Abstract

Lysosomal storage disorders (LSDs) are caused by defective enzyme activities in lysosomes, characterized by the accumulation of glycolipids, oligosaccharides, mucopolysaccharides, sphingolipids, and other biological substances. Accumulating evidence has suggested that early detection of individuals with LSDs, followed by the immediate initiation of appropriate therapy during the presymptomatic period, usually results in better therapeutic outcomes. The activities of individual enzymes are measured using fluorescent substrates. However, the simultaneous determination of multiple enzyme activities has been awaited in neonatal screening of LSDs because the prevalence of individual LSDs is rare. In this study, the activities of six enzymes associated with LSDs were examined with 6-plex enzyme assay using liquid chromatography-tandem mass spectrometry (LC-MS/MS). The accumulation of enzyme products was almost linear for 0–20 h at 37 °C. Dried blood spots (DBSs) provided by the Centers for Disease Control and Prevention (CDC) were used for quality control (QC). The intraday and interday coefficient of variance values were <25%. The enzyme activities of healthy individuals were higher than those of LSD-confirmed individuals. These results suggest that the levels of enzyme activities of six LSDs in a Japanese population were comparable to those of a recent report [Elliott et al. Mol Genet Metab 118 (2016) 304–309], providing additional evidence that the 6-plex LSD enzyme assay is a reproducible analytical procedure for neonatal screening.

1. Introduction

Lysosomal storage disorders (LSDs) are a group of congenital metabolic disorders caused by the accumulation of glycolipids, oligosaccharides, mucopolysaccharides, sphingolipids, and other biological substances induced by the defective activity of lysosomal enzymes [1–2]. Lysosomal enzymes are found in nearly all mammalian cells. Thus, lysosomal enzyme deficiency can lead to systemic manifestations of LSD symptoms. As regards therapy, a prior study demonstrated the efficacy of hematopoietic stem cell transplantation [5]. In this therapy, the wild-type enzyme in the transplanted hematopoietic cells is delivered to affected cells via a mechanism called cross-correction [4]. Enzyme replacement therapy plays an important role in the treatment of several LSDs, such as Pompe, Fabry, and Gaucher disease and mucopolysaccharidosis (MPS) I, II, and VI [5]. Substrate reduction therapy is also used to treat Gaucher disease [6].

Neonatal screening of six LSDs involving Pompe, Fabry, MPS I, Gaucher, Krabbe, and Niemann–Pick disease type A/B has attracted much attention [7]. Pompe disease is associated with defective α-glucosidase (GAA) activity, leading to muscle weakness [8]. Fabry disease is an X-linked disorder caused by a deficiency of α-galactosidase A (GLA), resulting in the accumulation of glycosphingolipids in biological fluids and tissues [9]. MPS I is linked to a deficiency of α-L-iduronidase (IDUA) [9]. There are three disease subtypes based on the phenotype: Hurler (severe), Hurler–Scheie (intermediate), and Scheie (mild) [10]. Gaucher disease is characterized by an accumulation of galactosylceramide due to a glucocerebrosidase (ABG) defect [11]. There are three disease subtypes based on the phenotype: Gaucher (mild), type I and II [11]. Gaucher disease leads to severe neurological manifestations and is linked to a galactosylceramidase (GALC) deficiency [11]. Currently, hematopoietic cell transplant therapy is used to treat Krabbe disease [3]. Niemann–Pick disease type A/B is caused by a deficiency of acid sphingomyelinase (ASM) [12]. Enzyme replacement therapy for the disease is currently under development (ClinicalTrials.gov: NCT017225256) [12].

To identify individuals with LSDs during the presymptomatic period, neonatal screening for LSDs has been performed [13–15]. In addition to neonatal screening, increasing evidence indicates that liquid chromatography-tandem mass spectrometry (LC-MS/MS)-based technology may be superior to previously performed assays for LSDs (Reviewed in [7]). Furthermore, accumulating evidence...
suggests that the MS/MS-based method seems to be feasible for neonatal screening [16–20]. In this study, we examined the ability of LC-MS/MS to detect 6-plex LSD enzyme activity and applied the methodology to random Japanese neonates.

2. Experimental procedure

2.1. Reagents

The substrates and internal standards for GAA, GLA, IDUA, ABG, ASM, and GALC were purchased from PerkinElmer (Waltham, MA). Acetonitrile and methanol were purchased from Fischer Scientific (Tokyo, Japan). Isopropanol was purchased from Wako Pure Chemicals (Tokyo, Japan). Deionized water was obtained through a Milli-Q water system from Millipore (Milford, MA). Formic acid was purchased from Kanto Chemical (Tokyo, Japan). The other reagents used in this study were of the highest grade commercially available.

2.2. Approval by institutional research ethics board

This study was approved by the Research Ethics Board of the National Center for Child Health and Development.

2.3. Dried blood spot (DBS) specimens for quality control (QC)

The DBSs for QC were kindly provided by Dr. Hui Zhou at the Newborn Screening and Molecular Biology Branch, Centers for Disease Control and Prevention (CDC) (Atlanta, GA) [21].

2.4. Determination of enzyme activities of six LSDs by LC-MS/MS

The preparation and analysis of the enzyme activities of the six LSDs by LC-MS/MS has been previously reported [22]. In brief, the enzymes were extracted from the DBSs (3 mm in diameter) using a punch and reacted with substrate in a buffer (30 μL) for 20 h at 37 °C in a 96-well plate. The concentrations of the substrates and internal standards were as follows: GAA, 0.35 mM; GLA, 1.2 mM; IDUA, 0.25 mM; ABG, 0.5 mM; ASM, 0.75 mM; and GALC, 0.85 mM. To terminate the reaction, a mixture of ethyl acetate/methanol (50/50, 100 μL) was added. This reaction mixture was then transferred to a 96-well deep plate, and ethyl acetate (400 μL) and water (200 μL) were added. After mixing and centrifugation, the supernatant (75 μL) was transferred to a 96-well shallow plate. This organic solution was then dried under an N2 stream, reconstituted with the supernatant (75 μL) for 20 h at 37 °C in a 96-well plate. The concentrations of the substrates and internal standards were as follows: GAA, 0.35 mM; GLA, 1.2 mM; IDUA, 0.25 mM; ABG, 0.5 mM; ASM, 0.75 mM; and GALC, 0.85 mM. To terminate the reaction, a mixture of ethyl acetate/methanol (50/50, 100 μL) was added. This reaction mixture was then transferred to a 96-well deep plate, and ethyl acetate (400 μL) and water (200 μL) were added. After mixing and centrifugation, the supernatant (75 μL) was transferred to a 96-well shallow plate. This organic solution was then dried under an N2 stream, reconstituted with the mobile phase (150 μL, H2O/CH3CN/formic acid in a 20/80/0.002 ratio), and analyzed using an LC-MS/MS with a Quattro Premier mass spectrometer and an ACQUITY ultra-high performance liquid chromatograph (Waters, Milford, MA). The activity of each enzyme was determined by the accumulation of the reaction product using the Chromolith column and found these were similar in 24 different wells in the plate were examined. Overall, the enzyme activities do not depend on the position in a 96-well plate, the enzyme activities each measured enzyme activity derived from a single adult donor is within the acceptable level in clinical laboratory medicine. The intra- and interday coefficient of variation values for the high and middle rates (a correlation of the activity of the GAA enzyme using LC-MS/MS and fluorometric methods.

3. Results

The LSD assay was validated in terms of (1) chromatographic separation of the enzyme reaction products using several commercially available reversed-phase columns, (2) QC validation using CDC-provided QC DBSs, (3) analysis of the enzyme activity in random neonates and LSD-confirmed individuals in a Japanese population, and (4) correlation of the activity of the GAA enzyme using LC-MS/MS and fluorometric methods.

3.1. Chromatographic separation

First, the chromatographic separation of the reaction products of the 6-plex LSD assay system was examined. Three commercially available analytical columns were tested: a silica-based conventional BEH C18 column (Waters) that is widely available worldwide and two silica-based monolith columns compatible with higher flow rates (a Chromolith RP-2 column [Merck-Millipore] and a MonoTower C18 column [GL Sciences]). Overall, the chromatographic properties of the three columns were almost the same. A BEH C18 column was used in a subsequent study of this assay due to its commercial availability, as the enzyme reaction products of GAA, GLA, IDUA, ABG, ASM, and GALC were readily detected under the analytical conditions tested (Fig. 1A). The peaks of the enzyme reaction products, indicated by arrows in Fig. 1A, were baseline separated from the corresponding in-source degraded compounds of the substrates of GAA, GLA, ABG, ASM, and GALC, leading to minimal inaccuracy in the measurement of the enzyme reaction products. The other two columns showed similar chromatographic behavior. The only difference in separation among the three columns was that the peak of substrate and internal standard for GALC migrated before those for ABG in the MonoTower C18 column (Supplementary Table 4). The accumulation of the enzyme reaction products of the six enzymes was almost linear over 20 h at 37 °C (Fig. 1B).

3.2. Validation of the assay using CDC-provided QC DBSs

Second, the 6-plex LSD assay was validated using QC DBSs provided by the CDC [21]. For this purpose, the enzyme activities of the six LSDs were determined in high/middle/low/baseline QC DBSs containing 100, 50, 5, and 0% control enzyme activity, respectively. As shown in Fig. 2A, the linear correlation between the measured enzyme activity and nominal enzyme content in the QC DBSs was acceptable. Notably, we regularly obtained a good linear correlation (i.e. R2 > 0.95), which is within the acceptable level in clinical laboratory medicine. The intraday and interday coefficient of variation values for the high and middle CDC-provided QC DBSs were within 25% when assessed using the BEH C18 column (Table 1). On average, the activity of the enzymes in the CDC-provided QC DBSs by our measurement was 15.3 μmol/h/L for GAA (92% of the reported enzyme activity in CDC analytical information), 9.9 μmol/h/L for GLA (105%), 5.8 μmol/h/L for IDUA (43%), 8.4 μmol/h/L for ABG (74%), 1.7 μmol/h/L for ASM (56%), and 4.6 μmol/h/L for GALC (86%), respectively (n = 6). To ensure that the each measured enzyme activity derived from a single adult donor does not depend on the position in a 96-well plate, the enzyme activities in 24 different wells in the plate were examined. Overall, the difference in enzyme activities of the six LSDs from mean value was within 20% (Supplementary Fig. 1). The linearity of enzyme activity in the QC DBSs and intraday and interday coefficient variation values were also measured using the Chromolith column and found these were similar (data not shown; see Supplementary Table 5).
Fig. 1. Formation of reaction products of the 6-plex enzyme assay. (A) Representative chromatograms of the reaction products of six LSD enzymes. A BEH C18 column (2 × 100 mm) was used. The arrows indicate the product of the enzyme reaction. P, product. (B) Time-dependent accumulation of enzyme reaction products of the LSD assay. The concentrations of the enzyme reaction products were determined at 0, 4 or 20 h of incubation at 37 °C. Details of the method are provided in the Experimental procedure section.
Fig. 2. Enzyme activity of six LSDs in CDC-provided QC DBSs and clinical samples. (A) Calibration curves of the enzyme activities of the six LSD enzymes using CDC QC DBSs. The levels of the enzymes in the high, middle, low, and baseline QC DBSs were 100, 50, 5, and 0% of whole blood, respectively. The enzyme activities were determined after 20 h of incubation at 37 °C, as described in the Experimental Procedure section. (B) The levels of the activities of the six LSD enzymes in Japanese neonatal DBSs determined by LC-MS/MS (n = 210). The number of LSD-conferred enzyme activity was as follows: GAA (n = 3), GLA (n = 2), IDUA (n = 5), and ABG (n = 1). Similarly, we analyzed enzyme activity for 6 LSDs in five filter papers for blank.
Table 1

| CDC QC                  | Intraday CV (%) | Interday CV (%) |
|-------------------------|-----------------|-----------------|
|                         | GAA      | GLA    | IDUA   | ABG     | ASM     | GALK    | GAA      | GLA    | IDUA   | ABG     | ASM     | GALK    |

3.3. Examination of enzyme activities in clinical samples

Third, the enzyme activity of random neonates in a Japanese population was determined. As shown in Fig. 2B, the levels of enzyme activity for blank detected in filter paper samples were low. The detected enzyme activity in the blank samples was as follows: GAA, 0.011 ± 0.014 (min, 0.003; max, 0.037; median, 0.005); GLA, 0.010 ± 0.011 (min, 0.005; max, 0.029; median, 0.004); IDUA, 0.085 ± 0.028 (min, 0.053; max, 0.112; median, 0.090); ABG, 0.015 ± 0.018 (min, 0.003; max, 0.042; median, 0.004); ASM, 0.005 ± 0.006 (min, 0.001; max, 0.015; median, 0.002); and GALC, 0.005 ± 0.004 (min, 0.001; max, 0.012; median, 0.004) (mean ± SD, n = 5). The enzyme activity of random neonates in a Japanese population was as follows: GAA, 24.1 ± 12.5 (min, 2.9; max, 81.4; median, 21.3); GLA, 8.3 ± 3.3 (min, 3.3; max, 27.4; median, 7.7); IDUA, 5.6 ± 2.2 (min, 2.3; max, 22.8; median, 5.1); ABG, 13.0 ± 5.1 (min, 4.0; max, 29.5; median, 11.8); ASM, 4.5 ± 1.4 (min, 2.0; max, 9.3; median, 4.3); and GALC, 3.5 ± 1.4 (min, 0.9; max, 12.9; median, 3.4) (mean ± SD, n = 210) (Fig. 2B). The frequency distribution of the activity of each enzyme in this population was nearly bell shaped (Supplementary Fig. 2). The enzyme activities of GAA (n = 3), GLA (n = 2), IDUA (n = 5), and ABG (n = 1) in LSD-confirmed patients were lower than those of healthy controls.

3.4. Comparison of GAA enzyme activity determined by the LC-MS/MS and fluorescence methods

Finally, we compared the level of GAA enzyme activity determined by LC-MS/MS to that measured by the fluorescent method. The mean value of GAA enzyme activity in the population according to the fluorescence method was 17.0 ± 6.6 (mean ± SD, n = 210, min = 2.53, max = 46.1, median = 16.2 μmol/h/L), indicating that these values seemed similarly to those by LC-MS/MS (Table 2). We also found that a positive linear correlation between the measurements of the two methods (R = 0.3439).

4. Discussion

The measurement of the enzyme activities of the six aforementioned LSDs using MS/MS-based technology has become the gold standard in large-scale assays (Table 2) [7]. This technology uses MRM, which enables simultaneous detection of multiple compounds. Accurate quantitation of endogenously accumulated enzyme products can be achieved by the inclusion of internal standards, which have a similar, but not the same, chemical structure to that of enzyme reaction products with 5–7 deuterium. The substrates and internal standards used for the GAA and GLA assays in the present study were used as originally synthesized, whereas others have been re-designed [20]. A recent study reported that the assay using the new substrates yielded comparable results to those obtained using substrates employed previously (Table 2) [20]. The alteration of the chemical structure of the substrates and internal standards results in the co-migration of the formed products and internal standards in ABS, ASM, and GALC assays in a chromatographic run, thereby making quantitation of each enzyme activity for these three assays much more accurate, even in LC-MS/MS assays.

The superiority of the LC-MS/MS method as compared to the fluorometric method has been attributed to its analytical range, which is calculated by dividing the enzyme activity in the high QC sample by that in the filter paper for blank (Table 3) [23]. Recently, Elliott et al. reported that the analytical range of the 6-plex MS/MS assay was higher than that of various fluorometric methods [20]. In the present study, the analytical range of the LC-MS/MS method was much wider than that of the MS/MS method (Tables 3 and 4). This finding was expected, as the remaining impurities after liquid–liquid extraction, as well as substrate-derived degradation products, can be eliminated using HPLC before MS/MS detection (Fig. 1A). Undoubtedly, the MS/MS-based method offers higher throughput in studies of large numbers of specimens. Thus, all reported studies of large numbers of samples have used the MS/MS-based assay (Table 2). Given the wider analytical range of the LC-MS/MS-based method, it may be more practical for diagnostic applications.

n, number of individuals; ND, not determined. WA, Washington state.
The mean GAA activity reported in this study (n = 210) was higher than that previously reported (Table 2). Using the MS/MS method, a Korean study also reported that the mean GAA activity was of approximately 24 μmol/L. [24]. Thus, higher GAA activity may be limited to Asian populations. A previous study reported that GAA activity was stable at or below 4 °C under proper storage conditions [21]. Based on the current evidence, the average enzyme activity of the six LSD enzymes in a Japanese neonatal population reported in the present study may be considered preliminary estimates. In conclusion, the present study examined the applicability of the 6-plex LSD assay using LC-MS/MS to neonatal screening. As enzyme activity depends on the population, region, and country, the cut-off value for neonatal screening needs to be based on assays samples derived from the local population. The wider analytical range of the LC-MS/MS method compared to the fluorometric method clearly distinguishes the LSD-affected individuals from healthy controls.

Acknowledgments

This work was supported by a grant-in-aid from the Japan Agency for Medical Research and Development to TO (15A01090500S0302) and a Grant-in-Aid for Scientific Research (C) from the Ministry of Education, Culture, Science, Sports and Technology to RM (16K08958). We thank Dr. Hui Zhou (Centers of Disease Control and Prevention) for providing the QC DBSs for validation of the assay.
