Peripheral arterial disease in the Middle East: Underestimated predictor of worse outcome

Ayman El-Menyar¹⁻³, Jassim Al Suwaidi⁴, Hassan Al-Thani⁵⁺*  

ABSTRACT
Peripheral arterial disease (PAD) is a common manifestation of systemic atherosclerosis and is associated with significant morbidity and mortality. The prevalence of PAD in the developed world is approximately 12% among adult population, which is age-dependent and with men being affected slightly more than women. Despite the strikingly high prevalence of PAD, the disease is underdiagnosed. Surprisingly, more than 70% of primary health care providers in the US were unaware of the presence of PAD in their patients. The clinical presentation of PAD may vary from asymptomatic to intermittent claudication, atypical leg pain, rest pain, ischemic ulcers, or gangrene. Claudication is the typical symptomatic expression of PAD. However, the disease may remains asymptomatic in up to 50% of all PAD patients. PAD has also been reported as a marker of poor outcome among patients with coronary artery disease. Despite the fact that the prevalence of atherosclerotic disease is increasing in the Middle East with increasing cardiovascular risk factors (tobacco use, diabetes mellitus and the metabolic syndrome), data regarding PAD incidence in the Middle East are scarce.

Keywords: Peripheral arterial disease, Middle East
THE ANCIENT HISTORY OF ATHEROSCLEROSIS IN THE MIDDLE EAST

Atherosclerosis was first identified in ancient Egyptians. In 1911, Sir Ruffer identified histologic evidence of atherosclerosis in the aorta and its large arteries on autopsies from 3,000-year-old Egyptian mummies. Recently, Allam et al. examined 52 ancient Egyptian mummies to identify cardiovascular structures and arterial calcifications. Forty-four of the 52 mummies had identifiable cardiovascular structures, and 20 of these had either definite atherosclerosis (defined as calcification within the wall of an identifiable artery) or probable atherosclerosis (defined as calcifications along the expected course of an artery). Calcifications were found in the aorta as well as in the coronary, carotid, iliac, femoral, and peripheral leg arteries. Definite coronary atherosclerosis was present in 2 mummies, including a princess who lived between 1550 and 1580 BCE. These findings represent the earliest documentation of coronary atherosclerosis in human beings.

PERIPHERAL ARTERIAL DISEASE (PAD)

PAD is a manifestation of systemic atherosclerosis; therefore, it shares its natural course of insidious and gradual progression. PAD is an indicator of widespread atherosclerosis in other vascular territories, such as the cerebral and coronary circulations. There is also considerable overlap between PAD, cerebrovascular disease (CVD) and coronary artery disease (CAD), with the presence of PAD being associated with increased risk of CAD and their consequences. Ethnicity has been shown to be an independent predictor of adverse cardiovascular outcomes in patients with atherothrombotic disease, including cardiovascular and all-cause mortality. Ethnicity-related variations in the treatment of atherothrombotic disease have been reported even after adjustment for risk factor, variability in access to care, adherence to medical therapies, and other socioeconomic factors. Prior epidemiologic reports have shown that blacks are disproportionately affected by PAD, with a two to three-fold increased risk compared to whites. On the other hand, Asians have similar to slightly lower PAD rates than whites. Though, major studies investigating associations between ethnicity and PAD have been confined to comparisons between blacks and whites. Criqui et al. considered black ethnicity a consistent and independent risk factor for PAD which is similar to other established risk factors. The predominance of PAD in certain ethnic groups could not be explained by the high incidence of diabetes mellitus (DM), hypertension, or increased susceptibility to other CVD risk factors. Therefore extensive studies are needed to investigate whether newer atherogenic, inflammatory, and prothrombotic markers, are associated with increased PAD incidence in a particular ethnic group.

PREVALENCE OF PAD

PAD has a variable yet relatively high prevalence in the western world. Patients with PAD are at increased risk of coronary, carotid and cerebrovascular atherosclerosis disease and all-cause mortality. These predictors are independent of the traditional risk factors of PAD. PAD is not a static disease and its progression from intermittent claudication to rest pain or gangrene can occur. The prevalence of PAD in the general population depends on the definition used and is substantially underestimated, if one considers only individuals who exhibit typical symptoms of claudication. Table 1 shows the clinical staging of PAD. It is possible that the functional impairment in patients with PAD may keep them from ambulating to the point of having angina to the extent that those patients may present with much more advanced coronary atherosclerosis. This risk increases with the severity of PAD. Several studies have shown worse prognosis in both selected and unselected western population admitted with acute cardiovascular events or followed up in outpatient settings such as Global Table 1. Clinical staging of PAD according to Fontaine and Rutherford classification.

| Stage | Clinical finding          | Fontaine classification | Rutherford classification |
|-------|--------------------------|-------------------------|--------------------------|
| I     | No symptom               | 0                       | 0                        | No symptom                     |
| II    | Intermittent claudication| I                       | 1                        | Mild claudication               |
| III   | Rest pain                | II                      | 4                        | Rest pain                      |
| IV    | Ulcer or gangrene        | III                     | 5                        | Minor tissue loss               |
|       |                          |                         | 6                        | Major tissue loss               |
Atherothrombosis Assessment study (AGATHA). Data specifically addressing this important issue in the Middle East is lacking which needs urgent inception of a registry database. Moreover, the prevalence and the impact of PAD in patients from the Middle-Eastern countries were limited by small sample size, and retrospective nature of the studies including our earlier reports. Table 2 shows review of population based studies investigating PAD in different ethnic groups including the Middle East. The low incidence of PAD in our region is underestimating the true figures, which may be due the fact that our PAD patients were diagnosed at their presentation with acute coronary syndrome. Table 3 & 4 demonstrate risk factors associated with PAD in different studies.

### Table 2. Examples of population based studies investigating PAD in different ethnic groups.

### Table 3. Risk factors associated with peripheral arterial disease.

| Reference                  | Risk factor | Association with PAD                                                                 |
|----------------------------|-------------|---------------------------------------------------------------------------------------|
| Heliovaara et al.          | Smoking     | As a sequelae of atherosclerosis, smoking can result in a 7-fold increase in PAD       |
| Premalatha et al.          | Diabetes mellitus | Smokers had 2.7 times higher risk for PAD DM is associated with 2-4 fold increased risk of developing CAD and PAD |
| Newman et al.              |             | 5-10% of PAD pts have type 1 and 90–95% have type 2 DM                                 |
| Lucher et al.              |             | In DM, the risk of PAD increased by age, DM duration, DM control and neuropathy       |
| Creager et al.             |             | 20% of symptomatic PAD pts had DM                                                     |
| Bennett et al.             |             | Prevalence of PAD in DM is 20% in > 40 yrs old and 29% in people aged > 50 yrs.        |
| Muraito et al.             |             | PAD and hypertension are associated with 35–55% of patients with PAD having hypertension |
| Hirsch et al.              |             | The prevalence of PAD in DM increases with the presence of hypertension. If hypertension is controlled, the progression of PAD can be slowed |
| Premalatha et al.          | Dyslipidemia | Limited data is available. Hypercholesterolemia and LDL-C are associated with development of PAD (OR 1.4 and 1.5 respectively) |
| Makin et al.               | Hypertension | PAD and hypertension are associated with 35–55% of patients with PAD having hypertension |
| Palumbo et al.             |             | The prevalence of PAD in DM increases with the presence of hypertension. If hypertension is controlled, the progression of PAD can be slowed |
| Liew et al.                | Chronic kidney disease (CKD) | CKD and PAD had higher mortality than patients with either CKD or PAD |
| Tzoulakis et al.           | Inflammation | IL-6, CRP and fibrinogen are associated with PAD, its progression and severity         |
| Danesh et al.              | Fibrinogen   | Fibrinogen has been associated with PAD development and severity and in patients with intermittent claudication, fibrinogen has been shown to be an independent predictor of death |
| Vainas et al.              | CRP          | CRP is be inversely associated with ABPI, endothelial dysfunction and PAD severity    |
| Brevetti et al.            | Lipoprotein (a) (Lp(a)) | Lp(a) correlates with ABPI and severer forms of PAD. It increases steadily from absence of PAD to mild and severe PAD. |
ANKLE-BRACHIAL INDEX & PAD

Non-invasive screening tool is essential for diagnosing PAD as atherothrombosis is mostly asymptomatic, and often, the first sign of the disease involves a major life-threatening vascular event.\textsuperscript{25,64} The ankle-brachial index (ABI) is a simple and useful assessment tool for measuring clinical bedside atherosclerotic burden and risk of future cardiovascular disease events.\textsuperscript{16} In general, ABI test has a sensitivity above 90% and a specificity of 95% for the diagnosis of PAD (0.00-0.40: Severe PAD sufficient to cause resting pain or gangrene, 0.41-0.90: PAD sufficient to cause claudication, 0.91-1.30: normal vessels, and 1.30: non-compressible (severely calcified) vessel. However, depending on the symptoms, further tests may be performed such as computed tomography, catheter angiography, magnetic resonance imaging, or duplex ultrasound imaging.\textsuperscript{65–66}

Nevertheless, the cut-offs for defining ABI risk differ from one study to another and remain controversial. The sensitivity and specificity associated with an ABI threshold of $0.90$ ranged from a sensitivity of 79% to 95% and specificity of 96% to 100% compared with angiography.\textsuperscript{67} McKenna et al.\textsuperscript{68} found ABI as an independent predictor of mortality with a 5-year mortality of 50% and 30% in patients with an ABI of 0.40 and 0.70, respectively. Sikkink et al. also showed a 5-year mortality of 37% in patients with an ABI,\textsuperscript{0.50}, 29% for patients with an ABI between 0.50 and 0.69, and 9% for patients with an ABI between 0.70 and 0.89.\textsuperscript{69} In another study, ABI,\textsuperscript{0.90} had an all-cause mortality of 1.69 and cardiovascular mortality of 2.52, while patients with an ABI,\textsuperscript{1.40} had a all-cause mortality of 1.77 and cardiovascular mortality of 2.09.\textsuperscript{70} Hence, similar association has been observed between high ABI and mortality versus low ABI and mortality.

Inaccurate ABI measurements may result from calcified or incompressible vessels (false high readings) and the presence of a subclavian-artery stenosis.\textsuperscript{68} Some studies have reported ABI of 1.3 as an indicative of medial arterial calcinosis and noncompressible arteries.\textsuperscript{64,71} Mild claudication or obstruction occurs with an ABI < 0.9—0.75. Moderate to severe claudication occurs with an ABI < 0.75—0.4. ABI value of < 0.50 was found to be correlated with the progression to critical leg ischemia during the follow-up of 6.5 years.\textsuperscript{72} Arterial calcification (medial calcinosis) can make the ankle arteries incompressible resulted in artificially high values of the ABI, which is commonly seen in diabetic patients.\textsuperscript{73} ABI value of 1.4 may be a good compromise.\textsuperscript{74–75} Compared with normal legs, legs with low-normal (0.91 to 0.99) and high-normal (\leq 1.40) ABIs had increased rate of pain, suggesting borderline disease and vascular stiffness.\textsuperscript{75} In more than 80% of cases with an ABI > 1.40, concomitant occlusive disease could be identified using other diagnostic modalities.\textsuperscript{76} This could explain the similar rates of intermittent claudication and association with subclinical disease in other vascular beds found in this ABI range, compared to an ABI < 0.90.\textsuperscript{76–75} With increasing prevalence of DM, metabolic syndrome and renal failure in the Middle East, particularly in the Gulf region there is a need to revise the ABI cutoff value for better management of the disease.\textsuperscript{77–80}

\* = Renal failure and MI were independent predictors (OR 2.5 and 4.4 respectively)
Peripheral arterial disease among chronic stable diseases

Data on the prevalence and outcome of Middle-Eastern patients with PAD are limited. A cross-sectional hospital-based study (402 patients) from Saudi Arabia reported high prevalence of PAD (ABI < 0.9) in elderly high-risk patients with DM (61.4%), chronic renal failure (13.4%) or ischemic heart disease (21.4%) when compared to controls (4.1%). Another cross-sectional study evaluated 1477 diabetic patients from Bahrain found foot ulcer in 5.9%, and PAD in 11.8% cases. Between 2004 and 2005, we conducted a multicenter study (AGATHA-ME) in 5 neighboring countries (United Arab Emirates, Kuwait, Qatar, Bahrain, and Oman). These countries are characterized by small populations and similar ethnic distribution. The study included 1341 patients who were recruited from the tertiary care settings and were divided into 2 groups; patients with or without atherosclerotic disease. Group with atherosclerotic disease included patients with history of prior vascular disease or with current symptoms: (a) prior cerebrovascular disease (CVD), that is, ischemic stroke, transient ischemic attack, or carotid angioplasty or endarterectomy; (b) prior coronary artery disease (CAD), i.e. unstable angina, MI, or coronary angioplasty or bypass graft; (c) PAD, that is, intermittent claudication, vascular lab diagnosis, or lower-limb arterial revascularization; (d) current cardiovascular symptoms, that is, angina pectoris or intermittent claudication. The second group constituted patients at risk of vascular disease (at-risk group) without history of prior disease or current symptoms, with age more than 55 years and with 2 or more of the following risk factors (RFs): DM; dyslipidemia; hypertension; obesity; or smoking history, (current or former smoker). The AGATHA-ME study confirms that atherothrombosis disease often occurs at more than one site and that ABI is related to the RF profile and to the site and extent of atherothrombosis. The studied populations have a higher prevalence of the traditional RFs in a unique fashion. Also, we found that gender and DM are associated with the worst outcome.

Peripheral arterial disease among hemodialysis (HD) patients

Prevalence of PAD defined by ABI < 0.90 in patients with end-stage renal disease is extremely high, estimated at 38% in a single-center study, to which should be added 14% of cases with incompressible ankle arteries. Prevalence of PAD is high among HD patients in our population. Between 2007 and 2010 we analysed the presence of PAD among hemodialysis patients in a prospective study of 3 years follow-up. Among 252 consecutive HD patients, PAD was diagnosed in 97 (38.5%) patients. Three-year all-cause mortality was higher in PAD group [unadjusted and adjusted hazard ratios (HR) were 3.6 (95% CI 2.11-6.01) and 2.92 (95% CI 1.55-5.51), respectively]. Other predictors for mortality were age (HR 1.06; 95% CI 1.04-1.10), number of vascular access (HR 2.3; 95% CI 1.04-5.01), and prior CAD (HR 1.8; 95% CI 1.05-3.49). Diabetic retinopathy was also found to be an independent predictor of PAD. Further, PAD and number of vascular access procedures were independently associated with long-term mortality. Hence, early detection of PAD is of utmost value in HD patients. Recently, we have also completed a 5-year follow-up of 252 HD patients. The observed 5-year mortality rate reached 72% in PAD vs 36% in no-PAD (unpublished data) in comparison to 40% vs 14% in the first 3-year follow-up. Table 5 shows different studies evaluating PAD in HD patients.

Peripheral arterial disease among acute coronary syndrome

In 2007, we studied PAD in acute coronary events, involving 6705 consecutive ACS patients collected from a 6-month prospective, multicenter study of the Gulf Registry of Acute Coronary Events (Gulf RACE) from 6 adjacent Middle Eastern Gulf countries (Bahrain, Kuwait, Qatar, Oman, United Arab Emirates and Yemen). Patients were recruited from 64 hospitals with the diagnosis of ACS including unstable angina (UA) and non-ST- and ST-elevation myocardial infarction (NSTEMI and STEMI). Out of the 6705 ACS patients, PAD was found in 177 (2.6%) patients. Our data were collected from an observational study, which is one of the limitations. Moreover, inconsistent cut-off points for ABI would potentially miss patients with milder PAD leading to potential outcome bias in different studies. The results of this study showed that patients with PAD and ACS are in high-risk group that require more attention for evaluation of risk factors and early detection. Certain traditional risk factors were also independently associated with PAD which necessitates aggressive preventive measures. PAD in patients with STEMI is an independent predictor for in-hospital death. Detection of PAD in ACS patients might be useful simple bedside tool for early risk-stratification. Table 6 shows risk factors and outcomes of PAD in patients presented with acute coronary syndrome in different studies in comparison to our previous
Table 5. Studies evaluate peripheral arterial disease in hemodialysis patients (adapted from 28).

findings in the Gulf region (8,19,22,23). The analysis showed PAD patients from the Arab Gulf region were relatively younger with higher prevalence of diabetes mellitus.

**Polyvascular disease**

Polyvascular disease (PolyVD) is defined as presence of more than one affected vascular bed i.e., any combination of the following: coronary artery disease (CAD), peripheral arterial disease (PAD) and cerebrovascular disease (CVD). Interestingly, we published the first study from the Middle East addressing the incidence and impact of PolyVD in ACS patients. This study included 428 patients of PolyVD comprised of ACS plus PAD (110 patients), ACS plus CVD (284 patients) and ACS plus PAD and CVD (34 patients). The limitation of this retrospective analysis is the diagnosis of PAD based on the clinical history and not on a standard measurement of ankle-brachial index (ABI) or angiography. This limitation could be explained in part by facts that clinical variables used were insensitive to identify PAD, as approximately half of subjects with ABI < 0.90 were asymptomatic. Moreover, only few cases had classic intermittent claudication in the symptomatic group. The presence of PolyVD is underdiagnosed in our daily practice which may underestimate its true prevalence and impact on the outcome. Although PolyVD patients represent a high-risk population in the setting of ACS, they received less aggressive therapy. Apart from major bleedings, PolyVD is an independent predictor for adverse hospital outcomes and short and long-term mortality. Great efforts should be directed to primary and secondary prevention. In ACS patients, assessment of the other affected vascular bed will add important step in risk stratification and management. We also observed that PolyVD is an independent predictor for the risk of strokes. Table 7 shows risk factors and in-hospital mortality in patients with versus without PolyVD presented with ACS in different clinical studies in comparison to our findings. Though the prevalence of PolyVD was lower in our region, the mortality rate was higher in comparison to other western studies. Moreover, the mortality in patients who had PAD and ACS was higher in the Gulf region in comparison to other regions.

**GENDER AND PERIPHERAL ARTERIAL SYNDROME**

Gender differences for the incidence and prevalence of PAD are inconsistent compared to other cardiovascular diseases. Prior reports showed that 12% of men and women in the community and 16% to 19% of the elderly population were affected with PAD. Intermittent claudication is the most common presenting symptom of PAD; however, it alone is an insufficient diagnostic indicator for PAD in women. Moreover, women with PAD were found to be more functionally impaired than men and had lower rates of revascularization of the lower extremity. Also, women who do undergo revascularization procedures had more adverse outcomes than men. However, PAD related mortality rates were comparable among both genders.

Data based on American and European populations have consistently demonstrated a sharp increase in PAD prevalence with age and higher rates in men than in women. Although women are less likely to be diagnosed on the basis of symptoms, they do have clinically significant PAD when tested. Since, symptomatic PAD predominates in men, many reports of surgical therapy do not analyze gender-specific outcomes. Reasons that may in part explain late diagnosis of PAD include economic considerations; women might focus more on seeking medical care for their families than for themselves, and are more likely to ignore mild-to-moderate symptoms.

Figure 1 – 3 shows the prevalence of PAD in women and men in different epidemiological studies. In contrast to western literature, our previous studies showed that women had higher prevalence of PAD in comparison to men.

Figure 4 shows the presence of PAD among hemodialysis patients stratified by gender and age in Qatar. Prevalence of PAD patient undergoing HD was higher in women aged between 41 and 50, otherwise it predominates in men.

Table 8 shows Men and Women in AGATHA-ME study in the Gulf region (GCC). It showed that women had the worse presentation and morbidity in comparison to men.

**OUTCOME IN PATIENTS WITH PAD**

The main cause of death in PAD patients is related to the coronary and/or cerebrovascular events, rather than complications related to PAD itself, as PAD is mostly a powerful indicator of progressive, systemic atherosclerotic disease. In a meta-analysis including nine studies, the likelihood of a low ABI

(between 0.80 and 0.90) to predict all-cause mortality was 4, rising to 5.6 when only cardiovascular deaths were considered. Several studies have shown the importance of the ABI as a predictor of cardiovascular or all-cause mortality in asymptomatic patients. A meta-analysis of 16 population cohort studies suggested the presence of ‘J’ or ‘U’-shaped association in which both low and high ABI are associated with increased cardiovascular morbidity and mortality. Criqui et al. has evaluated a
10-year follow up of 67 patients with a diagnosis of PAD and an ABI of 0.80 or less, showed significant increase in rate of mortality in both men (61.8%) and women (33.3%) when compared with men and women (11.6%) without disease.67,68 Our previous experience in the gulf region showed that patients with PAD had worse outcome when presented with ST-elevation myocardial infarction (STEMI), whereas in NSTEACS; PAD was associated with higher rate of heart failure in comparison to non-PAD patients. In diabetics, PAD was associated with 2-fold increase in mortality when compared to non-PAD (P = 0.028). Moreover, after adjustment, PAD was associated with higher mortality in STEMI (adjusted OR 2.6; 95% CI 1.23-5.65, P = 0.01).26 Table 9 shows outcome in patients withPAD.44,68,70,108-111

CONCLUSIONS

Consistent with the global trend, PAD among Middle Eastern patients is associated with poor outcome. However, the prevalence and impact of PAD in our region seems to be underestimated. As the prevalence of DM, metabolic syndrome and renal failure in the Middle East and particularly in the Gulf region is high, ABI cutoff value should be revised. Increased awareness and further research is urgently needed to control this “silent or underestimated killer” in the Middle East.
