
Figure 4: The normalized separations are compared with the numerical result (solid curves). The dashed curves are the result up to $O(1/\Delta^3)$. The numerical data is produced by the same method used in ref. [33].

4.3 Phase diagram

Following the calculation in ref. [33], the angular momentum to the mass ratio is given by

$$\frac{\mathcal{J}}{\mathcal{M}} = \Omega \ell^2_y + \Omega \int_0^\infty y^2 e^{\mathcal{R}(y)} dy \int_0^\infty e^{\mathcal{R}(y)} dy$$ (4.25)

Since the cut-off tails become sub-leading order in $\Omega$, the integrals are simply approximated by the sum of the Gaussian integrals over blobs at the leading order, which are easily evaluated for $N$-dumbbells as

$$\int_0^\infty e^{\mathcal{R}(y)} dy \simeq \sqrt{2\pi eN}, \quad \int_0^\infty y^2 e^{\mathcal{R}(y)} dy \simeq \sqrt{2\pi e} \left( N + 2 \sum_{k=1}^{|N|} L_k^2 \right).$$ (4.26)

Using the expansion of $L_k$ by $\Delta = 2\sqrt{-W_1(\pi\Omega^2/2)}$ up to $O(\Delta^{-1})$, we obtain

$$\frac{\mathcal{J}}{\mathcal{M}} = \frac{N^2 - 1}{12} \Omega \Delta^2 \left( 1 + \frac{j_1}{\Delta^2} + O(\Delta^{-4}) \right) + O(\Omega^2),$$ (4.27)

and

$$j_1 = 1 - \frac{192}{N(N^2 - 1)} \sum_{k=1}^s \left( k - \frac{1}{2} \right) \log \frac{\Gamma(s+k)}{\Gamma(s-k+1)} \left( N = 2s \right) \log \frac{\Gamma(s+k+1)}{\Gamma(s-k+1)} \left( N = 2s + 1 \right).$$ (4.28)

Recalling the black string analysis, the blob approximation is only convergent for $\Delta \gtrsim 2\pi$, which is now corresponds to

$$\Omega = (2\pi)^{-\frac{1}{2}} \Delta \frac{1}{2} e^{-\frac{\Delta^2}{12\pi}} \lesssim 0.13.$$ (4.29)

In figure 5, one can see the approximation reproduces the numerical result for $\Omega \lesssim 0.1$. Having more blobs worsen the approximation $L_{\text{max}} \ll \Omega^{-1}$, and hence, dumbbells with larger $N$ have smaller convergent range.
Figure 5: The phase diagram of dumbbells. The approximation up to NLO in $1/\Delta$ (dashed curves) is compared with the numerical result (solid curves). The numerical data is produced by the same method used in ref. [33]

5 Highly deformed black ripples

Black ripples, which are also called bumpy black holes, are axisymmetric deformed branches bifurcating from the zero modes of the ultraspinning instabilities on the Myers-Perry solution [39]. The numerical solutions were actually constructed for $D = 6, 7$ [40,41]. In the large $D$ limit, black ripples are obtained by solving the $2+1$ axisymmetric, rigidly-rotating effective equation [33],

$$R''(r) + \frac{1}{r} R'(r) + \frac{1}{2} R'(r)^2 + R(r) + \frac{1}{2} \Omega^2 r^2 = 0.$$ (5.1)

Black ripples bifurcate from the onsets of the axisymmetric instability on the Myers-Perry, which are given by

$$\Omega = \sqrt{2N - 1} \quad (N = 2, 3, 4, \ldots) ,$$ (5.2)

where $N$ corresponds to the number of bumps appear in the radial direction. In ref. [33], a cluster of concentric Gaussian-shaped rings were finally developed away from the axis in the highly deformed regime. This, which we call blob ring, is another example of the blob solution. The number of blob rings is given by $s = \lfloor N/2 \rfloor$. Odd ripples also formed the center blob at the axis, which is isolated from blob rings.

Different from the black strings and dumbbells, ripples involve two kinds of necks with separate length scales (figure 6). The axis region and innermost blob ring are connected by a long thin neck which scales as $\Omega^{-1}$ at the limit $\Omega \to 0$. The long neck takes disk shape for even $N$ and ring shape for odd $N$, respectively. Due to the dimensionality, these long neck region requires slightly different treatment. On the other hand, the blob rings are connected with each by (relatively) short necks which scales as $\sqrt{-\log \Omega}$ similar to the dumbbells.
Figure 6: The radial profile of ripples for $N = 4$ with $\Omega = 0.04$ (left) and $N = 3$ with $\Omega = 0.1$ (right). The blue and red curves are the Gaussian solution $R(r) = 1 - \frac{1}{2} \Omega^2 L_i^2 - \frac{1}{2}(r - L_i)^2$ with the fitted peak positions $L_i$. The green curve is the Myers-Perry solution.

5.1 Blob rings

From the numerical observation, even ripples are approximated by an array of several ring-shaped Gaussian profiles, blob rings, which are localized at $r \simeq \Omega^{-1}$ for $\Omega \to 0$. Blob rings themselves are also pulled apart from each other with the distance logarithmically growing in $\Omega$ as in dumbbells. Odd ripples have the same blob ring structure, but also form the center blob which is approximated by the Myers-Perry solution.

Now, we focus on one of blob rings, which is located at $r = L \sim \Omega^{-1}$. We take the limit $\Omega \to 0$, while keeping $w := \Omega L$ finite. By switching to the local coordinate $z := r - L$, the effective equation is expanded by $\Omega$,

$$R''(z) + \frac{1}{2} R'(z)^2 + R(z) + \frac{w^2}{2} = \sum_{i=1}^{\infty} \Omega^i S_i(z). \tag{5.3}$$

**Leading order** At the leading order, this reduces to the black string equation (3.1) which admits the Gaussian solution

$$R_0(z) = 1 - \frac{w^2}{2} - \frac{z^2}{2}. \tag{5.4}$$

Given the value of $\Omega$ and the peak position $L$, this profile already gives a good fit with the numerical result for sufficiently small $\Omega$ (figure 6).

Let us write the peak position of blob rings as $L_1 < L_2 < \cdots < L_s$ and $w_i = \Omega L_i$, where $s$ is the number of the rings. To determine the relation between $L_i$ and $\Omega$, we need an additional information about the global configuration. By integrating the master equation (5.1), we obtain an useful equation

$$\left[ \left( \frac{1}{2} (R')^2 + R - 1 + \frac{1}{2} \Omega^2 r^2 \right) e^R \right]_r^{\infty} = \int_r^{\infty} \left( -\frac{1}{r} (R')^2 + \Omega^2 r \right) e^R dr. \tag{5.5}$$

15
Assuming the compactness, the left hand side should vanish for \( r \to \infty \). On the other hand, inside the blob rings, the long tail from the innermost ring falls down until it meets the minimum on the very thin neck which is on the axis for even ripples, or halfway to the axis \( r \simeq \Omega^{-1}/2 \) for odd ripples. Therefore, if we integrate from the inner minimum to the infinity, the left hand side is estimated as \( \mathcal{O}\left(e^{-\frac{1}{2\Omega^2}}\right) \) for even ripples and \( \mathcal{O}\left(e^{-\frac{1}{8\Omega^2}}\right) \) for odd ripples, both of which are non-perturbatively small in \( \Omega \). On the right hand side, the integral over each single blob ring can be replaced by the full Gaussian integral

\[
\int_{i-th} \left( -\frac{1}{r} (R')^2 + \Omega^2 r \right) e^{R} dr \simeq \Omega \frac{\sqrt{2\pi e^{1-w_i^2}}}{w_i} (w_i^2 - 1),
\]

(5.6)

where the cut-off tail turns out to be \( \mathcal{O}(\Omega^3) \). The integral from the inner minimum \( r_{\min} \) to the infinity is, then approximated by the sum of the separate Gaussian integrals,

\[
\int_{r_{\min}}^{\infty} \left( -\frac{1}{r} (R')^2 + \Omega^2 r \right) e^{R} dr \simeq \Omega \sum_{i=1}^{s} \frac{\sqrt{2\pi e^{1-w_i^2}}}{w_i} (w_i^2 - 1).
\]

(5.7)

We also assume that the position of blobs are close to each other.

\[
L_i - L_j \ll L_k \simeq \Omega^{-1}.
\]

(5.8)

Since eq. (5.7) should be non-perturbatively small, this sets \( w_i \simeq 1 \) and \( ^7 \)

\[
L_i \simeq \Omega^{-1} (1 + \mathcal{O}(\Omega)).
\]

(5.9)

This means that blob rings are sustained from the collapse dominantly by the rotational effect, and the blob-blob interaction is secondary. It is worth noting that the similar hierarchical assumption was made for the blackfold approach study of multi-black rings/Saturns [42].

**Next-to-Leading order** Now, we estimate the interaction between blob rings by solving the short necks between neighboring twos. Since the next-to-leading order source

\[
S_1(z) = -\frac{1}{w} R'(z) + wz
\]

vanishes for the Gaussian solution (5.4) with \( w_i = 1 + \mathcal{O}(\Omega) \), the Gaussian solution remains the solution up to \( \mathcal{O}(\Omega) \). The leading order integral (5.6) is still valid up to \( \mathcal{O}(\Omega^2) \)

\[
\int_{i-th} \left( -\frac{1}{r} (R')^2 + \Omega^2 r \right) e^{R} dr \simeq 2\sqrt{2\pi e} \Omega^2 \delta L_i,
\]

(5.11)

\(^7\)If one allows \( L_k - L_{k+1} = \mathcal{O}(\Omega^{-1}) \), the left hand side again becomes non-perturbatively small \( \mathcal{O}\left(e^{-\mathcal{O}(\Omega^{-2})}\right) \) on the neck between \( L_k \) and \( L_{k+1} \) and then, one can to repeat the same analysis for smaller groups \( \{L_1, \ldots, L_k\} \) and \( \{L_{k+1}, \ldots, L_s\} \), which leads to the same conclusion \( L_i \simeq \Omega^{-1} \).
where we expanded by \( w_i = 1 + \delta L_i \Omega \). Then, eq. (5.5) close to the neck between \( i \)-th and \( i+1 \)-th blobs reduces to the black string equation with the tension

\[
\tau_i = 2e\sqrt{2\pi} \Omega^2 \sum_{j=i+1}^{s} \delta L_i + \mathcal{O}(\Omega^3),
\]

where the scaling is adjusted by multiplying by \( \sqrt{e} \). Following the match between the neck waists and blob peaks in the black string analysis, the tension is given by the function of the distance between blobs (3.25)

\[
\tau_i \simeq \frac{\Delta_i^2}{2} e^{1-\frac{\Delta_i^2}{\pi}} \left( 1 + \frac{2\pi^2}{3\Delta_i^2} \right)
\]

where \( \Delta_i := \delta L_{i+1} - \delta L_i \) and terms up to \( \mathcal{O}(\Delta_i^{-2}) \) are taken. Evaluating the integral (5.5) from the inner minimum, we obtain

\[
2\sqrt{2\pi} \Omega^2 \sum_{i=1}^{s} \delta L_i \simeq (R_{\text{min}} - 1)e^{R_{\text{min}}},
\]

where \( R_{\text{min}} \sim -\Omega^{-2} \) is the amplitude of the inner minimum. As in the leading order analysis, the left hand side becomes non-perturbatively small in \( \Omega \), and then, we obtain

\[
\langle \delta L \rangle := \frac{1}{s} \sum_{i=1}^{s} \delta L_i = \mathcal{O}(\Omega, e^{-C\Omega^{-2}}),
\]

where \( \langle \cdot \rangle \) denotes the average over blob rings and \( C \) is some constant. In fact, eq. (5.14) can be used to determine the non-perturbative corrections in \( L_i \), which reflects the interaction between the long neck and blob rings. We will come back to this later.

Now, we study the short necks between blob rings. In the following, we assume \( s > 2 \). Equating eqs. (5.12) and (5.13), we obtain the coupled equation about the blob separations,

\[
2e\sqrt{2\pi} \Omega^2 \sum_{j=i+1}^{s} \delta L_j = \frac{\Delta_i^2}{2} e^{1-\frac{\Delta_i^2}{\pi}} \left( 1 + \frac{2\pi^2}{3\Delta_i^2} \right).
\]

This justifies the assumption that the cut off contribution becomes sub-leading order in \( \Omega \). As in the dumbbell analysis, we start from assuming the separations are almost the same,

\[
\Delta_i \simeq \Delta + \mathcal{O}(\Delta^{-1}).
\]

Then, with the condition (5.15), we obtain

\[
\delta L_i = \frac{2i - s - 1}{2} \Delta + \mathcal{O}(\Delta^{-1}).
\]

Plugging this into eq. (5.16), the leading order is determined

\[
\Delta = 2\sqrt{-W_{-1}(-2\pi\Omega^4)}.
\]
Again, one can see the logarithmic growth in the separation $\Delta \simeq 4\sqrt{-\log \Omega}$. Expanding by $1/\Delta$, the sub-leading corrections are determined up to $O(\Delta^{-3})$, 

$$\Delta_i = \Delta - \frac{4c_i}{\Delta} + \frac{16d_i}{\Delta^3},$$  

(5.20a) 

where 

$$c_i = \log(i(s - i)),$$  

(5.20b) 

d_i = \frac{\pi^2}{6} - 2c_i - \frac{c_i^2}{2} + \frac{2}{i(s - i)} \log \left( \frac{G(s + 1)}{G(i + 1)G(s - i + 1)} \right).$$  

(5.20c) 

$G(n)$ is the Barnes G function defined in eq. (4.22). By taking the sum and using $\langle \delta L \rangle = 0$, the relative peak position is given by 

$$\delta L_i = \frac{2i - s - 1}{2} \Delta - \frac{4}{\Delta} \log \left( \frac{\Gamma(i)}{\Gamma(s - i + 1)} \right) + \frac{16}{\Delta^3} \left( \sum_{j=0}^{i-1} d_j \right),$$  

(5.21) 

where 

$$d_0 := - \sum_{i=1}^{s-1} \frac{s - i}{s} d_i.$$  

(5.22) 

**Next-to-next-to-leading order** One can continue determining the peak position higher order in $\Omega$ by expanding further 

$$\delta L_i = \delta^{[1]} L_i + \delta^{[2]} L_i \Omega + \ldots.$$  

(5.23) 

However, the calculation of $\delta^{[2]} L_i$ requires the detailed neck analysis with the non-constant tension, to which the black string result no longer applies. Instead, we focus on the average of the correction which contributes to the mass and angular momentum, 

$$\langle \delta^{[2]} L \rangle := \frac{1}{s} \sum_{i=1}^{s} \delta^{[2]} L_i.$$  

(5.24) 

By evaluating the integral (5.5) up to $O(\Omega^3)$, we obtain (see Appendix B.3 for the detail), 

$$\langle \delta^{[2]} L \rangle = \frac{1}{2} \langle \delta^{[1]} L^2 \rangle + O(\Delta^{-2}),$$  

(5.25) 

where the squared average of $\delta^{[1]} L_i$ is calculated by using NLO result (5.21), 

$$\langle \delta^{[1]} L^2 \rangle := \frac{1}{s} \sum_{i=1}^{s} (\delta^{[1]} L_i)^2 = \frac{s^2 - 1}{12} \Delta^2 - \frac{8}{s} \sum_{i=1}^{s} (2i - s - 1) \log \Gamma(i) + O(\Delta^{-2}).$$  

(5.26) 

In figure 7, the peak positions are compared with the numerical result for several branches.

### 5.2 Long neck analysis

Up to now, the existence of the center blob did not matter to blob rings. This is because the interaction decays exponentially by the distance of $O(\Omega^{-1})$, only giving the magnitude of $e^{-C\Omega^{-2}}$ which is non-perturbative in $\Omega$. 

5.2.1 Disk waist: even ripples

First, we consider even ripples which consist of concentric blob rings without Myers-Perry at the center. Let us assume the peak of the innermost blob ring appears at \( r = L \), which is \( L \approx \Omega^{-1} \). Then, we observe a narrow disk-like waist close to the axis origin, whose magnitude is roughly estimated by the Gaussian tail as \( R(r) \approx -L^2/2 = \mathcal{O}(\Omega^{-2}) \). As in the string neck, we zoom in on this region by rescaling

\[
R(r) = -\frac{L^2}{2} + \bar{R}(\xi), \quad \xi := Lr. \tag{5.27}
\]

The region \( r = \mathcal{O}(1) \) corresponds to \( \xi \gg 1 \) which allows the match at \( \xi \to \infty \). The effective equation is expanded by \( \Omega^2 \) with \( w := \Omega L \) as

\[
\mathcal{R}''(\xi) + \frac{1}{2} \mathcal{R}'(\xi)^2 + \frac{1}{\xi} \mathcal{R}'(\xi) - \frac{1}{2} = \sum_{i=1}^{\infty} \Omega^{2i} \bar{S}_i \tag{5.28}
\]

from which we assume

\[
\mathcal{R}(\xi) = \sum_{i=0}^{\infty} \Omega^{2i} \bar{R}_i(\xi). \tag{5.29}
\]

One can see that the leading order equation now slightly differs from that of the black string due to the dimensionality. Requiring the regularity on the axis, the leading order solution is given by the Bessel function

\[
\mathcal{R}_0(\xi) = \bar{r}_0 + 2 \log I_0(\xi/2), \tag{5.30}
\]

\[\text{We do not specify the detail form of } L = L(\Omega) \text{ throughout the long neck analysis.}\]
where \( \bar{r}_0 \) is the integration constant which sets the correction to the minimum on the axis,
\[
R_{\text{min}} = -\frac{L^2}{2} + \bar{r}_0 .
\]  

(5.31)

The leading order solution is expanded at \( \xi \to \infty \) by
\[
\bar{R}_0(\xi) = \bar{r}_0 + \xi - \log \xi - \log \pi + \frac{1}{2\xi} + O \left( \xi^{-2}, e^{-\xi} \right) .
\]

(5.32)

The next-to-leading order equation is given by
\[
\frac{d}{d\xi} \left( \xi I_0(\xi/2)^2 \frac{d}{d\xi} \bar{R}_1(\xi) \right) = w^{-2} \xi I_0(\xi/2)^2 (\bar{r}_0 + 2 \log I_0(\xi/2)) .
\]

(5.33)

We cannot find the closed form solution at this order, but the asymptotic form is still available
\[
\bar{R}_1(\xi) = -\frac{\xi^2}{2w^2} + \frac{\xi}{w^2} (\bar{r}_0 + \log \pi + \log \chi) + O(\xi^0, e^{-\xi}) .
\]

(5.34)

Combining the expansion up to NLO, the matching condition is obtained by restoring the scaling while keeping \( r = \mathcal{O}(1) \),
\[
\bar{R} \simeq -\frac{w^2}{2\Omega^2} + \bar{R}_0(\xi) + \Omega^2 \bar{R}_1(\xi)
\]
\[
= \bar{A}_0 + \bar{A}_1 r - \frac{r^2}{2} + \frac{2\Omega}{r} + (\Omega r - 1) \log r + O \left( \Omega^2 \right) ,
\]

(5.35a)

where
\[
\bar{A}_0 = -\frac{w^2}{2\Omega^2} + \bar{r}_0 - \log \pi + \log \Omega ,
\]

(5.35b)

\[
\bar{A}_1 = \frac{w}{\Omega} - (\bar{r}_0 + \log \Omega - \log \pi - \log w) \frac{\Omega}{w} .
\]

(5.35c)

Therefore, the minimum on the axis (5.31) should be determined by the match with the outer region.

### 5.2.2 Ring waist : Odd ripples

On the other hand, odd ripples have the ring-type waist between the center blob and innermost blob ring. Assuming the minimum is located at \( r = \mu \Omega^{-1} \), we consider the rescaling
\[
\bar{R}(r) = -\frac{\mu^2}{2\Omega^2} + \bar{R}(\xi) , \quad \xi := \frac{\mu}{\Omega} (r - \mu \Omega^{-1}) ,
\]

(5.36)

where the solution is matched at \( \xi \to \pm \infty \), which corresponds to the matching region \( z := r - \mu \Omega^{-1} = \mathcal{O}(1) \). The effective equation is expanded by \( \Omega^2 \) as
\[
\bar{R}''(\xi) + \frac{1}{2} \bar{R}'(\xi) + \frac{1}{2} = \sum_{i=1}^{\infty} \Omega^2 \bar{S}_i
\]

(5.37)
This is also solved by

\[ \mathcal{R}(\xi) = \sum_{i=0}^{\infty} \Omega^{2i} \mathcal{R}_i(\xi). \]  

(5.38)

The solution up to NLO is given by

\[ \mathcal{R}_0(\xi) = \bar{r}_0 + 2 \log \cosh(\xi/2). \]  

(5.39)

\[ \mathcal{R}_1(\xi) = -\frac{\xi}{\mu^2} + \frac{4}{\mu^2} \log \cosh(\xi/2) - \frac{2}{\mu^2} \text{Li}_2\left(-e^{-\xi}\right) \tanh(\xi/2) \]
\[ + \frac{1}{2\mu^2} \left(-\xi \left(2 + \mu^2 + 2\bar{r}_0 - 4 \log 2\right) - \xi^2 - \frac{\pi^2}{3} + 4\right) \tanh(\xi/2) \]  

(5.40)

where \( \bar{r}_0 \) gives the minimum at the waist.

\[ \mathcal{R}_{\text{min}} = -\frac{\mu^2}{2\Omega^2} + \bar{r}_0. \]  

(5.41)

By fixing \( z := \Omega \xi / \mu \), the asymptotic expansion for \( \xi \to \pm \infty \) leads to

\[ \mathcal{R} = \tilde{A}_0 + \tilde{A}_{1,\pm} z - \frac{z^2}{2} + \mathcal{O}(\Omega^2) \]  

(5.42a)

where

\[ \tilde{A}_0 = -\frac{\mu^2}{2\Omega^2} + \bar{r}_0 - 2 \log 2, \]  

(5.42b)

\[ \tilde{A}_{1,\pm} = \pm \frac{\mu}{\Omega} \pm \frac{\Omega}{2\mu} \left(2 - \mu^2 - 2\bar{r}_0 + 4 \log 2 \mp 2\right). \]  

(5.42c)

**Match with the center Myers-Perry** The expansion at \( \xi \to -\infty \) in eq. (5.42) is easily matched with the Myers-Perry solution expanded by \( r = \mu\Omega^{-1} + z \),

\[ \mathcal{R}_{\text{MP}}(r) = \left(1 + \sqrt{1 - 4\Omega^2}\right) \left(1 - \frac{r^2}{4}\right) = -\frac{\mu^2}{2\Omega^2} + 2 + \frac{\mu^2}{2} - \left(\frac{\mu}{\Omega} + \mu\Omega\right) z - \frac{z^2}{2} + \mathcal{O}(\Omega^2), \]  

(5.43)

which determines

\[ \bar{r}_0 = \frac{\mu^2}{2} + 2 + 2 \log 2 + \mathcal{O}(\Omega^2). \]  

(5.44)

**5.2.3 Stretched tail**

The matching region for the previous neck waists are still far from the blob rings at \( r \simeq \Omega^{-1} \). In fact, we need another patch that feels the gradual change in the centrifugal barrier \( \frac{1}{2} \Omega^2 r^2 \), since the coordinate patch for blob rings is too small for such global change. It is worth noting that the center Myers-Perry blob in the odd ripple does not need such stretched patch, since it is a solution to the full effective equation, and hence already includes the rotational effect. To this end, we impose a coarse-grained scaling to capture the Gaussian tail stretched by the rotation,

\[ \mathcal{R}(r) = \Omega^{-2} \tilde{\mathcal{R}}(Y), \quad Y := \Omega r. \]  

(5.45)
The effective equation is rewritten as
\[
\frac{1}{2} \tilde{R}'(Y)^2 + \tilde{R}(Y) = -\Omega^2 \left( \tilde{R}''(Y) + \frac{1}{Y} \tilde{R}'(Y) + \frac{Y^2}{2} \right).
\] (5.46)
The solution is obtained by the expansion in $\Omega^2$,
\[
\tilde{R}(Y) = \sum_{i=1}^{\infty} \Omega^{2i} \tilde{R}_i(Y).
\] (5.47)
The leading order solutions is solved by
\[
\tilde{R}_0(Y) = -\frac{1}{2} (Y - C)^2,
\] (5.48)
where $C$ is the integration constant. This constant sets the singular point in the subsequent equations. Here we set it at the first peak of the blob ring $C = w := \Omega L$ from which the tail appears. The next-to-leading order solution is obtained straightforwardly,
\[
\tilde{R}_1(Y) = \frac{Y^2}{2} + \beta (Y - w) + \left( \frac{Y}{w} - 1 \right) \log \left( \frac{Y}{w} \right) + (1 - w^2) \frac{1}{2} \log \left| 1 - \frac{Y}{w} \right|
\] (5.49)
where $\beta$ is an integration constant.

**Match with the innermost blob ring** First, we match the long tail to the innermost blob ring, which can be done regardless of whether $N$ is even or odd. Switching to the coordinate from the peak $z := r - w \Omega^{-1} = \Omega^{-1}(Y - w)$, the matching region with the innermost blob ring is given by $1 \ll |z| \ll \Omega^{-1}$, and the matching condition becomes
\[
\mathcal{R} = 1 - \frac{w^2}{2} + \Omega (\beta + 1) z - \frac{1}{2} z^2 + \mathcal{O} (\Omega^2).
\] (5.50)
The match with eq. (5.4) fixes the translation degree of freedom,
\[
\beta = -1 + \mathcal{O} (\Omega).
\] (5.51)
Here, we note that one can also match with the outermost blob ring in the same manner, which we will not show, since it does not have further information.

**Match with disk waist** Now, we consider the match on the axis for even ripples. Assuming $r = Y/\Omega = \mathcal{O} (1)$, we obtain
\[
\mathcal{R} = \tilde{A}_0 + \tilde{A}_1 r - \frac{r^2}{2} + (\Omega r - 1) \log r + \frac{\Omega}{2r} + \mathcal{O} (\Omega^2).
\] (5.52a)
where
\[
\tilde{A}_0 = -\frac{w^2}{2\Omega^2} - \beta - \log \Omega, \quad \tilde{A}_1 = \frac{w}{\Omega} + (\beta + \log \Omega) \Omega.
\] (5.52b)
The match between $\bar{A}_i$ in eq. (5.35) shows
\[ \bar{r}_0 = \log \left( \frac{e\pi w}{\Omega^2} \right) + O(\Omega^2), \] (5.53)
where we used $\beta \simeq -1$. Therefore, the minimum on the axis for the even ripple is given by
\[ R_{\text{even}, \text{min}} = -\frac{w^2}{2\Omega^2} + \log \left( \frac{e\pi w}{\Omega^2} \right) + O(\Omega^2). \] (5.54)

**Match with ring waist** For odd ripples, the ring waist should be connected to both the long tail from the innermost ring as well as the center Myers-Perry. Assuming the long neck minimum is at $r = \mu L = \mu\Omega^{-1}$, the matching condition is available by introducing $z := r - \mu\Omega^{-1} = \Omega^{-1}(Y - \mu)$. Expanding by $\Omega$, we obtain
\[ \mathcal{R} = \tilde{A}_0 + \tilde{A}_1 z - \frac{1}{2} z^2 + O(\Omega^2), \] (5.55a)
where
\begin{align*}
\tilde{A}_0 &= -\frac{(w - \mu)^2}{2\Omega^2} + \frac{\mu^2}{2} + \beta(\mu - w) + \left( \frac{\mu}{w} - 1 \right) \log \left( \frac{\mu}{w} \right) + (1 - w^2) \left( 1 + \left( 1 - \frac{\mu}{w} \right) \log \left( 1 - \frac{\mu}{w} \right) \right), \quad \text{(5.55b)} \\
\tilde{A}_1 &= \frac{w - \mu}{\Omega} + \left( \beta + \mu - \mu^{-1} + w + (w - w^{-1}) \log \left( 1 - \frac{\mu}{w} \right) + w^{-1} \log \left( \frac{\mu}{w} \right) \right) \Omega. \quad \text{(5.55c)}
\end{align*}
The match with $A_{i,+}$ in eq. (5.42) determines
\[ \mu = \frac{w}{2} + \left( w + w^{-1} - \frac{1}{2} w \log 2 - \frac{1}{2} \right) \Omega^2 + O(\Omega^4), \] (5.56)
and hence from eq. (5.44), we obtain
\[ \bar{r}_0 = \frac{w^2}{8} + 2 + 2 \log 2 + O(\Omega^2). \] (5.57)
Plugging these into eq. (5.41), we obtain the minimum on the ring waist
\[ R_{\text{odd}, \text{min}} = -\frac{w^2}{8\Omega^2} + \frac{12 + 2w - 3w^2}{8} + \frac{w^2 + 8}{4} \log 2 + O(\Omega^2). \] (5.58)

**5.3 Phase diagram**

For the ripples, the mass and angular momentum is given by
\[ M = 2\pi \int_0^\infty dr r e^{\mathcal{R}(r)}, \quad J = 2\pi \Omega \int_0^\infty dr r^2 e^{\mathcal{R}(r)}. \] (5.59)
Figure 8: The phase diagram of black ripples. The blob approximation (dashed) and the numerical result (solid) are compared. Myers-Perry and Black bars are also plotted with the gray dotted and solid curves for the reference. The numerical data is produced by the same method used in ref. [33].

Ignoring the non-perturbative terms, we can calculate the integrals up to $O(\Omega^2)$ by simply summing the contributions from all blobs

\[
\frac{\Omega M}{2\pi} = \sqrt{2\pi e} s \left(1 - \Omega^2 \langle \delta^{[1]}L^2 \rangle \right) + \epsilon_{MP} e^2 \Omega - \sqrt{e} \sum_{i=1}^{s} \left( \int_{\text{cut off}} e^{-\frac{z^2}{2}} dz_i - \Omega^2 \int \delta R^{(i)}(z_i)e^{-\frac{z^2}{2}} dz_i \right),
\]

\[
\frac{\Omega^2 J}{2\pi} = \sqrt{2\pi e} s \left(1 + \Omega^2 \left(3 + 2 \langle \delta^{[2]}L \rangle \right) \right) - \sqrt{e} \sum_{i=1}^{s} \left( \int_{\text{cut off}} e^{-\frac{z^2}{2}} dz_i - \Omega^2 \int \delta R^{(i)}(z_i)e^{-\frac{z^2}{2}} dz_i \right),
\]

where $\delta R^{(i)}$ is $O(\Omega^2)$ correction to the blob rings shown in eq. (B.6) and the cut off by the short necks between blobs also contributes to $O(\Omega^2)$. However, since $\delta R^{(i)}$ and the cut off effects appear in the same manner in both quantities, they simply cancel out in the ratio. $\epsilon_{MP}$ corresponds to the existence of the center blob, which is set to be 1 for the odd ripples and 0 for the even ripples. Using eqs. (5.25) and (5.26), we obtain

\[
\frac{J}{M} \simeq \frac{1}{\Omega} + \Omega \left( \frac{s^2 - 1}{6} \Delta^2 + j_1 \right) - \epsilon_{MP} \left( \frac{e^3}{\sqrt{2\pi} s} - \frac{e^3}{2\pi s^2} \Omega \right),
\]

\[
j_1 = 3 - \frac{16}{s} \sum_{i=1}^{s} (2i - s - 1) \log \Gamma(i).
\]

In figure 8, this is compared with the numerical result for several ripples. One can see that odd ripples have less angular momentum per mass, because the center blob carries smaller angular momentum. With the larger number of blob rings, the center blob takes the smaller portion, and hence the reduction becomes smaller.
5.4 Non-perturbative correction

Here, we evaluate the back reaction from the long neck tension which is non-perturbative in \( \Omega \). Since, the short necks between the blob rings complicate the analysis, we consider only \( N = 2 \) and \( N = 3 \) ripples which have only a single ring blob. Due to the absence of the short neck structure, we can easily solve only by expanding in \( \Omega \) (see appendix B.1). It turns out \( w = 1 + \mathcal{O} ( \Omega^4, \; e^{-C \Omega^2} ) \) and hence, eqs. (5.54) and (5.58) leads to

\[
R_{\text{min}, N=2} = -\frac{1}{2\Omega^2} + \log \left( \frac{e\pi}{\Omega^2} \right), \quad \text{(5.63)}
\]

\[
R_{\text{min}, N=3} = -\frac{1}{8\Omega^2} + \frac{11}{8} + \frac{9}{4} \log 2. \quad \text{(5.64)}
\]

Substituting this to eq. (5.14), we obtain the non-perturbative shift in the blob peaks

\[
\delta L_{NP, N=2} = \frac{1}{4} \sqrt{\frac{\pi}{2}} \Omega^{-6} e^{\frac{1}{2} - \frac{1}{2\Omega^2}}, \quad \text{(5.65a)}
\]

\[
\delta L_{NP, N=3} = \frac{1}{4} \times 2^2 \sqrt{\pi} \Omega^{-4} e^{\frac{7}{8} - \frac{1}{8\Omega^2}}. \quad \text{(5.65b)}
\]

We also evaluate the non-perturbative correction to the phase diagram in \( N = 2 \) and \( N = 3 \) cases. It turns out that both the cut off effect on the long neck and the non-perturbative correction to the blobs \( \mathcal{R}(r) = \mathcal{R}_0(r) + \tau_{NP} \delta \mathcal{R}(r) \) contribute only in some positive power of \( \Omega \) in the mass and angular momentum, which is much smaller than the non-perturbative change in the blob position eq. (5.65). Therefore, the leading non-perturbative correction is given by the non-perturbative shift in the blob peak,

\[
\mathcal{J} \bigg|_{\text{pert}} \simeq \mathcal{J} \bigg|_{\text{pert}} + 2\delta L_{NP}. \quad \text{(5.66)}
\]

Using the single blob ring solution (B.1), the perturbative part is obtained up to \( \mathcal{O} ( \Omega^{-9}) \),

\[
\mathcal{J} \bigg|_{\text{pert}, N=2,3} = \frac{1}{\Omega} + 3\Omega + 9\Omega^3 + 63\Omega^5 + 617\Omega^7 + \frac{22436}{3} \Omega^9 - \varepsilon_{MP} \mu \left[ 1 - \mu \Omega + \left( \mu^2 + \frac{3}{2} \right) \Omega^2 - (\mu^3 + 2\mu) \Omega^3 + \left( \mu^4 + \frac{5\mu^2}{2} + \frac{75}{8} \right) \Omega^4 - (\mu^5 + 3\mu^3 + 12\mu) \Omega^5 
\right.
\] 

\[
+ \left( \mu^6 + \frac{7\mu^4}{2} + \frac{119\mu^2}{16} + \frac{3605}{48} \right) \Omega^6 
- \left( \mu^7 + 4\mu^5 + 18\mu^3 + \frac{280\mu}{3} \right) \Omega^7 
\] 

\[
+ \left( \mu^8 + \frac{9\mu^6}{2} + \frac{171\mu^4}{16} + \frac{1821\mu^2}{128} + \frac{95091}{128} \right) \Omega^8 
- \left( \mu^9 + 5\mu^7 + 25\mu^5 + \frac{410\mu^3}{3} + \frac{2690\mu}{3} \right) \Omega^9 \right]. \quad \text{(5.67)}
\]

where \( \varepsilon_{MP} \) takes 0 for \( N = 2 \) and 1 for \( N = 3 \). For the compactness, we write \( \mu := e^{3/2}/\sqrt{2\pi} \).

In figure 9, one can see that the rise of the non-perturbative correction corresponds to the sudden inflection around \( \Omega \sim 0.18 \) for \( N = 2 \) and \( \Omega \sim 0.1 \) for \( N = 3 \) both in the
Figure 9: The normalized peak positions of blob ring and phase diagram for $N = 2$ and $N = 3$. The blue and red solid curves are the numerical result for $N = 2$ and $N = 3$. The dashed and dotted curves with corresponding colors are the blob approximation with and without non-perturbative shift. The perturbative part is expanded up to $\mathcal{O}(\Omega^{10})$ as in eq. (B.2), so that the expansion is convergent for $\Omega \lesssim 0.2$. In the right panel, the black bars are also plotted by the gray curve for the reference.

peak position and phase diagram. Unfortunately, since the factor of the non-perturbative correction is determined only up to the leading order in $\Omega$, the curves after the inflection do not fit the numerical data well. In the phase diagram, the non-perturbative effect leads to the increase in $J/M$. This is because the attraction between blobs requires more separations to balance it.

5.5 Blob rings and black rings

Lastly, the single blob ring result is compared with the other black ring results. The comparison indicates that, in a certain range of $\Omega$, blob rings encode black rings/Saturns as the Myers-Perry blob encodes the Myers-Perry black hole.

Blackfold at large $D$ It turns out that the perturbative correction in the blob ring (5.67) corresponds to the finite size effect from the elastic bending energy for the black ring solved in the blackfold approach. For $n \to \infty$, eq.(32) in ref. [43] becomes

$$\omega_H = \frac{1}{2j} \left( 1 + \frac{3}{4nj^2} \right),$$

where the normalized angular velocity and angular momentum at the large $D$ are rewritten by the current variables as

$$\omega_H \to \frac{n}{4\pi T} \sqrt{n\Omega}, \quad j \to \frac{4\pi T}{n} \frac{J}{2\sqrt{nM}},$$

where we also used $J/M|_{\text{phys}} = J/M/n$ due to the spacial rescaling by $1/\sqrt{n}$ in the brane setup (2.1). Recalling that the large $D$ effective theory has $T = n/(4\pi)$ at the leading
order, eq. (5.68) coincides with the terms up to $\mathcal{O}(\Omega)$ in eq. (5.67). This coincidence would imply the equivalence between the blob approximation and blackfold at large $D$. It is also interesting to see whether the non-perturbative effect coincides with the self-gravitational effect in the blackfold approach.

**Slowly rotating limit** In the slowly rotating limit $\Omega = \mathcal{O}(1/\sqrt{D})$, the $1/D$ expansion around the long neck waist will break down, in which the effective theory needs to be identified with the other coordinate patch. Assuming the slowly rotating ansatz, the large $D$ black rings were also solved in the effective theory on the ring coordinate $[25, 28, 30]^9$. Here, instead of the detailed match, we simply show an evidence that the blob ring in the slow rotating limit can be identified as a part of the ring coordinate. First, we evaluate the physical quantities of the asymptotically flat, vacuum large $D$ black ring $[25]$ at the leading order, which were written in the integral form,

\[
M = \frac{n\Omega_n}{8G_D} \int_{-1}^{1} dy \frac{(R^2 - 1)e^{P(y)}}{R\sqrt{1 - y^2}} \left( \frac{R\sqrt{1 - y^2}}{R + y} \right)^n,
\]

\[
J = \frac{\sqrt{n}\Omega_n}{8G_D} \int_{-1}^{1} dy \frac{(R^2 - 1)^{5/2}e^{P(y)}}{R(R + y)^2\sqrt{1 - y^2}} \left( \frac{R\sqrt{1 - y^2}}{R + y} \right)^n,
\]

\[
\Omega_H = \frac{1}{\sqrt{n}} \frac{\sqrt{R^2 - 1}}{R^2},
\]

where $P(y)$ is a regular function. One should note that $R$ here is a parameter related to the ring radius but not an observable, and hence should be eliminated in the comparison. To extract the leading order contribution from the integrals, we expand the integrand around the extremum in the $n$-powered term,

\[
y = -\frac{1}{R} + \frac{R^2 - 1}{R^2} \frac{z}{\sqrt{n}}.
\]

The limit $n \to \infty$ leads to

\[
M \simeq M_0 \int_{-\infty}^{\infty} dz e^{-z^2} = \sqrt{2\pi} M_0,
\]

\[
J \simeq \frac{R^2}{\sqrt{n}\sqrt{R^2 - 1}} M_0 \int_{-\infty}^{\infty} dz e^{-z^2} = \frac{\sqrt{2\pi} M_0}{n \Omega},
\]

where eq. (5.72) is used and,

\[
M_0 = \frac{\sqrt{n}\Omega_n}{8G_D} \left( \frac{R}{\sqrt{R^2 - 1}} \right)^{n-2} \sqrt{R^2 - 1} e^{P(-1/R)}.
\]

Taking into account the difference in the scaling by $1/n$ in the definition of $J$, this coincides with the phase diagram of the single blob ring up to the leading order.$^{10}$ Besides, one

$^9$AdS background also allows fast rotating rings with $\Omega = \mathcal{O}(D^0)$ $[44]$.

$^{10}$The same relation is obtained by using the large $D$ charged ring in $[28]$.  

27
can notice that eq. (5.73) locally rescales the coordinate that of the brane effective theory, instead of the compact polar coordinate. Therefore, the small region around \( y = -1/R \) should correspond to the slowly rotating blob ring, since the leading contribution comes from there.

6 Kinematic motion of blobs

In [34–36], one can observe that blobs are attracted to each other during the collision process. In some cases, they even orbit several rounds before the collision. Here we show these resurgent kinematic features in the effective theory are described by the neck interaction.

The quasi-local stress tensor for the \( p+1 \) effective theory is given by

\[
T^{tt} = m, \quad T^{ti} = mv^i, \quad T^{ij} = mv^i v^j + \tau^{ij},
\]

\[
\tau_{ij} = -2m \partial_i v^j - m \delta_{ij} - m \partial_i \partial_j \log m,
\]

(6.1)

The effective equation (2.2) is equivalent to the conservation of this tensor

\[
\partial_{\mu} T^{\mu\nu} = 0.
\]

(6.2)

Let us consider there are several traveling blobs sufficiently separate from each. Then, we divide the space domain into several regions, so that each region covers each blob. The boundaries run on the pits between them, which will pass through the neck waists. For the simplicity, we assume the time dependence of the boundaries is absent or negligible. By integrating over each region, the physical quantities of each blob are defined,

\[
\mathcal{M}_I(t) := \int_{V_I} T^{tt} dV, \quad \mathcal{P}_I^i(t) := \int_{V_I} T^{ti} dV,
\]

(6.3)

where \( I = A, B, C, \ldots \) denotes each blob and corresponding region. Obviously, the total sum of each quantity recovers total conserved quantities. We also define the blob position by

\[
X_I^i(t) := \frac{1}{\mathcal{M}_I(t)} \int_{V_I} x^i T^{tt} dV,
\]

(6.4)

which strictly gives the peak position for the single Gaussian blob. By using the conservation equation with the fixed boundary, the change in each quantity is expressed by

\[
\dot{\mathcal{M}}_I(t) = -\int_{\partial V_I} mv^i dS_i,
\]

\[
\dot{X}_I^i(t) = \mathcal{P}_I^i(t) - \frac{1}{\mathcal{M}_I(t)} \int_{\partial V_I} (x^i - X_I^i(t)) mv^j dS_j
\]

\[
\dot{\mathcal{P}}_I^i(t) = -\int_{\partial V_I} (mv^i v^j + \tau^{ij}) dS^j,
\]

(6.5)
where the dot denotes the time derivative. Assuming that the boundary flux terms are sub-leading order, each blob mass becomes constant, and the forces on blobs only come from the boundary stress tensor

\[
\mathcal{M}_I \ddot{X}_i^I(t) = - \int _{\partial V_i} \tau_{ij} dS_j. \tag{6.6}
\]

Now, we consider the interaction between two blobs \(A\) and \(B\) (Figure 10). For the simplicity, we assume the two have the equal mass. Since the blobs are separate with each other, on the straight line from a peak to another peak, the solution looks like that of the black string. From the symmetry around that line, it is natural to expect the solution still carries Gaussian profiles in the other directions,

\[
m \simeq e^{\mathcal{R}(z)} e^{-\frac{|y|^2}{2}}, \tag{6.7}
\]

where \(z\) is the coordinate along the peak-to-peak line and \(y\) other perpendicular directions. We assume \(\mathcal{R}(z)\) follows eq. (3.1) with the appropriate mass scale. Similarly, the neck tension on the waist would also be approximated by

\[
\tau_{zz} \simeq -e^C \tau e^{-\frac{|y|^2}{2}}, \quad \tau_{ij} \simeq 0 \text{ for other } (i,j), \tag{6.8}
\]

where \(\tau\) is given by eq. (3.25) and \(C\) is the mass scale. By evaluating the Gaussian integrals, each mass is given by

\[
\mathcal{M}_A = \mathcal{M}_B \simeq (2\pi)^{\frac{n-1}{2}} \int _{-\infty}^{\infty} dz e^{1+C-\frac{z^2}{2}} \simeq (2\pi)^{\frac{n}{2}} e^{1+C}. \tag{6.9}
\]

Assuming the blob \(A\) is in the positive side of \(z\) and \(B\) in the negative side, we obtain the equation of motion

\[
\ddot{X}_A(t) = -\ddot{X}_B(t) \simeq -\frac{(2\pi)^{\frac{n-1}{2}} e^C \tau}{\mathcal{M}_A} \simeq -\frac{L_{AB}^2}{2\sqrt{2\pi}} e^{-\frac{L_{AB}^2}{8}}, \tag{6.10}
\]
where $L_{AB} = |X_A - X_B|$. Since this force goes from a peak to another peak, we can rewrite this in more general form

$$
\ddot{X}_I = -\sum_{J \neq I} |X_I - X_J| (X_I - X_J) e^{-\frac{||X_I - X_J||^2}{8}} / 2\sqrt{2\pi},
$$

(6.11)

where the index $J$ runs for all other neighboring blobs. Here, all blobs are assumed to have the equal mass.

In the two body problem, it is convenient to use the center mass coordinate, in which the coordinate becomes

$$
X_A(t) = r(t)/2, \quad X_B(t) = -r(t)/2,
$$

(6.12)

and the equation of motion is rewritten as

$$
\ddot{r}(t) = F(r)\hat{r}, \quad (r := |r|, \quad \hat{r} := r/|r|),
$$

(6.13)

where the neck tension becomes the central force

$$
F(r) = -\frac{r^2}{2\sqrt{2\pi}} e^{-\frac{r^2}{8}}.
$$

(6.14)

This seems to give a nonlinear elastic force with the yield point at $r = 2\sqrt{2}$. However, one should recall that the formula (3.25) does not converge already below $r \sim 2\pi$. Instead, one can expect the blobs start merging inside that radius. In [36], the outgoing impact parameter after the fission is estimated as $b_{\text{out}} \approx 8$. This corresponds to the fact that the tension decays almost zero until $r \simeq 8$. The fusionless $2 \rightarrow 2$ events are also observed for some part of $b_{\text{in}} \gtrsim 4$. Although, there are no clear distinction between $2 \rightarrow 1 \rightarrow 2$ and $2 \rightarrow 2$, these fusionless events should be due to the exponentially decaying feature of the tension as well.

If the two blobs are stationary rotating with the angular velocity $\Omega$, then the tension should balance with the centrifugal force

$$
\frac{1}{2} \Omega^2 r = \frac{r^2}{2\sqrt{2\pi}} e^{-\frac{r^2}{8}}.
$$

(6.15)

This actually reproduces the balance condition for 2-dumbbells (4.12).

7 Conclusion

In this article, we developed the analytical treatment of the blob-blob interaction in the blob approximation in the large $D$ effective theory, in which the motion of blobs is approximately described by Newtonian mechanics. It turned out that the brane tension on the thin neck between blobs plays a key role in generating the attraction force.

We started from revisiting the black string analysis for the small tension, in which non-uniform black strings were solved by expanding from the zero tension Gaussian solution.
The scaling hierarchy between the neck waist and compactification length $L$ enabled the matched asymptotic expansion between the narrow waist and blob tail.\textsuperscript{11} This hierarchy was also kept in the physical quantities as the trans-series with respect to $L$.

In rigidly rotating cases, black dumbbells and ripples found in ref. [33] were also studied by using the interactive blob approximation. The logarithmically extending necks in the limit $\Omega \to 0$, observed in the numerical analysis, were analytically confirmed for both solutions as the result of the balance between the centrifugal force and brane tension. In the ripples, the long neck which grows as $\Omega^{-1}$ was also resolved in the same way.

In the slowly rotating limit $\Omega = \mathcal{O}(1/\sqrt{D})$, the thermodynamics of the single blob ring turned out equivalent with the large $D$ black rings constructed in the effective theory on the ring coordinate [25], which implies that the blob rings are identified as part of the large $D$ black rings/Saturns solved in the ring coordinate. Above the slow rotation, however, it remains unclear whether ripples are actually ripples or rings/Saturns, since the leading order theory cannot see the breakdown of the $1/D$ expansion.

The large $D$ results were also shown to be consistent with the large $D$ limit of the blackfold result [43, 45]. Remarkably, we confirmed that the elastic bending effect on the blackfold coincides with the correction perturbative in $\Omega$ for the blob ring. This implies that the blob approximation is the large $D$ equivalent of the blackfold approximation.

Finally, we formulated the mechanics of interactive blobs. For the equal mass blobs, the equation of motion was obtained with the effective attraction force. It turned out that the attraction comes from the boundary integrals around blobs, in which thinly connecting necks provides dominant contribution. The equation of motion explained the kinematic aspects in the blob-blob collisions [34–36] as well as the power balance in the dumbbell. Unfortunately, the current analysis remains somewhat empirical, specific to the configuration. It is important to find a more generic and sophisticated formulation. The effective Newtonian description pursued in section 6 will be a clue in this direction. Some simplifications like fixed boundaries, no boundary fluxes and equal mass setting should be reconsidered to make a more general effective theory. We also ignored the boundary viscosity in the tension, which was important for the entropy production during the collision [36]. For the motion of extended blob objects like blob rings, one will need further extension which can describe both extrinsic and intrinsic motions as in the blackfold approach.

In the leading order theory, the refined blob approximation guarantees that the neck extends arbitrary long as its thickness gets arbitrary thin. However, one can expect the $1/D$ expansion breaks down at the sufficiently thin neck, which will lead to the topology-changing transition. In ref. [22], by numerically solving 4NLO effective equation, the zero tension condition admitted $D^{1/4}$ dependence on the maximum period for the non-uniform black string. This scaling is a little smaller than $L = \mathcal{O}(\sqrt{D})$ in which the

\textsuperscript{11}For $L \simeq \mathcal{O}(\sqrt{D})$, this scaling hierarchy would smoothly continue to the near-neck structure in the fused conifold [10].
topology-changing transition was observed in the large $D$ conifold ansatz \[10\]. The blob approximation with the $1/D$ correction would solve this puzzle.

The phase of black ripples includes both actual black ripples and black rings/Saturns. At $D = \infty$, since the horizon can be arbitrary thin, the entire part becomes the ripples and rings/Saturns exist only at $\Omega = 0$, $J/M = \infty$. In other word, the leading order theory cannot see the transition from the ripples to the rings/Saturns. On the other hand, at the slow rotation limit $\Omega = O(1/\sqrt{D})$, the blob ring result is shown to be consistent with the large $D$ result by the effective theory in the ring coordinate, in which the $1/D$ expansion breaks down around the long neck waist. This implies that the transition should occurs somewhere for $\Omega > O(1/\sqrt{D})$. The $1/D$ correction should be taken into account to get further information on the transition. Since the transition point goes to $J/M \to \infty$ for $D \to \infty$, at sufficiently large $D$, entire parts of black rings/Saturns would be treated as thin ring where the blob approximation is applicable, and there would be thin/fat ripples instead.\[^{12}\] The critical value $\Omega_c$ would increase as the dimension gets lower. Finally, as was shown in $D = 6, 7$ \[40\], the thin rings/Saturns take the place of the thin ripples and a part of fat ripples turns to fat rings/Saturns.

One might use blob rings to study the black ring dynamics at large $D$ as in case of Myers-Perry. It is known that thin rings are unstable to the Gregory-Laflamme (GL) type non-axisymmetric fluctuations \[5, 46, 47\]. At the large $D$ limit, the same instability was found in the effective theory on the ring coordinate \[25\]. Surprisingly, as the large $D$ black string, the end point of the instability was shown to be the stable non-uniform black ring by numerically evolving the ring effective equation \[30\]. The dynamical study of blob rings would help the understanding beyond the slowly rotating regime.

The elastic instability numerically found in $D = 5$ \[5\] is another interesting subject, which deforms the ring with its thickness almost unchanged unlike the GL instability. Recently, it was shown that thin black rings are free of this type of instability within the scope of the blackfold approximation \[47\].\[^{13}\] It is interesting to see if blob rings admit the elastic-type instability with or without the non-perturbative correction caused by the blob-blob interaction.

As a quick application, one can construct black flowers \[33\] or black brane lattice \[18, 48\] in their highly deformed regime. By balancing the neck tension (6.11) with centrifugal forces, the multiple rotating blob configuration can be constructed for black flowers. In the brane lattice setup, while the power balance would be rather trivial from the periodicity, one should evaluate the back reaction to the blobs from the neck tension to see the physical quantities, which would rise the multipole perturbation around blobs.

The analysis developed here should be similarly applied with the Maxwell charge. Especially, in the rigidly rotating case, the effective equation was shown to coincide with the neutral one by redefinition of variables \[32\]. It is interesting to see how the charge

\[^{12}\text{Here, the terms ‘thin’ and ‘fat’ are used regarding the applicability of the blob approximation.}\]

\[^{13}\text{The elastic instability found in the large $D$ ring \[27\] was questioned in ref. \[47\].}\]
repulsion (attraction) competes with the neck tension. With the cosmological constant, as long as the blob solution exists, the same technique should apply. One should note that the effective theory should have the negative pressure to have the blob solution. Since the negative pressure originates from the large dimensional sphere curvature, the blob approximation will not apply to the planer AdS configuration.

**A Neck solution at Next-to-next-to-leading order**

Using LO and NLO results in the section 3, NNLO neck solution is given by

\[
\bar{R}_2(\xi) = \bar{r}_2 - 96\zeta(3) + \frac{64\pi^2}{3} - 128(\log^2 2 + \log 2) + \frac{4}{9}\left(432\zeta(3) - 96\pi^2 + \pi^4\right) - \frac{4\pi^4}{9X^2} \\
+ \frac{4(X - 1)}{X^2} \log^4 (X - 1) + \frac{32(1 - X)}{X^2} \log^3 (X - 1) + \left(- \frac{8(24 + \pi^2)}{3X^2} + \frac{8\pi^2}{3X} + 64\right) \log^2 (X - 1) \\
+ \left(\frac{32\pi^2}{3X^2} - \frac{32(\pi^2 - 12)}{3X} - 128\right) \log (X - 1) + \frac{32(2 - X)}{X} \log^3 X \\
+ \left(\frac{96(X - 2)}{X} \log (X - 1) + 128\right) \log^2 X + \left(128 + \frac{80\pi^2}{3} - \frac{160\pi^2}{3X}\right) \log X \\
+ \left(\frac{16(2 - X)}{X} \log^2 (X - 1) - \frac{64(X + 2)}{X} \log (X - 1)\right) \log X + \frac{64(X - 1)}{X^2} \text{Li}_2(1 - X)^2 \\
+ \text{Li}_2(1 - X) \left(256 + \frac{32(\pi^2 - 48)}{3X} - \frac{32\pi^2}{3X^2} + \frac{32(X - 1)}{X^2} \log^2 (X - 1) + \frac{128(X - 2)}{X} \log X \\
- \frac{64(X^2 - 2)}{X^2} \log (X - 1)\right) + \frac{96(X - 2)}{X} \left(\text{Li}_3(1 - X) + 2\text{Li}_3\left(\frac{1}{X}\right)\right). \tag{A.1}
\]

where \(X := e^{-\xi} + 1\). The integration constant corresponds to the value at \(\xi = 0\).

\[
\bar{R}_2(0) = \bar{r}_2. \tag{A.2}
\]

For \(|\xi| \to \infty\), the solution is expanded by

\[
\bar{R}_2(\xi) \simeq \bar{r}_2 - \frac{64\pi^2}{3} - 96\zeta(3) - 128(\log 2 + \log^2 2) + \mathcal{O}\left(e^{-|\xi|}\right). \tag{A.3}
\]
B Calculations for ripples

B.1 Single blob ring

The absence of the short neck simplifies the analysis of the single blob ring in \( N = 2 \) and \( N = 3 \) ripples. Ignoring the non-perturbative correction, the solution is found by simply expanding in \( \Omega \),

\[
R(z) = \frac{1}{2} - \frac{z^2}{2} + \frac{3}{2} \Omega^2 (z^2 - 2) - \frac{1}{2} \Omega^3 z^3 + \Omega^4 \left( \frac{z^4}{3} + 4z^2 - \frac{19}{2} \right) - \Omega^5 \left( \frac{z^5}{4} + \frac{11z^3}{6} \right) + \Omega^6 \left( \frac{z^6}{5} + \frac{97z^4}{72} + \frac{71z^2}{3} - \frac{805}{12} \right) - \Omega^7 \left( \frac{z^7}{6} + \frac{67z^5}{60} + \frac{247z^3}{18} \right) - \Omega^8 \left( \frac{z^8}{7} + \frac{1769z^6}{1800} + \frac{6137z^4}{540} + \frac{34853z^2}{180} - \frac{231767}{360} \right) - \Omega^9 \left( \frac{z^9}{8} + \frac{2257z^7}{2520} + \frac{37723z^5}{3600} + \frac{74213z^3}{540} \right) + \Omega^{10} \left( \frac{z^{10}}{9} + \frac{6543z^8}{7840} + \frac{1921093z^6}{189000} + \frac{29460041z^4}{226800} + \frac{74689297z^2}{37800} - \frac{570064693}{75600} \right),
\]

(B.1)

where \( z := r - L \) and we show the terms up to \( O(\Omega^{10}) \). The blob peak is determined by

\[
L = \Omega^{-1} + \frac{3}{2} \Omega^3 + \frac{79}{4} \Omega^5 + \frac{3065}{12} \Omega^7 + \frac{256251}{720} \Omega^9 + O(\Omega^{11}).
\]

(B.2)

The integration constant is fixed so that the balance condition holds up to the relevant order

\[
\int_{-\infty}^{\infty} dz \left( -\frac{R'(z)^2}{L+z} + \Omega^2 (L+z) \right) e^{R(z)} = 0.
\]

(B.3)

B.2 \( O(\Omega^2) \)-correction to blob rings

Up to \( O(\Omega) \), the \( i \)-th blob ring solution is expressed by

\[
R_0^{(i)}(z_i) = 1 - \frac{w_i^2}{2} - \frac{z_i^2}{2},
\]

(B.4)

where

\[
z_i := r - L_i, \quad w_i := \Omega L_i = 1 + \delta^{[1]} L_i \Omega + \delta^{[2]} L_i \Omega^2 + \ldots
\]

(B.5)

The \( O(\Omega^2) \) correction \( R^{(i)}(z_i) = R_0^{(i)}(z_i) + \Omega^2 \delta R^{(i)}(z_i) \) is solved by

\[
\delta R^{(i)}(z) = -3 + \frac{3z^2}{2} - 2\delta^{[1]} L_i z - \delta^{[1]} L_i z^2 F_2 \left( 1, 1; \frac{1}{2}, 2; -\frac{z^2}{2} \right) + \sqrt{2\pi} \delta^{[1]} L_i z^2 e^{-\frac{z^2}{2}} \text{erfi}\left( \frac{z}{\sqrt{2}} \right)
\]

\[
+ \left( C_i + \sqrt{2\pi} \delta^{[1]} L_i \text{erf}\left( \frac{z}{\sqrt{2}} \right) \right) \left( e^{\frac{z^2}{2}} - \sqrt{\frac{\pi}{2}} z \text{erfi}\left( \frac{z}{\sqrt{2}} \right) \right)
\]

(B.6)

where \( C_i \) is the integration constant which modifies the peak maximum by \( \delta R^{(i)}(0) = C_i - 3 \).

The limit \( z \to \pm \infty \) admits the exponential growth,

\[
\delta R^{(i)}(z) \simeq z^{-2} e^{\frac{z^2}{2}} \left( C_i \mp \sqrt{2\pi} \delta^{[1]} L_i \right).
\]

(B.7)
To determine the integration constant, we evaluate the integral (5.5) from the neck waist \( r = L_i - \Delta_{i-1}/2 \) to the peak \( r = L_i \),

\[
\left[ \left( \frac{1}{2} \mathcal{R}^2 + \mathcal{R} - 1 + \frac{1}{2} \Omega^2 r^2 \right) e^{\mathcal{R}} \right]_{L_i - \frac{\Delta_{i-1}}{2}}^{L_i} = \sqrt{\epsilon} \Omega^2 \left( C_i - 3 + 2\sqrt{2} \sum_{j=i}^s \delta^{[1]} L_i \right),
\]

(B.8)

where the neck tension in eq. (5.12) is used. The left hand side integral is easily evaluated with \( \mathcal{R}_0^{(i)}(z) \)

\[
\int_{L_i - \frac{\Delta_{i-1}}{2}}^{L_i} dr \left( -\frac{1}{r} (\mathcal{R}')^2 + \Omega^2 r \right) e^{\mathcal{R}} = \sqrt{\epsilon} \Omega^2 \left( -3 + 2\sqrt{2} \delta^{[1]} L_i \right) + \mathcal{O}(\Omega^3).
\]

(B.9)

Therefore, we obtain

\[
C_i = -2\sqrt{2} \pi \sum_{j=i+1}^s \delta^{[1]} L_i - \sqrt{2} \pi \delta^{[1]} L_i.
\]

(B.10)

By substituting this to eq. (B.7), one can see that the innermost and outermost blob rings are absent of the exponential growth in the inward or outward direction, which enables the connection to the long neck or asymptotic region.

**B.3 Evaluation of \( \langle \delta^{[2]} L \rangle \)**

To calculated the average of \( \mathcal{O}(\Omega^2) \)-correction to \( L_i \), we evaluate the integral on the right hand side of eq. (5.5) from the long neck waist to the infinity up to \( \mathcal{O}(\Omega^3) \). First, we focus on the integral over \( i \)-th blob ring

\[
\int_{i \text{-th}} dr \left( -\frac{1}{r} (\mathcal{R}')^2 + \Omega^2 r \right) e^{\mathcal{R}(r)} \simeq \sqrt{2} \pi e \Omega^2 (2\delta^{[1]} L_i - 2\delta^{[2]} L_i) = 3\Omega
\]

\[
\Omega \left[ z_i e^{-\frac{z_i^2}{4}} \right]_{z_i}^{z_{i+1}} + \Omega^3 \int_{z_i}^{z_{i+1}} dz_i \left( 2z_i \delta^{(i)}(z_i) + (1 - z_i^2) \delta^{(i)}(z_i) \right) e^{1 - z_i^2}
\]

(B.11)

where \( z_i := r - L_i \) and the cut off is given by

\[
z_{i,+} = \frac{\Delta_i}{2} + \frac{2}{\Delta_i} \xi_c, \quad z_{i,-} = -\frac{\Delta_{i-1}}{2} + \frac{2}{\Delta_{i-1}} \xi_c.
\]

(B.12)

As in the black string analysis, we expect the cut off dependence will cancel out together with the neck contribution. Here, instead of evaluating the neck contribution, we simply neglect the cut off dependence. One should note that the neck integral can also provide the finite contribution at higher order in \( 1/\Delta \) as in eq. (3.31). The integral involving \( \delta^{(i)}(z_i) \) is evaluated by using eqs. (B.6) and (B.10),

\[
\int_{z_i}^{z_{i+1}} dz_i \left( 2z_i \delta^{(i)}(z_i) + (1 - z_i^2) \delta^{(i)}(z_i) \right) e^{1 - z_i^2}
\]

\[
= 3\sqrt{2} \pi e + \sqrt{2} \pi e \left( \sum_{j=i+1}^{j=s} \delta^{[1]} L_j \Delta_j + \sum_{j=i}^{j=s} \delta^{[1]} L_j \Delta_{j-1} \right) + \mathcal{O}(\Delta^{-2}).
\]

(B.13)

\(^{14}\text{For } i = 1, \text{ the same result is obtained by replacing the integral domain with } [L_i, L_i + \Delta_i/2].\)
By summing the contribution from all blob rings, we obtain the condition

\[ \sqrt{2} \pi e s \Omega^3 \left( 2\langle \delta^{[2]}L \rangle - 3\langle \delta^{[1]}L^2 \rangle - \frac{1}{s} \sum_{i=1}^{s-1} \sum_{j=i}^{s} \delta^{[1]}L_j \Delta_i \right) = \mathcal{O}(\Omega^4), \quad (B.14) \]

where NLO result \( \langle \delta^{[1]}L \rangle = 0 \) is already used. Recalling the definition \( \Delta_i := \delta^{[1]}L_{i+1} - \delta^{[1]}L_i \), the resummation leads to the identity,

\[ \frac{1}{s} \sum_{i=1}^{s-1} \sum_{j=i}^{s} \delta^{[1]}L_j \Delta_i = \langle \delta^{[1]}L^2 \rangle, \quad (B.15) \]

with which eq. (5.25) is obtained.
