Abstract

Graded nilpotent Lie groups, or Carnot groups, are to subRiemannian geometry as Euclidean spaces are to Riemannian geometry. They are the metric tangent cones for this geometry. Hoping that the analogy between subRiemannian and Riemannian geometry is a strong one, one might conjecture that the subRiemannian geodesic flow on any Carnot group is completely integrable. We prove this conjecture is false by showing that the subRiemannian geodesic flow is not algebraically completely integrable in the case of the group whose Lie algebra $\mathcal{N}_-$ consists of 4 by 4 nilpotent triangular matrices. We use this to prove that the centralizer for the corresponding quadratic “quantum” Hamiltonian $H$ in the universal enveloping algebra of $\mathcal{N}_-$ is “as small as possible”.

1 Introduction

Geometry would be in a sorry state if the Euclidean geodesic flows were not completely integrable – in other words, if we did not have explicit algebraic descriptions of straight lines in Euclidean space. Riemannian geometry, being infinitesimally Euclidean, makes frequent use of these explicit descriptions. For example the Euclidean lines play a role in the exponential map and in Jacobi fields.

SubRiemannian geometries, also called Carnot-Caratheodory geometries, are not infinitesimally Euclidean. Rather they are, at typical points, infinitesimally
modelled by Carnot groups. We will review these geometries and groups, and the relation between them momentarily. **The point of this note is to show that the Carnot geodesic flows need not be integrable.** We do this by giving an example of a ‘chaotic’ Carnot geodesic flow.

A subRiemannian geometry consists of a nonintegrable subbundle (distribution) $V$ of the tangent bundle $T$ of a manifold, together with a fiber-inner product on this bundle. These geometries arise, among other places, as the limits of Riemannian geometries. In such a limit we penalize curves for moving transverse to $V$ so that in the limit any curve not tangent to $V$ has infinite length. The distance between two points in a subRiemannian manifold is defined as in Riemannian geometry: it is the infimum of the lengths of all absolutely continuous paths connecting the two points. A theorem attributed to Chow asserts that if $V$ generates $T$ under repeated Lie brackets, and if the manifold is connected then this distance function is everywhere finite. Equivalently, and two points can be connected by a curve tangent to $V$. In this manner, every subRiemannian manifold becomes a metric space.

By a Carnot group we mean a simply connected Lie group $G$ whose Lie algebra $\mathcal{G}$ is finite-dimensional, nilpotent, and graded with the degree 1 part generating the algebra and endowed with an inner product. Specifically:

$$\mathcal{G} = V_1 \oplus V_2 \oplus \ldots V_r$$

as a vector space. The Lie bracket satisfies

$$[V_i, V_j] \subset V_{i+j}$$

where $V_s = 0$ for $s > r$. Also:

$$V_{i+1} = [V_i, V_i]$$

and $V_i$ is an inner-product space. We may think of $V = V_1$ as a left-invariant distribution on the group $G$. Its inner product then gives $G$ a subRiemannian geometry.

Given a distribution $V \subset T$, we can, at typical points $q$ of $Q$, obtain a graded nilpotent Lie algebra. In order to do this, let $V$ also stand for the the sheaf of smooth vector fields whose values lie in $V$. Form

$$V^2 = [V, V]$$

$$V^3 = [V, V^2]$$

$$\vdots$$

where the brackets denote Lie brackets of vector fields. (Exercise: Show that, as sheaves: $V^j \subset V^{j+1}$.) We assume that $V$ is bracket generating, which means that in a neighborhood of any point there is an integer $r$ such that $V^r = T$. 

2
A point $q$ of the manifold is called **regular** if the sheaves $V^r$ correspond to vector bundles near $q$. This means that if we evaluate each of these spaces of vector fields at a point $q \in Q$ thus obtaining a flag of subspaces:

$$V_q \subset V^2_q \subset V^3_q \subset \ldots \subset V^r(q) = T_qQ$$

then the integers $\dim(V^j(q))$ are constant in some neighborhood of $q$. For a generic distribution, generic points are regular. Associate to the filtration $V \subset V^2 \subset \ldots \subset T$ of sheaves its corresponding graded object

$$\text{Gr}(V, T)_q = V \oplus V^2 \oplus \ldots V^r$$

where $V_j = V^j/V^{j-1}$ is the quotient sheaf. Because the Lie bracket of vector fields $X, Y$ satisfies $[X, fY] = f[X, Y]$ mod $X, Y$ where $f$ is a function, it induces bilinear maps $V^j \otimes V_k \to V^{j+k}$. Putting these maps together defines, at any regular point, a Lie algebra structure on $\text{Gr}_q = \text{Gr}(V, T)(q) = V(q) \oplus V^2(q) \oplus \ldots V^r(q)$. The subspace $V_q = V_1(q)$ of $\text{Gr}(V, T)_q$ is the original $k$-plane field at that point, and Lie-generates $\text{Gr}_q$. It follows that $G = \text{Gr}(V, T)_q$ is the Lie algebra of a Carnot group. If the distribution $V$ comes with an inner product, then this generating subspace inherits it. Consequently $G$ comes with a canonical left-invariant subRiemannian structure. This $G$ is called the **nilpotentization** of the subRiemannian structure at the regular point $q$.

Gromov, using the idea of the Hausdorff limits of a family of metric spaces, showed how to define a “tangent space” to any point of any metric space. (See Gromov et al [Gr2].) This limiting space, called the metric tangent cone, only exists for ‘nice’ metric spaces. For a Riemannian manifold it is the usual tangent space with its Euclidean structure. The metric tangent cone also exists for subRiemannian metrics. A theorem of of Mitchell [3] asserts that at a regular point it is the nilpotentization. We urge the reader to consult Gromov [Gr2], [Gr1] and Bellaiche [Bell].

The nilpotentization is the closest object we have in subRiemannian geometry to the Euclidean tangent space in Riemannian geometry. The match is not perfect but it is the best thing we have.

### 1.1 The geodesic flow

The data of a subRiemannian geometry can be re-encoded as a fiber-quadratic non-negative form $H : T^*Q \to R$ on the cotangent bundle $T^*Q$. The kernel $\{H = 0\}$ of $H$ is the annihilator of the distribution $V$. Upon polarization $H$ becomes a bilinear non-negative form, and thus a symmetric map $g : T^*Q \to TQ$. The image of this map is $V$ and the map satisfies $\langle g(p), v \rangle_q = p(v)$ for any $p \in T^*_{q^*}q, v \in V_q, q \in Q$, where $\langle \cdot, \cdot \rangle$ is the inner product on $V$. The Hamiltonian flow associated to $H$ generates curves in the cotangent bundle whose projections to $Q$ are subRiemannian geodesics. By a subRiemannian geodesic we mean a
curve in $Q$ with the property that the length of any sufficiently short subarc of the curve equals the subRiemannian distance between the endpoints of this arc. Such curves are necessarily necessarily tangent to $V$.

To write down $H$ explicitly, pick any local orthonormal frame $\{X_1, \ldots, X_k\}$ for the distribution $V$. Now the $X_i$ can be viewed as fiber-linear functions on the cotangent bundle $T^*$ and hence their squares $X_i^2$ are fiber-quadratic functions. The Hamiltonian is:

$$H = \frac{1}{2}(X_1^2 + X_2^2 + \ldots X_k^2).$$

**Remark.** Unlike Riemannian geometry, there may be subRiemannian geodesics which are not the projections of these solutions to Hamilton’s equations in $T^*Q$. See [M1], [M2], me3, [LS]. But ‘most’ geodesics are obtained as projections of these solutions.

In view of the analogies between Riemannian and subRiemannian geometries, the question naturally arises: **Is geodesic flow on a Carnot group always integrable?** The answer is “yes” for two step nilpotent groups. (The flow on the Heisenberg group has been integrated in many places.) The purpose of this note is to provide an example of a 3 step Carnot group whose subRiemannian geodesic flow is not algebraically completely integrable. Roughly speaking, this means that there is no uniform algebraic description of its “straight lines”. We expect nonintegrability to hold for generic $r$ step nilpotent graded groups, $r > 2$.

In order to proceed we need to describe how the geodesic flow for a Lie group can be pushed down to a Hamiltonian flow on the dual of its Lie algebra. We will also need to recall the definition of “complete integrability”.

In the particular case where the subRiemannian geometry is that of a Carnot group $G$, then the frame $X_i$ for $V = V_1$ can be realized by left-invariant vector fields. We may identify the space of left-invariant vector fields with the Lie algebra. Thus $X_i \in \mathcal{G}$. Then $H$ becomes identified with a fiber-quadratic function on the dual $\mathcal{G}^*$ of the Lie algebra of $G$. We recall that the dual of any Lie-algebra has a Poisson structure, the so-called “Lie-Poisson structure”. This can be defined by insisting that

$$\{X_i, X_j\} = -[X_i, X_j]$$

where we identify elements $X_i$ of the Lie algebra $\mathcal{G}$ with linear functions on its dual $\mathcal{G}^*$. Thus $H$ induces a Hamiltonian vector-field on $\mathcal{G}^*$.

Geometrically, what we are doing by studying this Hamiltonian flow on $\mathcal{G}^*$ is studying the ‘Poisson reduction’ of the subRiemannian geodesic flow on $T^*G$. The function $H$ on $T^*G$ is left-invariant, and hence so is its subRiemannian geodesic flow. The vector field defining this flow can then be pushed down to the quotient space $(T^*G)/G$ of the cotangent bundle by the left $G$ action, thus defining the “Poisson-reduced” flow. Now $(T^*G)/G = \mathcal{G}^*$ in a natural way and when we push down the Hamiltonian vector field for $H$ we obtain the one discussed in the previous paragraph on $\mathcal{G}^*$. 
We recall the definition of completely integrable. A Hamiltonian $H$ (or its flow) on a symplectic manifold of dimension $2n$ is called completely integrable if we can find $n$ functions $f_1, \ldots, f_n$ which are almost everywhere functionally independent ($df_1 \wedge \ldots \wedge df_n \neq 0$), which Poisson-commute ($\{f_i, f_j\} = 0$), and such that $H$ can be expressed as a function of them ($H = h(f_1, \ldots, f_n)$).

If the flows of the $f_i$ are complete then their common level sets $\{f_1 = c_1, \ldots, f_n = c_n\}$ are, for typical constants $c_i$, diffeomorphic to the quotient of $\mathbb{R}^n$ by a lattice, and on each such level, the flow of $H$ is linear up in the covering space $\mathbb{R}^n$. The diffeomorphism is provided by action angle coordinate.

We are interested in whether the subRiemannian geodesic flow on $T^*G$, $G$ a Carnot group, is complete integrable. In order to proceed we will assume that if the flow ‘upstairs’ on $T^*G$ is completely integrable, then so is the flow ‘downstairs’ on $G^*$. The converse is certainly true: if the flow downstairs is integrable then the flow upstairs is integrable. (See the paper by Fomenko and Mishchenko [FM], or [A].) Our assumption is probably false in general, but we expect the exceptions to be ‘pathological’.

We need to say a few words about what we mean by “the flow downstairs being integrable”. Any Hamiltonian vector field on $G^*$ is necessarily tangent to the orbits of the co-adjoint action of $G$ on $G^*$. The Poisson structure induces a symplectic structure on these orbits, sometimes called the Kirillov-Kostant-Souriau structure. When we say that the flow on $G^*$ is ‘completely integrable’ what we mean is that the Hamiltonian flows restricted to typical co-adjoint orbits are completely integrable in the sense just described. By a typical orbit we mean one whose dimension is maximal, say $2k$. Now $2k = n - r$ where $r$ is the rank of the Lie algebra, which is the dimension of its maximal Abelian subalgebra. In any case, complete integrability on the orbit means that there are $k$ functionally independent functions $f_1, \ldots, f_k$ on the typical orbit which Poisson-commute with each other and such that $H$ can be expressed in terms of them. We assume that these functions vary smoothly with the orbit. The typical orbit is defined by the vanishing of $r$ functions $C_1, \ldots, C_r$. These functions are Casimirs: they Poisson commute with every function on $G^*$. Pulled back to $T^*G$, and set of $r$ Casimirs forms a a functional basis for the bi-invariant functions on $T^*G$. In the nilpotent case it is known that the Casimirs are rational functions (see ....). Thus: to say that the reduced system is integrable means that $H = h(f_1, \ldots, f_k; C_1, \ldots, C_r)$ for some smooth function $h$. We say it is algebraically completely integrable if the $f_i$ and $h$ are rational functions.

2 The example

Take $G$ to be the group of all 4 by 4 lower triangular matrices with 1’s on the diagonal. Its Lie algebra $\mathcal{N}_-$ is the space of all strictly lower triangular matrices:
It is generated by the three-dimensional subspace $V_1$ consisting of the subdiagonal matrices:

$$
\begin{pmatrix}
0 & 0 & 0 & 0 \\
x & 0 & 0 & 0 \\
y & 0 & 0 & 0 \\
w & v & z & 0
\end{pmatrix}.
$$

and is coordinatized by $x, y, z$. The functions $x, y, z, u, v, w$ are linear coordinates on the dual of the Lie algebra, and hence left-invariant fiber linear functions on $T^*G$. The space $V_2 = [V_1, V_1]$ is the $uv$ plane, and $V_3 = [V_1, V_2]$ is the $w$-axis. For the inner product on $V_1$ we take the standard Euclidean one so that $x, y, z$ correspond to the standard orthogonal axes. Thus the subRiemannian Hamiltonian is

$$H = \frac{1}{2}(x^2 + y^2 + z^2).$$

The Poisson structure is the standard Kirillov-Kostant structure defined by the formula:

$$\{F, G\}(x) = \langle x, [dF(x), dG(x)] \rangle.$$

It is well known that this structure is nondegenerate on the orbits of coadjoint action. Casimirs, i.e. functions invariant under the coadjoint action, are generated by $w$ and $uv - yw$, see, for example, [1].

**Theorem 1** The geodesic flow on $N^*_{-\ast}$ generated by $H$ is not algebraically completely integrable.

**Proof.** The Kirillov-Kostant-Souriau Poisson bracket is given by the relations:

$$\begin{align*}
\{z, u\} &= w \\
\{v, x\} &= w \\
\{y, x\} &= u \\
\{z, y\} &= v
\end{align*}$$

with all the other Poisson brackets of the coordinate functions equaling zero. We choose $x, z, \tilde{u} = \frac{u}{w}$ and $\tilde{v} = \frac{v}{w}$ as Darboux coordinates on generic orbit. “Generic” means that $w = w_0 \neq 0$ and $uv - yw = C \neq 0$. One easily checks that $x, z, \tilde{u}$ and $\tilde{v}$ are independent coordinates on a generic orbit and that

$$\begin{align*}
\{z, \tilde{u}\} &= 1 \\
\{\tilde{v}, x\} &= 1 \\
\{z, x\} &= \{z, \tilde{v}\} = \{x, \tilde{u}\} = \{\tilde{u}, \tilde{v}\} = 0.
\end{align*}$$
In these coordinates Hamiltonian has a form
\[ H(x, z, \tilde{u}, \tilde{v}) = x^2 + z^2 + \left( \frac{C - \mathbf{w}v}{w_0} \right)^2 \]
\[ = x^2 + z^2 + \left( \frac{C}{w_0} - \mathbf{w}_0 \mathbf{u} \mathbf{v} \right) \left( \frac{1}{\sqrt{w_0}} \right)^2. \]

Under the following linear symplectic change of coordinates
\[ x = 3\sqrt{w_0} \hat{x}, \quad z = \sqrt{w_0} \hat{z}, \quad \hat{u} = \frac{\hat{u}}{\sqrt{w_0}}, \quad \hat{v} = \frac{\hat{v}}{\sqrt{w_0}} \]
the Hamiltonian becomes
\[ w_0^{\frac{3}{2}} \left( \hat{x}^2 + \hat{z}^2 - 2C^3 \mathbf{w}_0 \hat{u} \hat{v} + \hat{u}^2 \hat{v}^2 + K \right), \]
where \( K \) is some constant depending on \( w_0 \) and \( C \) only. This Hamiltonian is proportional to a famous Yang-Mills Hamiltonian, which Ziglin proved to be rationally non-integrable. See Ziglin [Zi1], [Zi2].

\[ \blacksquare \]

3 Quantization: Extension to the Universal Enveloping Algebra

The non-integrability in rational functions of the system considered above has some purely algebraic consequences.

**Lemma 1** Let \( N^- \) be the algebra of nilpotent lower triangular \( 4 \times 4 \)-matrices and \( \text{Pol}(N^-^*) \) be the algebra of polynomials on its dual space \( N^-^* \). Let \( \{ F, H \} = 0 \), where \( H = \frac{1}{2}(x^2 + y^2 + z^2) \) and \( F \in \text{Pol}(N^-^*) \). Then \( F = P(H, w, uv - yw) \). Here \( x, y, z, u, v, w \) were defined in the previous section and \( P \) is a polynomial.

**Proof.** Taking into account the fact that the dimension of the generic orbit of the coadjoint representation in \( N^-^* \) is 4, we see that if \( F \) commuted with \( H \) but were not of the form \( P(H, w, uv - yw) \) then the system defined by \( H \) would be completely integrable. But this contradicts Theorem 1. \( \square \)

Given any function \( f \) in \( \text{Pol}(N^-^*) \) its centralizer with respect to Poisson bracket always contains the polynomials \( F(f, w, uv - yw) \). For, as mentioned earlier, \( w, uv - yw \) are the Casimirs for \( N^-^* \): they generate the center of \( \text{Pol}(N^-^*) \). Thus the lemma asserts that the centralizer of \( H \) is as small as possible.

We will finish off by proving a similar result for the universal enveloping algebra \( U(N^-) \). \( U(N^-) \) can be thought of as the algebra of left-invariant differential operators on the Lie group \( N \) of upper triangular matrices with 1’s on the diagonal (or on certain homogeneous spaces for \( N \)). It is is generated as an algebra over \( \mathbb{R} \) by \( N^- \) (the 1st order differential operators) and the unit 1 (the identity operator). Let \( E_{ij} \) be the standard unit matrix with only nonzero \((i, j)\) entry equal to 1. Set \( X = E_{21}, Y = E_{32}, Z = E_{43}, U = E_{31}, V = E_{42}, \)
W = E_{41}. Then X, Y, Z, U, V, W together with 1 generate U(N\_). Observe that this notation is consistent with that used for the elements x, y, z, u, v, w for Pol(N\_\*). Thus w is a linear function on N\_\*, which is to say an element of N\_.

Let \( \tilde{H} = \frac{1}{2} (X^2 + Y^2 + Z^2) \in U(N\_). \) It is the “quantization” of our \( H \in Pol(N\_\*) \). By a theorem of Hormander, it is a hypoelliptic differential operator which is almost as good as being elliptic. It is well-known that the center of \( U(N\_) \) is generated by \( W \) and \( UV - YW \). (See Dixmier [3].) Consequently if \( R \) is any element of \( U(N\_) \) then its commutator algebra contains the subalgebra generated by \( R, W \) and \( UV - YW \).

**Theorem 2** Any element \( F \) in \( U(N\_) \) which commutes with \( \tilde{H} \) is of the form \( F = P(\tilde{H}, W, UV - YW) \) for some polynomial \( P \).

There is no ordering problem in defining the element \( P(\tilde{H}, W, UV - YW) \) since \( W \) and \( UV - YW \) commute with everything. The theorem asserts that \( \tilde{H} \) commutes only with those elements which every operator must commute with. It suggests that \( \tilde{H} \), as an operator, should exhibit “quantum chaos”.

This theorem is a special case of a result which holds for any finite-dimensional Lie algebra \( G \). The result may be well-known to experts but we will present it here in any case.

Let \( U(G) \) be the universal enveloping algebra of the finite-dimensional Lie algebra \( G \), \( Z(G) \subset U(G) \) its center. \( U(G) \) is filtered by degree. An element is said to have degree less than or equal to \( k \) if it is a sum of monomials of the form \( X_1X_2 \ldots X_s \) with \( X_i \in G \) and \( s \leq k \). If \( s = k \) for one of these monomial terms then its degree equals \( k \). The corresponding graded algebra \( Gr(U(G)) \) is canonically isomorphic to the algebra \( Pol(G^*) \) of polynomials on \( G^* \). The operator bracket respects the filtration so that it induces a Lie bracket on \( Pol(G^*) \). This is of course the KKS Poisson-bracket \{ \cdot , \cdot \} on \( G^* \).

Let \( U(G)_k \) denote the subspace of elements of degree \( k \) or less. The quotient map \( \sigma_k : U(G)_k \to U(G)_{k}/U(G)_{k-1} \cong Pol(G^*)_k \) takes elements of degree \( k \) to homogeneous polynomials of degree \( k \). If an element \( \tilde{F} \in U(G) \) has degree \( k \) then we call \( \sigma_k(\tilde{F}) \) its principal symbol. If two elements in \( U(G) \) commute then their principal symbols must Poisson-commute in \( Pol(G^*) \). This follows directly from the relation between the operator and Poisson brackets.

There is a symmetrization map \( \phi : Pol(G^*) \to U(G) \) which is a kind of inverse to the symbol maps. It is a linear isomorphism but of course not an algebra homomorphism. When restricted to the subspace of homogeneous polynomials of degree \( k \) it satisfies \( \sigma_k \circ \phi = Id \).

The center \( Z(G) \) of \( U(G) \) is finitely generated by elements \( \tilde{f}_1, \ldots, \tilde{f}_r \). These elements may be chosen so that their principal symbols \( f_1, \ldots, f_r \) generate the the center of \( Pol(G) \) and so that \( \tilde{f}_i = \phi(f_i) \). (See Dixmier, or Varadarajan [4], Thm. 3.3.8, p. 183.) Elements of either center are called Casimirs. (If \( G \) is semi-simple then the number \( r \) of Casimirs is the rank of the Lie algebra.)
Proposition 1  Let $\tilde{H}$ be an element of $U(G)$ of degree $m$ and $H = \phi_m(\tilde{H})$ its principal symbol. Suppose that the commutator algebra of $H$ in $\text{Pol}(G^*)$ is generated by the Casimirs $f_1, \ldots, f_r$ together with $H$. Then the commutator algebra of $\tilde{H}$ in $U(G)$ is generated by the Casimirs $\tilde{f}_1, \ldots, \tilde{f}_m$ together with $\tilde{H}$.

In other words, if the commutator of the principal symbol is as small as possible, the same is true for its quantization $\tilde{H}$.

Proof. Suppose $\tilde{F}$ commute with $\tilde{H}$. Let $k$ denote the degree of $\tilde{F}$ and set $F = \sigma_k(\tilde{F})$. As discussed above, $F$ Poisson-commutes with $H$. By hypothesis $F = p(f_1, \ldots, f_r, H)$ for some polynomial $p$. Since the $\tilde{f}_i$ are in the center of $U(G)$, the element $\tilde{p} = p(\tilde{f}_1, \ldots, \tilde{f}_r, H)$ is a well-defined element of $U(G)$, independent of the ordering of the factors $\tilde{f}_i, H$. Clearly $\tilde{p}$ commutes with $H$. Moreover $\sigma_k(\tilde{p}) = F$ so that $\sigma_k(\tilde{F} - \tilde{p}) = 0$. It follows that $\tilde{F} - \tilde{p} = \tilde{F}_2$ is an element whose degree is $k - 1$ or less which commutes with $H$.

Repeating this argument with $\tilde{F}_2$ in place of $\tilde{F}$ we obtain a polynomial $p_2$ in $f_1, \ldots, f_r, H$ and a corresponding element $\tilde{p}_2$ in $U(G)$ such that $\tilde{F} - (\tilde{p} + \tilde{p}_2)$ commutes with $H$ and has degree $k - 2$ or less. Continuing in this fashion we eventually descend to degree 0, in which case:

$$\tilde{F} = \tilde{p} + \tilde{p}_2 + \ldots + \tilde{p}_{k-1}$$

is a polynomial in the $\tilde{f}_i, H$ as claimed. QED
