Abstract: Vegetation encroachment along electric power transmission lines is one of the major environmental challenges that can cause power interruption. Many technologies have been used to detect vegetation encroachment, such as light detection and ranging (LiDAR), synthetic aperture radar (SAR), and airborne photogrammetry. These methods are very effective in detecting vegetation encroachment. However, they are expensive with regard to the coverage area. Alternatively, satellite imagery can cover a wide area at a relatively lower cost. In this paper, we describe the statistical moments of the color spaces and the textural features of the satellite imagery to identify the most effective features that can increase the vegetation density classification accuracy of the support vector machine (SVM) algorithm. This method aims to distinguish between high- and low-density vegetation regions along the power line corridor right-of-way (ROW). The results of the study showed that the statistical moments of the color spaces contribute positively to the classification accuracy while some of the gray level co-occurrence matrix (GLCM) features contribute negatively to the classification accuracy. Therefore, a combination of the most effective features was used to achieve a recall accuracy of 98.272%.

Keywords: satellite images; SVM; vegetation encroachment; transmission lines

1. Introduction

The process of delivering electrical power to end users involves three main steps: generation, transmission, and distribution. The power transmission line is the backbone infrastructure of the transmission process. There are many environmental factors that can pose a risk to the transmission process, such as forest fires, wind storms, and vegetation encroachment [1–3]. Vegetation encroachment is a major challenge that is faced in the installation, operation, and maintenance processes of transmission lines in areas with high-density vegetation. The overgrowth of trees can cause flashovers when there is contact between tree branches and transmission lines, as illustrated in Figure 1. In Malaysia, more than 60% of the country is forested terrain, where, in the state of Sarawak, approximately from 2005–2008, 17.58% of power interruptions were due to vegetation encroachment [4].

There are many different methods available for monitoring vegetation encroachment. Patrol inspection is one of the traditional monitoring techniques, where a team of inspectors visits the area of possible risk periodically [5]. This technique is time-consuming and needs to be conducted by a large group of inspectors. Other monitoring methods use advanced optical remote sensing technologies such as light detection and ranging (LiDAR) data, synthetic aperture radar (SAR) data, and airborne photogrammetry, which can be very effective for remote areas [5]. Despite their effectiveness, the data acquisition process is very expensive with respect to the coverage area. To overcome the high-cost limitation,
high-resolution satellite images can be used to provide wide geographic coverage at relatively low cost [6–8]. Generally, satellites are equipped with various types of onboard sensors that can observe a wide range of the electromagnetic wave spectrum. However, the price of satellite images increases with respect to the image resolution and the available multispectral bands.

Figure 1. Low- and high-density vegetation encroachment on the power line corridor right-of-way (ROW).

Many works have studied the feasibility of using satellite images for monitoring vegetation encroachment. These studies can be categorized into two main groups. The first group used the vegetation index methods to detect the vegetation activity along the power line right-of-way (ROW) such as the normalized difference vegetation index (NDVI), enhanced vegetation index (EVI), and atmospherically resistance vegetation index (ARVI) [9]. Most of the previous studies focused on using the NDVI for the vegetation detection process [9,10]. The basic concept behind the NDVI is the natural ability of green plants to absorb the red light band and reflect the near-infrared (NIR) and green bands, where the normalized difference between the red band and the NIR band represents the NDVI [11–13]. Figure 2 shows the electromagnetic reflectance from the Earth’s surface of different natural elements. Vegetation index methods can detect plants with different densities based on the vegetation index calculation. However, this type of detection depends on the availability of multispectral satellite data for the target location.

The second group used the stereo satellite images to create a digital elevation model (DEM) map. The DEM method uses more than one satellite image with different observation perspectives [14,15]. This method has the advantage of estimating the heights of objects around the transmission line corridor area. However, the lack of available stereo image data of suitable resolution can pose a limitation of using this method.

The visible light band of high-resolution satellite images can be a low-cost alternative to the previous methods as well as being widely and freely accessible by a many satellite imagery platforms such as Google Maps, Google Earth, and ESRI Imagery. In this paper, we describe the feasibility of using the visible light band spectrum and the texture properties of satellite images to classify the vegetation regions besides the power line ROW using the support vector machine (SVM) algorithm.
2. Materials and Methods

In this section, we will discuss the proposed vegetation encroachment detection process as shown in Figure 3. The overall process has two steps: training and testing. The training step consists of four processes: manual patch extraction and labeling, automatic feature extraction, SVM training, and weight storing. While the testing step has three processes: automatic patch extraction, automatic feature extraction, and class prediction.

2.1. Dataset Preparation

Multispectral satellite images contain several electromagnetic bands. The visible light band can be found in most satellite images. The availability of the visible light band facilitates the process of data collection from different satellite image sources. In this work, the collected dataset was pre-corrected geometrically, radiometrically, and atmospherically.

The training data were manually collected from different satellite image sources including Google Maps, Google Earth, and ESRI Imagery. The collected satellite images had different resolutions and scales. The reason for collecting data from different sources is to understand the behavior of the extracted features under different conditions which can contribute to finding a general vegetation density classification solution. There was a total...
of 12,344 training samples gathered. Each sample had a 32 × 32 pixels patch in which 6172 of samples contained high-density vegetation regions and the rest of the samples contained low-density vegetation regions. The dataset was divided into an 80%, 20% ratio where 80% of the dataset was used for training and 20% for testing.

2.2. Feature Extraction

The process of analyzing and selecting features from satellite images datasets is a challenging task. A study by Berberoğlu et al. [17] assessed the incorporation of spatial and spectral features. The study used the variogram texture feature which was extracted from the gray level co-occurrence matrix (GLCM) on six bands of Landsat TM satellite imagery to classify the land-cover areas. A study by Li et al. [18] used a combination of vegetation index features and image texture features to identify vegetation regions. The texture features included the GLCM features and the local binary pattern (LBP) feature. On the other hand, the vegetation index features included the NDVI, radio vegetation index (RVI), and perpendicular vegetation index (PVI). The authors used the SVM algorithm for the classification process and the study concluded that the mean value of the NDVI represents the most effective feature. Additionally, a similar study by Iovan et al. [19] extracted the GLCM texture features from three color spaces: hue saturation and value (HSV) color space, XYZ color space, and the CIELAB color space, for two types of images: the first type was the high-resolution color infrared (CIR) and the second the digital surface model image. The study concluded that the GLCM features which were extracted from the HSV color space achieved the best classification accuracy of 95.84%. However, multispectral satellite data can increase the cost of the monitoring process. Based on the previous works on vegetation detection from satellite images, we divided the input features into two categories: color-based features and textural-based features. The color features consist of the statistical moments of three types of color spaces, which are: the RGB color space, the HSV color space, and the CIELAB color space, where the color space is the mathematical representation of colors in different dimensions [20]. In contrast, the textural-based features consist of the GLCM features, which are: homogeneity, energy, contrast, dissimilarity, correlation, and angular second moment. The statistical moments were calculated after flattening the patch image into a one-dimensional vector shape. The statistical moments are described in (1) to (6) [21,22].

\[
\begin{align*}
\mu &= \frac{\sum_{i=0}^{N-1} p_i}{N} \\
\sigma^2 &= \frac{\sum_{i=0}^{N} (p_i - \mu)^2}{N} \\
\sigma &= \sqrt{\sigma^2} \\
\mu_k &= \sum_{i=0}^{N-1} (p_i - \mu)^k \\
\tilde{\mu}_3 &= \frac{\mu_3}{\sigma^3} \\
Kurt[p_i] &= \frac{\mu_4}{\sigma^4}
\end{align*}
\]

where \(\mu, \sigma, \sigma^2, \tilde{\mu}_3,\) and \(Kurt\) are the mean, standard deviation, variance, skewness, and kurtosis moments, respectively. \(N\) is the vector length and \(p_i\) is the vector element. The textural features have properties that are not affected by the color values. The GLCM describes the frequent occurrence of values in a specific direction as illustrated in Figure 4. This method gives an impression of the relationship between neighboring pixel values [23]. In this work, we extracted the GLCM at a fixed angle of zero degrees. The GLCM features are the features which were extracted from the GLCM map. In this work, the extracted GLCM features are described in (7) to (12) [23,24]. Figures 5 and 6 show the boxplot analysis of the statistical moments of the color spaces and the texture features. The boxplots (b), (e),
and (f) in Figure 6 which are the contrast dissimilarity and correlation, respectively, show indistinct differences in the range of values between high- and low-density classes.

\[
\text{contrast} = \sum_{i,j=0}^{N-1} p_{ij} (i - j)^2
\]

\[
\text{energy} = \sum_{i,j=0}^{N-1} p_{ij}^2
\]

\[
\text{homogeneity} = \frac{\sum_{i,j=0}^{N-1} p_{ij}}{1 + (i - j)^2}
\]

\[
\text{correlation} = \sum_{i,j=0}^{N-1} p_{ij} \left| \frac{(i - \mu_i)(j - \mu_j)}{\sqrt{\sigma_i^2 \sigma_j^2}} \right|
\]

\[
\text{angular second moment} = \sum_{i} \sum_{j} (p_{ij})^2
\]

\[
\text{dissimilarity} = \sum_{i,j=0}^{N-1} p_{ij} |i - j|
\]

In addition to the GLCM features, the LBP feature was also used as an additional textural feature. The LBP is used in many applications such as face recognition and texture analysis [25,26]. The basic concept of the LBP is to convert the gray level image into a set of labels. The labels are constructed by creating a binary image by taking the threshold value from a center pixel point against a set of neighboring pixels, usually 3 x 3 pixels, then converting the binary values into a decimal gray level representation [25]. Figure 7 shows the conversion steps of the LBP image.
Figure 5. Comparison of high- and low-density vegetation patches for color space statistical moments where (a–c) are the mean values of the color spaces, (d–f) are the standard deviations of the color spaces, (g–i) are the variances of the color spaces, and (j,k) are the skew and kurtosis of the RGB color space.
Figure 6. Comparison of the high- and low-density vegetation patches for GLCM texture features where (a) is the homogeneity, (b) is the contrast, (c) is the angular second moment (ASM), (d) is the energy, (e) is the dissimilarity, (f) is the correlation, and (g) is the LBP.

In addition to the GLCM features, the LBP feature was also used as an additional textural feature. The LBP is used in many applications such as face recognition and texture...
Local binary pattern (LBP) conversion process where (a) is the RGB satellite image, (b) is the gray level image, and (c) is the LBP image.

The LBP labeled image contains a two-dimensional integer matrix which can be impractical for use as a feature, while the rest of the features have a scalar representation. As an abstraction, we used the sum of all binary values as a single scalar value to represent the LBP feature. This feature can be described as the sum of the LBP.

2.3. SVM Training

The SVM [27,28] has been used in a wide range of applications. The problems that the SVM algorithm can solve are related to statistical problems such as regression and classification problems. Figure 8 represents a simple linear classification problem where there are two features and two classes that are annotated with blue and red, respectively. The output of the SVM classifier is one of the labeled classes. The process of training the SVM model involves finding the optimal slope of the hyperplane and the largest possible margin that can separate the data with respect to the number of classes, as shown in Figure 8. The hyperplane equation can be described as in (13) where $\omega$ determines the slope of the plane, $b$ is the bias value, and $x$ is the input feature vector. The optimal margin width can be determined by the nearest data points from the hyperplane which are called the support vectors, as shown in Figure 8. The purpose of the margin function is to predict the output class for every new data point, as in (14) where $\hat{y}$ is the predicted class.

\begin{align}
\omega^T x + b &= 0 \\
\hat{y} &= \begin{cases} 0, & \text{if } \omega^T x + b < 0 \\
1, & \text{if } \omega^T x + b \geq 0 \end{cases}
\end{align}

Figure 7. Local binary pattern (LBP) conversion process where (a) is the RGB satellite image, (b) is the gray level image, and (c) is the LBP image.

Figure 8. Two-dimensional support vector machine (SVM).
The ability of machine learning algorithms to learn corresponds to the ability of minimizing the error loss. In the SVM, the process of maximizing the margin is proportional to minimizing error loss. There are two types of margins: soft and hard. The hard margin is the optimal case where no data points are allowed inside the margin. On the other hand, the soft margin allows a few margin violations, which provides more dynamic classification to avoid overfitting. The number of points that can violate the margin can be regulated by a margin error cost $c$ parameter where a larger $c$ value means fewer margin violations. However, not all classification problems can be solved using linear models. A kernelized SVM version can be used to transform the classification problems into higher dimensions, resulting in non-linear transformations. The SVM algorithm has several kernels for solving different types of classification complexity. Equations (15)–(18) show the SVM kernels used in this study, which are: linear, Gaussian radial basis function (RBF), polynomial kernels, and sigmoid [27,28].

\[
\text{linear} = k(x, x_i) = (x)^T . (x_i) \tag{15}
\]

\[
\text{Gaussian RBF} = k(x, x_i) = \exp \left( -\gamma \|x - x_i\|^2 \right) \tag{16}
\]

\[
\text{polynomial} = k(x, x_i) = \left( \gamma x^T . x_i + r \right)^d \tag{17}
\]

\[
\text{sigmoid} = k(x, x_i) = \tanh \left( \gamma x^T . x_i + r \right) \tag{18}
\]

\[
\text{standard value} = \frac{(x_i - \text{mean})}{\text{STD}} \tag{19}
\]

The symbol $(x, x_i)$ is the data elements, $\gamma$ is a parameter, $d$ is the polynomial order, and $r$ is a constant. The input feature vector was scaled using (19) to enhance the fitting process. Parameter optimization algorithms can be used to set the optimal values of the kernel parameters and the error cost parameter in order to achieve the best performance. In this work, the grid search algorithm [29] has been used to optimize the parameters of four SVM kernels and the corresponding margin error cost parameter for every kernel, as shown in Table 1. The grid search algorithm has two steps, firstly, a grid of parameters values is proposed by the user, and secondly, the grid search algorithm uses the k-fold cross-validation technique to evaluate the performance of all the possible parameter combinations. The best cross-validation performance achieved by the RBF kernel is shown in Table 1. Figure 9 represents the training metrics of the SVM algorithm with the optimized Gaussian RBF kernel. Despite the large value of the error cost parameter, the cross-validation curve proves that there is no overfitting as the testing results are very close to the training results.

| Parameter | C   | $\gamma$ | $r$ | $d$ | Cross-Validation Accuracy |
|-----------|-----|----------|-----|-----|--------------------------|
| Kernel    |     |          |     |     |                          |
| Linear    | 10  | -        | -   | -   | 0.96421                  |
| RBF       | 100 | 0.01     | -   | -   | 0.98274                  |
| Polynomial| 1000| 0.01     | 1   | 2   | 0.98003                  |
| Sigmoid   | 1000| -        | 0   | -   | 0.866830                 |
Figure 9. Training metrics of the optimized SVM classifier with a radial basis function (RBF) kernel.

Additionally, Figure 9 describes the scalability and the performance of the trained SVM model. The scalability curve measures the ability of the trained model to be scaled using many workstations to deal with a large amount of input data without losing the classification performance. The recall accuracy can be described as the number of total true positive labels $TP$ over the sum of the total true positive labels and false negative $FN$ labels, as shown in (20) [30].

$$\text{recall} = \frac{TP}{TP + FN}$$  \hspace{1cm} (20)

2.4. Automatic Patch Extraction

The input image was divided into $n \times n$-pixels patches where the total number of patches $N$ represents the total segments.

$$N = \left\lfloor \left( \frac{w}{n + s} \right)^2 \right\rfloor$$ \hspace{1cm} (21)

$$N = \left\lfloor \left( \frac{w}{n + s} \right) + \left( \frac{h}{n + s} \right) \right\rfloor$$ \hspace{1cm} (22)

If the input image has a square shape, the width $w$ and the height $h$ are equal. The total number of patches $N$ can be calculated as in (21). The offset between patches $s$ controls the density of the patches as shown in Figure 10. If the input image is not square, then the number of patches $N$ can be described as in (22).

Figure 10. The process of patch creation where $n$ is the patch width and height, $w$ is the image width, $h$ is the image height, and $s$ is the step between patches.

The process of dividing the image into small patches aims to reduce the processing time. However, the detection time is proportional to the number of sliced patch images, where more images require more execution time. Table 2 shows the relation between patch size, image slicing time, and classification time in seconds. However, the patch should...
have a reasonable size, for example, a patch size of $4 \times 4$ pixels cannot be used due to the poor-quality extracted values. Figure A1 shows an example of vegetation encroachment detection with different patch sizes.

Table 2. SVM kernel parameter optimization.

| Patch Size (Pixel) | Feature Extraction + Classification Time (s) | Total Detection Time (s) |
|-------------------|---------------------------------------------|--------------------------|
| $128 \times 128$  | 9.429314                                    | 9.872241                 |
| $64 \times 64$    | 12.76653                                    | 13.58487                 |
| $32 \times 32$    | 18.02610                                    | 20.44133                 |
| $16 \times 16$    | 111.42492                                   | 193.7228                 |

3. Results

In this section, we will discuss the performance when using different feature configurations and the corresponding detection results.

After training the SVM model, the model was tested on a new subset of data and Figure 11 shows the SVM testing confusion matrix. The trained SVM model achieved a testing recall classification accuracy of 98.55% for the low-density vegetation class and 98.78% for the high-density vegetation class. Figure 12 shows the SVM receiver operating characteristic (ROC) curve of the support vector classifier (SVC), where AUC represents the area under the curve. As illustrated previously in Figures 5 and 6, there were some features that did not have any apparent difference in range between high- and low-density vegetation patches. These features can affect the classification accuracy. Table 3 shows the cross-validation performance of different feature configurations.

Figure 11. SVM testing confusion matrix (RBF kernel).
As observed from Table 3, some features are essential to increase the classification accuracy, such as the RGB statistical moments and the HSV statistical moments. However, not all the GLCM features are effective.

We selected only the most effective GLCM features, which were: homogeneity, ASM, and energy. In addition, we used the LBP as we observed an enhancement in the cross-validation recall accuracy when we used the LBP feature with the GLCM features, as shown in Table 3. The selected features represent the total effective features, which were: the statistical moments of the RGB color space, the statistical moments of the HSV color space, homogeneity, ASM, energy, and the LBP. Figure 13 shows an example of the proposed vegetation density classification result around the power line corridor ROW, where the green regions represent the low-density vegetation patches and the red regions represent the high-density vegetation patches. The recall accuracy of the SVM classifier was compared to other machine learning classifiers, which were: tree, random forest, k-nearest neighbor
(KNN) and naïve Bayes, as shown in Figure 14. All the machine learning classifiers were optimized and evaluated with the best performance against the SVM (RBF kernel), where the SVM classifier scored the best recall accuracy of 98.274%.

Figure 13. Examples of the vegetation density classification results along the power line corridor area with a patch size of 32 × 32-pixels and step size of s = 4. The red regions represent high-density vegetation and the green regions represent low-density vegetation.

Despite the effectiveness of the visible light band on the vegetation density classification accuracy, the topography of the land plays a major role in deviating the reflected electromagnetic wave from the Earth’s surface. A heterogeneous surface affects the anisotropy of the reflected electromagnetic solar irradiance due to the diffusion between the terrain slopes, which can provide a deviated pixel value [31]. However, this effect can be analyzed at the macro- and micro-level using different methods. The diffused equivalent slope model (dESM) is one of the proposed solutions to simulate and analyze the effect of the micro-slope on the anisotropy reflectance under different illumination conditions, which can help to evaluate the level of pixel value deviation [32].
Figure 14. Recall accuracy comparison between SVM (RBF kernel) and other optimized machine learning classifiers.

4. Conclusions

In this paper, we discussed the effect of using color and texture features to classify the vegetation density along the power line corridor ROW from the visible light band of high-resolution satellite images into two classes of high- and low-density vegetation. We proposed to use only the most effective features by analyzing the behavior of both color and texture features. The results showed that there were some features that reduced the classification accuracy, which were: the CIELAB statistical moments, correlation, dissimilarity, and contrast. The proposed feature configurations gave the best result among the other configurations, where the recall classification accuracy was 98.272% using the SVM RBF kernel. The results emphasize the possibility of using satellite images with the visible light band only to detect the vegetation encroachment along the power line ROW. The limitation of the study was the inability to identify tree heights around the power line corridor.
