Revealing proton shape fluctuations with incoherent diffraction at high energy

Heikki Mäntysaari and Björn Schenke
Physics Department, Brookhaven National Laboratory, Upton, NY 11973, USA

The differential cross section of exclusive diffractive vector meson production in electron proton collisions carries important information on the geometric structure of the proton. More specifically, the coherent cross section as a function of the transferred transverse momentum is sensitive to the size of the proton, while the incoherent, or proton dissociative cross section is sensitive to fluctuations of the gluon distribution in coordinate space. We show that at high energies the experimentally measured coherent and incoherent cross sections for the production of $J/\Psi$ mesons are very well reproduced within the color glass condensate framework when strong geometric fluctuations of the gluon distribution in the proton are included. For $\rho$ meson production we also find reasonable agreement. We study in detail the dependence of our results on various model parameters, including the average proton shape, analyze the effect of saturation scale and color charge fluctuations and constrain the degree of geometric fluctuations.

I. INTRODUCTION

Measuring the partonic structure of the proton has been one of the main motivations of deeply inelastic scattering (DIS) experiments. To date, the most precise data on the proton structure is provided by the H1 and ZEUS experiments at HERA [1, 2]. Fundamentally, one is interested in the Wigner distributions of the proton’s constituents [3], which carry information on both the three dimensional momentum and spatial distributions. It is not known how to measure this distribution itself, such that typically some of the variables are integrated out. Most commonly both the spatial structure and transverse momentum are integrated out, yielding ordinary parton distribution functions (pdfs), only depending on the longitudinal momentum fraction $x$. If only either the transverse momentum or the spatial coordinates are integrated out, one obtains generalized parton distribution functions (GPDs) [4–7] or transverse momentum dependent parton distribution functions (TMDs) [8–14], respectively. These pdfs also carry detailed information on the angular momentum carried by partons, including their spin and orbital motion.

In this work we are interested in an additional piece of information, namely how much the spatial distribution of gluons within the proton fluctuates event-by-event. This information is experimentally accessible via exclusive incoherent diffractive vector meson production, namely scattering events that produce a single vector meson and, separated by a rapidity gap, remnants of the dissociated proton. Together with data on coherent diffractive vector meson production, in which the proton stays intact, the shape and fluctuations of the gluon distribution in the proton can be constrained [15].

We are particularly interested in large center of mass energies, where we are sensitive to the small $x$ part of the constituents in the proton. We will thus work in the framework of the color glass condensate (CGC) effective theory [16, 17] of quantum chromodynamics (QCD). Within the CGC framework, experimental data on the proton structure function have been well reproduced [18–20]. Furthermore, a large variety of observables in high energy collisions, including, for example, single [20–25] and double inclusive [26–28] particle production in proton-proton and proton-nucleus collisions, can be described. The CGC framework has also been extensively applied to study diffractive DIS in current and future experiments, including ultra-peripheral heavy ion and proton-nucleus collisions [29–37]. Incoherent diffraction with proton targets, however, has only been studied in a few publications [38, 39]. The importance of significant geometric fluctuations in the description of the incoherent cross section measured at HERA was pointed out in a recent Letter [15], on which we expand in this work. In the near future, before the realization of an Electron Ion Collider [40, 41], new data in a wide range of photon-nucleon center-of-mass energies can be obtained from ultra-peripheral heavy ion [42–45] and proton-nucleus collisions [46, 47].

Besides its fundamental interest, the fluctuating geometric shape of the proton is potentially an important ingredient for describing high multiplicity proton-proton and proton-nucleus collisions. Many collective phenomena have been observed in such collisions [48–51] (see also Ref. [52] for a recent review). One possible explanation for such collectivity are strong final state interactions, which are responsible for the generation of anisotropic flow in heavy ion collisions. They can be modeled by applying hydrodynamic simulations [53]. A successful description of the experimental data in p+A collisions by hydrodynamic models with sophisticated initial states, requires knowledge of the proton’s initial state geometry and its fluctuations [54]. Various analyses of geometric and interaction strength (equivalent to proton size) fluctuations in p+p and p+A collisions have been performed in the literature [55–60]. To really test the physical picture of hydrodynamic behavior in small collision systems, it is necessary to constrain proton shape fluctuations from other data than that from p+A (or p+p) collisions themselves, which will be done in this work.
This paper is organized as follows. In Sec. II we present the calculation of diffractive vector meson production cross sections in the CGC framework. Various phenomenological corrections to the cross sections are analyzed in Sec. III. Geometric fluctuations are implemented in Sec. IV and saturation scale fluctuations in Sec. V. The numerical results are shown in Sec. VI. In the appendices we show the quantitative effect of the phenomenological corrections and study various parameter dependencies in more detail.

II. DIFFRACTIVE DIS IN THE DIPOLE PICTURE

We study the exclusive production of a vector meson \( V \) with momentum \( P_V \) in deeply inelastic scattering of leptons from protons:

\[
\ell(P) + p(P) \to \ell'(P') + p'(P') + V(P_V).
\]

Here \( \ell \) and \( \ell' \) are the lepton momenta and \( P \) and \( P' \) are the proton momenta before and after the scattering, respectively. The Lorentz invariant quantities that characterize the scattering process are

\[
Q^2 \equiv -q^2 = -(\ell - \ell')^2,
\]

\[
t = -(P' - P)^2,
\]

\[
x_p \equiv \frac{(P - P') \cdot q}{P \cdot q} = \frac{M^2 + Q^2 - t}{W^2 + Q^2 - m_N^2}.
\]

Here \( m_N \) is the proton mass, \( M \) is the mass of the produced vector meson and \( W^2 = (P + q)^2 \) is the total center-of-mass energy squared of the virtual photon-proton scattering. The fraction of the longitudinal momentum of the proton transferred to the vector meson is \( x_p \), where \( \mathbb{P} \) stands for ‘pomeron’. The relation to the pomeron comes from the fact that in diffractive processes no color is exchanged between the proton and the produced system. This means that there are no color strings between them, leading to a rapidity gap, i.e., a region in rapidity with no produced particles, which is used experimentally to identify diffractive events. The scattered proton \( p' \) can either remain intact or break up, leading to coherent and incoherent diffractive events, respectively.

In the Good-Walker picture [61], diffraction is described in terms of states that diagonalize the scattering matrix. At high energy, these states are the ones where a virtual photon fluctuates into a quark-antiquark dipole with fixed transverse separation and impact parameter, and with a particular configuration of the target. The cross section is obtained by averaging over target configurations. Performing the average on the level of the scattering amplitude is equivalent to assuming that the target remains intact (coherent diffraction), and the cross section is proportional to the average proton structure. On the other hand, averaging on the level of the cross section includes events in which the target breaks up, resulting in the total diffractive cross section. Subtracting the coherent contribution leaves us with only events where the target breaks up (incoherent diffraction), which is proportional to the variance of the target profile, see e.g. Refs. [33, 62–64]. For a pedagogical discussion of diffractive scattering and its description within perturbative QCD, we refer the reader to Ref. [65].

Explicitly, in coherent diffraction the cross section can be written as [62, 66]

\[
\frac{d\sigma^{\gamma* p \to V p}}{dt} = \frac{1}{16\pi} \left| \langle A^{\gamma* p \to V p}(x_p, Q^2, \Delta) \rangle \right|^2,
\]

(5)

where \( A^{\gamma* p \to V p}(x_p, Q^2, \Delta) \) is the scattering amplitude. The incoherent cross section can be written as the variance [62] (see also e.g. Refs. [33, 34, 63, 64]):

\[
\frac{d\sigma^{\gamma* p \to V p'}}{dt} = \frac{1}{16\pi} \left( \left| \langle A^{\gamma* p \to V p}(x_p, Q^2, \Delta) \rangle \right|^2 - \left| \langle A^{\gamma* p \to V p}(x_p, Q^2, \Delta) \rangle \right|^2 \right).
\]

(6)

We note that in [67] and [68] the different averaging procedures leading to above expressions are discussed in the context of a semi-classical description of small \( x \) processes [69], such as the CGC picture employed in this work. In [68] it is shown that the total diffractive cross section is obtained by averaging over the target fields on the level of the cross section, while in [67] the coherent cross section is computed by averaging on the amplitude level as done in Eq. (5). Following Ref. [66], the scattering amplitude for diffractive vector meson production can be written as

\[
A^{\gamma* p \to V p}(x_p, Q^2, \Delta) = i \int d^2r \int d^2b \int \frac{dz}{4\pi} \times (\Psi^* \Psi_V)_{T,L}(Q^2, r, z)
\]

\[
\times e^{-i[b-(1-z)]r} \Delta \frac{d\sigma^{p}_{dip}}{d^2b}(b, r, x_p).
\]

(7)
ties related to the vector meson wave functions. Thus, our main results are not sensitive to the uncertain-
but the different wave functions mainly affect the overall
are also other wave functions available in the literature, used to describe HERA diffractive measurements. There
parametrization from Ref. [66] as it has been successfully
In this work we use the Boosted Gaussian wave function
In the CGC framework the energy (or $x_P$) evolution of the
dipole amplitude is given by evolution equations that can
be derived using perturbative techniques. Initial condi-
tions for the small-$x$ evolution (dipole amplitude at initial
Bjorken-$x$) can be determined by performing a fit to the
HERA DIS data as in Refs. [18, 20]. Then one can evolve
the amplitude to smaller $x$ by solving the JIMWLK [71–
74] or Balitsky-Kovchegov (BK) [75, 76] evolution equa-
tion.
Alternatively, the small-$x$ evolution can be modeled
along with the impact parameter and $Q^2$ dependence of
the dipole cross section, as done in the impact parameter
dependent saturation (IPSat) model [77]. Because this
approach has been very successful in describing a wide
range of data from HERA and it avoids problems with
the QCD evolution equations for finite size systems, such
as the emergence of unphysical Coulomb tails [78, 79],
we will use the IPSat model and the IP-Glasma model,
[80, 81], where IPSat is coupled to classical Yang-Mills
dynamics of the initial gluon fields.
In the IPSat model the dipole cross section is given
by [77]
$$\frac{d\sigma^{p}_{\text{dip}}(\mathbf{b}, r, x_P)}{d^2\mathbf{b}} = 2 \left[ 1 - \exp \left( -r^2 F(x_P, r^2) T_p(\mathbf{b}) \right) \right].$$
(9)
Here $T_p(\mathbf{b})$ is the proton (transverse) spatial profile func-
tion which is assumed to be Gaussian:
$$T_p(\mathbf{b}) = \frac{1}{2\pi B_p} e^{-b^2/(2B_p)}. \quad (10)$$
The function $F$ is proportional to the DGLAP evolved
gluon distribution [82],
$$F(x_P, r^2) = \frac{\pi^2}{2N_c} \alpha_s(\mu^2) x_P g(x_P, \mu^2), \quad (11)$$
with $\mu^2 = \mu_0^2 + 4/r^2$. The proton width $B_p$, $\mu_0^2$ and
the initial condition for the DGLAP evolution of the gluon
distribution $x_P g$ are parameters of the model. They are
obtained in Ref. [19] by performing fits to HERA DIS
data. For consistency with these fits we shall use the
same scale $\mu^2$ also in the calculation of the diffractive
cross section. See however Ref. [83] for a discussion of a
possible $|t|$ dependence of the scale choice in diffractive
scattering. We use a charm mass of $m_c = 1.4 \text{ GeV}$.
In the IP-Glasma model [80] the dipole amplitude $N$
can be calculated from the Wilson lines $V(x)$ as
$$N \left( \mathbf{b} = \frac{x + y}{2}, r = x - y, x_P \right) = \frac{1}{N_c} \text{Tr} \left( V(x) V^\dagger(y) \right). \quad (12)$$
Here the $x_P$ dependence of the Wilson lines is left implicit.
To get the Wilson lines, we first sample the color charges $\rho^a(x)$ from a Gaussian distribution
$$\langle \rho^a(x^-, x) \rho^b(y^-, y) \rangle = g^2 \delta^{ab} \delta^{(2)}(x - y) \delta(x^- - y^-) \mu^2. \quad (13)$$
The color charge density $g a$ is set to be proportional to the
saturation scale $Q_s(x_P, x)$ determined from the IPSat
model. We treat the proportionality constant as a free
parameter that mainly affects the overall normalization
of our results. We will use $Q_s = 0.7 g^2 \mu$ when we include
geometric fluctuations of the proton and $Q_s = 0.65 g^2 \mu$
without. For a more detailed discussion on the relation
between the saturation scale and color charge density, we
refer the reader to Ref. [84].
Solving the Yang-Mills equations for the gluon fields, one obtains
\[ V(x) = P \exp \left( -ig \int dx^{-} \rho(x^{-}, x) \frac{\nabla^2}{\nabla^2 + m^2} \right). \] (14)

Here \( P \) indicates path ordering and \( m \) is an infrared cutoff. Its role is to suppress infrared long-distance Coulomb tails, and consequently it affects the proton size. Generally one expects \( m \sim \Lambda_{\text{QCD}} \), and unless otherwise noted we will use \( m = 0.4 \text{ GeV} \). Sensitivity on the infrared cutoff \( m \) is discussed in Appendix C.

The path ordering is calculated by discretizing the expression in (14) as
\[ V(x) = \prod_{k=1}^{N_y} \exp \left( -ig \frac{\rho_k(x)}{\nabla^2 + m^2} \right). \] (15)

This corresponds to dividing the longitudinal direction into \( N_y \) slices. The continuum limit is obtained by taking \( N_y \to \infty \). In our calculations we use \( N_y = 100 \). We have checked that for \( N_y > 100 \) our results remain unchanged.

Calculations are performed on a 2-dimensional lattice with transverse spacing \( a = 0.02 \text{ fm} \). We have checked that smaller lattice spacings do not alter the results. For more details on the IP-Glasma framework, the reader is referred to Ref. [85].

As already discussed above, the coherent diffractive cross section is related to the Fourier transform of the dipole cross section \( \sigma^p_{\text{dip}} \) from coordinate space to momentum space (see Eqs. (5) and (7)). Thus, the coherent cross section as a function of \( |t| \) is directly related to the Fourier transform of the impact parameter profile of the proton. In the IPsat model the density profile is Gaussian, resulting in an approximately Gaussian spectrum in momentum space. The proton size can then be characterized by the diffractive slope \( B_D \) defined by fitting the coherent cross section by a function \( \sim e^{-B_D |t|} \) in the small \( |t| \) region. Notice that \( B_D \) is not exactly the \( B_p \) parameter in the IPsat model. The growth of the proton size (parameter \( B_D \)) as a function of energy has been observed at HERA [86] and in ultra-peripheral collisions by the ALICE collaboration [46]. Because in the IPsat model the density profile is assumed to factorize from the gluon distribution function \( x g \), it is not possible to explain this measured proton growth within this framework as the width of the Gaussian does not change when the overall normalization (gluon density) increases [66]. When performing explicit small \( x \) QCD evolution as done in [79] the growth of the proton with energy naturally emerges.

The incoherent cross section, on the other hand, is given by the variance of the scattering amplitude (see Eq. (6)). Thus, it is proportional to the event-by-event fluctuations of the proton density profile in coordinate space. As discussed in Ref. [62], at small \( |t| \) it is dominated by fluctuations of the overall proton density (in our case driven by the value of \( Q_s \) and possible color charge fluctuations). As we will demonstrate, at larger \( |t| \), the effect of these fluctuations is negligible compared to the contribution originating from the geometric fluctuations.

### III. PHENOMENOLOGICAL CORRECTIONS

#### A. Real part of the diffractive amplitude

Derivation of the diffractive scattering amplitude (7) relies on an assumption that the dipole scattering amplitude is purely real and the diffractive amplitude imaginary. The real part of the amplitude can be taken into account by multiplying the calculated cross section by a factor \((1 + \beta^2)\), where the ratio of real to imaginary parts of the scattering amplitude is [66]
\[ \beta = \tan \frac{\pi \lambda}{2}, \] (16)
where
\[ \lambda = \frac{d \ln A_{T,L}^{p-p\rightarrow V_p}^{\gamma^*}}{d \ln 1/x_p}. \] (17)

In our calculation this correction is calculated without any event-by-event fluctuations.

Because in the IP-Glasma framework the dipole amplitude has both real and imaginary parts, we do not include the real part correction when an IP-Glasma proton is used. However, we note that the contribution from the imaginary part of the dipole amplitude to the cross section is around 1%, significantly less than the correction \( \sim 10\% \) calculated from Eq. (16) in the kinematics relevant to this work (see Appendix A).

#### B. Skewness correction

At lowest order the dipole-target scattering involves an exchange of two gluons, because there cannot be an exchange of color charge. The two gluons in the target are probed at different values of Bjorken \( x \) (\( x_1 \) and \( x_2 \) satisfying \( x_1 - x_2 = x_p \)). Because we calculate the imaginary part of the scattering amplitude, the dominant contribution is obtained when the intermediate propagators are close to the mass shell. Thus, the first gluon exchange has to bring the \( qq \) dipole mass close to the mass of the produced vector meson. Then, there is only a significantly smaller longitudinal momentum fraction \( x_2 \) left for the second gluon. The dominant kinematical regime is then \( x_2 \ll x_1 \approx x_p \) [87–89].

In the IPsat model the collinear factorization gluon distribution \( x g g(x_p, \mu^2) \) is corrected to correspond to the off-diagonal (or skewed) distribution, which depends on both \( x_1 \) and \( x_2 \), by multiplying it by a skewness factor \( R_s \) following the prescription of Ref. [66]:
\[ R_s = 2^{2s+3} \frac{\Gamma(\lambda_g + 5/2)}{\sqrt{\pi} \Gamma(\lambda_g + 4)} \] (18)
with
\[ \lambda_g = \frac{\ln x g(x, \mu^2)}{\ln 1/x_g}. \] (19)

In the IP-Glasma model the gluon distribution function does not enter explicitly in the calculation of the diffractive scattering amplitude. In that case the skewness correction is approximated by calculating its effect to the diffractive cross section within the IPsat model without geometrical fluctuations, and using the obtained correction factors to scale the calculated diffractive cross section.

Especially the skewness correction is numerically important and needed to describe the HERA diffractive measurements. We will study the relative importance of these corrections in Appendix A.

IV. FLUCTUATING PROTON SHAPE

While the average (or root-mean-square) proton radius\(^1\) is constrained relatively well, little is known about fluctuations in the proton’s geometry. Here we explore several models for the fluctuating shape of the proton’s gluon distribution and use experimental data on incoherent diffractive vector meson production to constrain the degree of fluctuations.

A. Constituent quark proton

The simplest profile we use to model proton event-by-event fluctuations is inspired by the constituent quark picture. Here, the large-\(x\) valence quarks can be thought of as sources of small-\(x\) gluons, emitted around the constituent quarks \([79]\).

We implement this picture by sampling the constituent quarks’ positions in the transverse plane relative to the origin, \(b_i\), from a Gaussian distribution with width \(B_q\). The angular distribution of quarks is assumed to be uniform and we neglect any possible correlations between the quark positions. The density profile of each constituent quark in the transverse plane is also assumed to be Gaussian
\[ T_q(b) = \frac{1}{2\pi B_q}e^{-b^2/(2B_q)}, \] (20)

with width parameter \(B_q\). This corresponds to the replacement
\[ T_p(b) \rightarrow \frac{1}{N_q} \sum_{i=1}^{N_q} T_q(b - b_i) \] (21)

\(^1\) One can define e.g. the magnetic, charge \([90–93]\), Zemach \([94, 95]\), axial \([96]\) and gluonic \([97, 98]\) radius of the proton. In this work we deal with the gluonic content of the proton.

FIG. 3: Examples of proton density profiles at \(x \approx 10^{-3}\) with two parametrizations used in this work.

in Eq. (9). \(N_q\) can be interpreted as the number of large \(x\) partons, typically chosen to be 3, for the constituent quarks. We will also study larger values of \(N_q\) in Appendix B, representing the situation of additional large \(x\) gluons or sea-quarks.

For fixed \(N_q\), the degree of fluctuations is controlled by the parameters \(B_{qc}\) and \(B_q\). Examples of the sampled proton density profiles for \(N_q = 3\) are given in Fig. 3. We show a “lumpy” proton configuration in panel a) and a “smooth” proton that has little fluctuations in panel b). In case of no geometric fluctuations, when the proton density profile is Gaussian with width \(B_p\) (see Eq. (10)), the two-dimensional gluonic root mean square radius of the proton is \(r_p = \sqrt{2B_p}\). When coherent HERA data is fitted, one obtains \(r_p = 0.55\) fm. Similarly, we can define the average radius of our fluctuating proton to be \(\sqrt{2(B_q + B_{qc})}\), which in case of the parameter sets used in Fig. 3 has the same value.

In the IP-Glasma model geometric fluctuations are implemented by first performing the replacement (21) in the IPsat model, which then provides the saturation scale
values according to the modified thickness functions. In the IP-Glasma framework the additional parameter \( m \) controls the infrared physics and thus affects the spatial size of the gluon distribution. Because of this the values for the parameters \( B_p \), and \( B_q \) in both models cannot be directly compared. Examples of the proton density profiles obtained from the IP-Glasma model with the parametrization used in this work are illustrated in Fig. 4 by showing \( 1 - \text{Re} \text{Tr} V(x)/N_c \).

The total photon-proton cross section, and the proton structure functions, are proportional to the integral of the dipole amplitude over impact parameter. As the modification (21) is done in the exponent and the impact parameter dependence factorizes only in the dilute region, the replacement (21) affects the overall normalization of, for example, \( F_2 \). In practice, including geometric fluctuations \((B_q = 3.3 \text{ GeV}^{-2}, B_p = 0.7 \text{ GeV}^{-2})\) decreases \( F_2 \) at \( x \approx 10^{-3}, Q^2 \sim 10 \text{ GeV}^2 \) by approximately 8%. The diffractive cross section changes more, as it is proportional to the squared amplitude. Ideally one should perform a new fit to HERA DIS data with geometric fluctuations included, but this is beyond the scope of this work. However, this normalization uncertainty is similar for both coherent and incoherent cross sections and will not affect our conclusions about the required amount of geometric fluctuations in the proton wave function.

To determine the sensitivity on the details of the assumed proton shape we will also calculate the diffractive cross sections using a three-dimensional exponential density profile for the constituent quark

\[
T_q(b) = \frac{1}{8\pi B_q^3} e^{-b/B_q},
\]

and sample the constituent quark locations from a three-dimensional exponential distribution \( \sim e^{-b/B_q} \). The sampled quarks are then projected on the transverse plane. We note that the resulting transverse density profile is not exactly exponential.

### B. Stringy proton

In order to explore the dependence on the model details we also implement the geometric fluctuations using a color string inspired picture. Here, the idea is that based on quenched lattice QCD calculations, the constituent quarks are connected via gluon fields that merge at the Fermat point\(^2\) of the quark triangle [99] (see also Ref. [56]). We are not aware of calculations beyond the quenched approximation, which would be a more appropriate input to our model.

We implement this picture by sampling the constituent quark positions from a three dimensional Gaussian distribution with width \( B_q \). Then, the density profile is obtained by connecting the constituent quarks to the Fermat point of the triangle by tubes whose transverse shape is Gaussian with width \( B_q \). The 2-dimensional density profile of the proton \( T_q(b) \) is then obtained by integrating over the longitudinal direction.

In this picture the total gluonic content of the proton also fluctuates event-by-event, as when the quarks are sampled to be further away from each other, the flux tubes are longer at a constant density, leading to more gluons in the proton. This adds normalization fluctuations to the picture, which are similar to those introduced by saturation scale fluctuations (see the following section). The overall normalization factor, which controls the energy density of the tube, is fixed by requiring that the proton structure function \( F_2 \) calculated from the stringy proton at \( Q^2 = 10 \text{ GeV}^2, x = 10^{-3} \) is the same as that from the original IP-Glasma parametrization without fluctuations. Example density profiles (integrated over the longitudinal direction) are shown in Fig. 5. The parameters \( B_t \) and \( B_r \) are fixed by requiring a good description of HERA coherent and incoherent diffractive \( J/\Psi \) production measurements [100].

\(^2\) The Fermat point of a triangle is defined such that the total distance from that point to the vertices of the triangle is the smallest possible.
VI. RESULTS

We present results on coherent and incoherent diffractive vector meson production from the IPsat model with and without geometric fluctuations in Section VI A. We show the effect of saturation scale fluctuations in Section VI B and present results for the same observables in the IP-Glasma model in Section VI C.

A. IPsat

We start by calculating the diffractive \( J/\Psi \) photoproduction \((Q^2 = 0)\) cross section that has been measured at HERA \([86, 100, 104–106]\) in the IPSat model with and without geometric fluctuations. We compare our results with the HERA measurements at \( \langle W \rangle = 100 \text{ GeV} \), corresponding to \((\text{in case of } J/\Psi \text{ photoproduction at } t = 0) x_p = 9.6 \cdot 10^{-4}[86, 104–106] \), and \( \langle W \rangle = 75 \text{ GeV} \) that corresponds to slightly larger \( x_p = 1.7 \cdot 10^{-3} [100] \).

\[ P(\ln Q_s^2 / \langle Q_s^2 \rangle) = \frac{1}{\sqrt{2\pi}\sigma} \exp \left[ -\frac{\ln^2 Q_s^2 / \langle Q_s^2 \rangle}{2\sigma^2} \right], \tag{23} \]

with the amount of fluctuations controlled by \( \sigma \approx 0.5 \).

Because the log-normal distribution (23) leads to the expectation value \( E(\ln Q_s^2 / \langle Q_s^2 \rangle) = e^{\sigma^2/2} \), sampling the \( Q_s \) fluctuations directly from that distribution would make the average \( Q_s^2 \) to be \( \approx 13\% \) larger (for \( \sigma = 0.5 \)) than in case of no saturation scale fluctuations. This would not be consistent with the IPSat model fit to the HERA data. Thus, when the saturation scale is sampled from the distribution (23), we normalize it by the mean of the distribution in order to get a fluctuating \( Q_s \) distribution that always results in positive saturation scales and does not change the desired mean value.

In our constituent quark picture a natural way to include \( Q_s \) fluctuations is to let the saturation scale of each constituent quark fluctuate independently. In case of no geometric fluctuations, we implement the \( Q_s \) fluctuations by dividing the transverse space into a grid, where the cell size is set by the typical \( 1/Q_s^2 \) (cf. [103]), which for the EIC and HERA kinematics we consider corresponds to \( a \times a \) cells with \( a \approx 0.4 \text{ fm} \).
a large incoherent cross section comparable with the experimental data. In particular, the much smoother proton configuration ($B_q = 1.0 \ \text{GeV}^{-2}, \ B_p = 3.0 \ \text{GeV}^{-2}$) underestimates the incoherent cross section by several orders of magnitude while still being compatible with the measured coherent cross section. For typical proton configurations in these two situations see Fig. 3. One can further see that when the constituent quark size $B_q$ is decreased at constant $B_q$, the amount of fluctuations increases leading to a larger incoherent cross section. Also, the $|t|$ slope of the incoherent cross section at large $|t|$ is directly given by the constituent quark size [34]. Note that the overall normalization is affected by the inclusion of geometric fluctuations as discussed above.

Comparison to the H1 data [100] at the lower $\langle W \rangle = 75 \ \text{GeV}$ is shown in Fig. 7. Conclusions are the same as for $\langle W \rangle = 100 \ \text{GeV}$. The agreement with the lumpy proton structure ($B_q = 3.3 \ \text{GeV}^{-2}, \ B_p = 0.7 \ \text{GeV}^{-2}$), that also worked well with $\langle W \rangle = 100 \ \text{GeV}$ data, is good, while a smoother proton is incompatible with the incoherent data. We do not reproduce accurately the change in total coherent cross section from $\langle W \rangle = 100 \ \text{GeV}$ to $\langle W \rangle = 75 \ \text{GeV}$. For the lumpy proton the incoherent cross section is only underestimated at very low $|t|$, where the contribution from e.g. saturation scale fluctuations is expected to be dominant [62]. The effect of $Q_s$ fluctuations is studied numerically in Sec. VI B. In order to study the dependence on the exact form of the geometric fluctuations, we next present diffractive cross sections calculated using the “stringy proton” density profile introduced in Sec. IV B. The results are shown in Fig. 8 and compared with H1 data at $\langle W \rangle = 75 \ \text{GeV}$ [100] where we again see that we need large geometric fluctuations, corresponding to a “tube width” $B_\tau$ much smaller than the average distance of the quarks from the center set by $B_t$. A good description of the data is obtained with $B_t = 4.2 \ \text{GeV}^{-2}$ and $B_\tau = 0.6 \ \text{GeV}^{-2}$. Example density profiles from the parametrization that has large fluctuations are shown in Fig. 5. A smoother parametrization that has $B_t = B_\tau$ is comparable with the coherent cross section measurements but underestimates the incoherent cross section by more than an order of magnitude. Comparing to the results obtained using constituent quark protons shown in Fig. 7, we conclude that the precise nature of the fluctuating shape cannot be constrained by the incoherent diffractive $J/\Psi$ production.

The effect of replacing Gaussian density distributions by exponential distributions (see Eq. (22)) in the constituent quark picture is shown in Fig. 9. We obtain a good description of the H1 data with parameters $B_{qc} = 0.91 \ \text{GeV}^{-1}$ and $B_q = 0.42 \ \text{GeV}^{-1}$. With these parameters, we get the same 2-dimensional root mean square distance of the quarks from the center set by $B_q$. A good description of the data is obtained with $B_t = 4.2 \ \text{GeV}^{-2}$ and $B_\tau = 0.6 \ \text{GeV}^{-2}$. Example density profiles from the parametrization that has large fluctuations are shown in Fig. 5. A smoother parametrization that has $B_t = B_\tau$ is comparable with the coherent cross section measurements but underestimates the incoherent cross section by more than an order of magnitude. Comparing to the results obtained using constituent quark protons shown in Fig. 7, we conclude that the precise nature of the fluctuating shape cannot be constrained by the incoherent diffractive $J/\Psi$ production.

The coherent cross section is experimentally challenging to measure at large $|t|$ where the incoherent background starts to dominate. We can also see that in Fig. 6 the H1 and ZEUS results start to deviate in the largest $|t|$ bins. A precise measurement of the coherent cross section at large $|t|$ would allow us to further constrain the details of the average shape of the proton. Lacking such
constituent quark proton model we allow the saturation scale of each quark to fluctuate individually. The spectra obtained with the same constituent quark proton parametrizations as used in Fig. 7 and with additional saturation scale fluctuations are shown in Fig. 10. In the figure we also show the cross sections obtained by allowing the saturation scale of a round proton \((B_p = 4 \text{ GeV}^{-2})\) to fluctuate independently between different cells of size \(a^2 = (0.4 \text{ fm})^2\) in the transverse plane as discussed in Sec. V. As anticipated, we find that including saturation scale fluctuations improves the agreement with the experimental incoherent cross section, particularly at small \(|t|\), with the effect diminishing at higher \(|t|\). This is in line with early discussions of the effect of different kinds of fluctuations on incoherent diffraction [62]. The \(Q_s\) fluctuations alone underestimate the measured incoherent cross section by approximately an order of magnitude.

In addition to \(J/\Psi\), also diffractive production of lighter \(\phi\) and \(\rho\) mesons has been measured at HERA [105, 107–111]. The small mass of these mesons makes the photoproduction cross section calculation unreliable, because the cross section would receive significant contributions from large dipoles where non-perturbative effects become more relevant. The IPsat model includes some non-perturbative physics by requiring the dipole amplitude to reach unity in the large dipole limit. However, the model is still expected to reach the limits of its applicability as the dipole becomes large. Thus, in the following we study the diffractive production of \(\rho\) mesons at values of \(Q^2\) that are large enough to allow for the perturbative treatment of the scattering process. However, even at \(Q^2\) up to \(\sim 20 \text{ GeV}^2\) the relative contribution from large dipoles is stronger than in \(J/\Psi\) photoproduction [66], which means that non-perturbative physics may be more relevant.

The H1 collaboration has measured coherent and incoherent \(\rho\) production in the range \(Q^2 = 3.3 \ldots 33.0 \text{ GeV}^2\) [111]. We calculate the corresponding cross sections within our framework by using the IPsat model with constituent quarks and the same parameters that were used to describe the \(J/\Psi\) photoproduction data. The results are shown in Fig. 11 (upper panel) for coherent and in Fig. 11 (lower panel) for incoherent \(\rho\) production. For coherent cross section, the agreement with the data is better for the highest \(Q^2\) bins. For small \(|t|\) the coherent cross section is underestimated, especially at low \(Q^2\). The measured incoherent cross section would prefer slightly larger constituent quark size which would make the calculated \(|t|\) slope steeper, but such a change would not be favored by the incoherent \(J/\Psi\) production cross section which is theoretically under better control. As discussed above we expect our model to be less reliable in diffractive \(\rho\) production due to contributions from large dipoles even at moderate values of \(Q^2\). When saturation scale fluctuations are included, the description of the small-\(|t|\) part of the incoherent cross section is improved.

**FIG. 9:** Coherent (thick lines) and incoherent (thin lines) cross section as a function of \(|t|\) calculated with Gaussian \((B_{qc} = 3.3 \text{ GeV}^{-2}, B_q = 0.7 \text{ GeV}^{-2})\) and exponential \((B_{qc} = 0.91 \text{ GeV}^{-1}, B_q = 0.42 \text{ GeV}^{-1})\) density profile compared with HERA data [100]. The bands show statistical errors of the calculation.

**FIG. 10:** Coherent (thick lines) and incoherent (thin lines) cross section as a function of \(|t|\) compared with HERA data [100] at \(\langle W \rangle = 75 \text{ GeV}\). The bands show statistical errors of the calculation. Saturation scale fluctuations are included in the round proton case \((B_p = 4.0 \text{ GeV}^{-2})\), and their effect on top of proton geometric fluctuations is also shown.

**Constraining data** we choose to use a Gaussian distribution in the rest of this work.

**B. Including saturation scale fluctuations**

Having analyzed the effect of geometric fluctuations we now turn to the study of additional fluctuations of the saturation scale. As described in Sec. V within the
FIG. 11: Coherent (upper) and incoherent (lower) diffractive $\rho$ production cross section at $W = 75$ GeV as a function of $|t|$ compared with HERA data [111]. The bands show statistical errors of the calculation. Geometric fluctuations are included using the constituent quark picture with

\[ B_{q_{c}} = 3.3 \text{ GeV}^{-2}, B_{q} = 0.7 \text{ GeV}^{-2}. \]

$Q_{s}$ fluctuations are included in the results represented by solid lines.

C. IP-Glasma model

Finally, we present results for coherent and incoherent diffractive $J/\Psi$ and $\rho$ production in the IP-Glasma model. The two main differences to the IPsat model are the existence of color charge fluctuations (in addition to possible saturation scale and geometric fluctuations), and the emergence of long-distance Coulomb tails in the gluon fields from the solution of the Yang-Mills equation. These infrared tails are regulated by the mass parameter $m$ (see Eq. (14)) for which we use $m = 0.4$ GeV. Other values of $m$ reduce the simultaneous agreement with experimental coherent and incoherent HERA data using any combination of parameters $B_{q_{c}}$ and $B_{q}$ as we will demonstrate in Appendix C. Other than these differences, and the fact that the dipole amplitude is computed from the Wilson lines (14) according to Eq. (12) instead of Eq. (9), the physics content of the two models is the same. In particular, the geometry characterized by the different thickness functions is the same, only modified by the effects of large infrared tails in the IP-Glasma model, which are mainly compensated by the cutoff $m$.

First we compare coherent and incoherent cross sections with the HERA data for diffractive $J/\Psi$ production at $\langle W \rangle = 100$ GeV. The results are shown in Fig. 12. We find that the color charge fluctuations alone are not enough to describe the large incoherent cross section. Large geometric fluctuations ($B_{q_{c}} \gg B_{q}$) on top of color charge fluctuations are needed to obtain an incoherent cross section compatible with the experimental data\(^3\). Because $m$ does affect the size of the system, it is the combination of $B_{q_{c}}$, $B_{q}$ and $m$ that determines the geometry and its fluctuations in the IP-Glasma model. A direct comparison of $B_{q_{c}}$ and $B_{q}$ between IPSat and IP-Glasma is thus difficult.

We next compare with H1 data at $\langle W \rangle = 75$ GeV, where the incoherent cross section is measured also at smaller $|t|$ [100]. The results are shown in Fig. 13. We find again that only when including large geometric fluctuations is the large-$|t|$ part of the incoherent cross section described well. The small-$|t|$ part of the incoherent cross section can only be reproduced with additional saturation scale fluctuations. This was expected based on Ref. [62], as saturation scale fluctuations contribute

---

\(^3\) Note that in our previous calculation in [15] the center of the proton was moved to the origin after the constituent quark positions were sampled, effectively making the proton smaller. This transformation is not done in this work which changes the numerical value of $B_{q_{c}}$. Concerning the related issue of retaining the proton’s center of mass see [112].
to the incoherent cross section dominantly at small $|t|$. Fluctuations at different distance scales are visible in the incoherent cross section: the lowest-$|t|$ part is sensitive to $Q_s$ fluctuations that are visible at the largest distance scales, as they correspond to fluctuations of overall density. Geometrical fluctuations become dominant at $|t| \gtrsim 0.2 \text{ GeV}^2$, where we become sensitive to distance scales smaller than the proton size. Color charge fluctuations take place at very small distance scales but also affect the overall normalization. As shown explicitly in Fig. 12, their effect is thus mainly visible at very small $|t|$. Overall, including geometric, $Q_s$, and color charge fluctuations in the IP-Glasma model, we are able to achieve excellent agreement with the experimental data at all values of $|t|$.

The $\rho$ production cross sections calculated using the same fluctuating proton parametrizations are shown in Fig. 14. The coherent cross section measured at large $Q^2$ is described well, and $Q_s$ fluctuations are again found to improve the description of incoherent cross section data at small $|t|$. Neither the coherent cross section at small $Q^2$ nor the incoherent cross section at large $|t|$ are described accurately by our calculation. This is likely due to contributions from large dipoles that are not correctly described within our framework as discussed earlier in case of the IPSat model. In the IP-Glasma model the situation is even worse as the dipole cross section does not go to one at large $r$ like in the parametrized IPSat expression. This is evident from Eq. (12): as soon as one end of the dipole is outside the proton, the expression for $N$ goes to zero (also see Ref. [79]).

VII. CONCLUSIONS AND OUTLOOK

We have presented a detailed event-by-event computation of exclusive diffractive vector meson production in the color glass condensate framework. Within the IPSat and IP-Glasma models, whose parameters are almost entirely constrained by HERA data on deeply inelastic scattering, we find that in order to describe the experimental incoherent cross section of both $J/\Psi$ and $\rho$ production, large geometric fluctuations are needed. This finding is independent of the details of the model. These include different density distributions of gluons in the proton, of which we studied Gaussian and exponential distributions, as well as a stringy model, motivated by QCD in the limit of large quark masses. Apart from geometric fluctuations, we included fluctuations of the saturation scale.
and in the case of the IP-Glasma model, color charges. They contribute at all values of |t| but dominate in the limit |t| → 0. In particular in the IP-Glasma model, which includes all relevant fluctuations, we find excellent agreement of both the coherent and incoherent diffractive J/Ψ production cross sections. The diffractive production of ρ mesons is less accurately described, which we can attribute to more significant contributions from large dipoles that are not well described in our framework.

Our analysis provides constraints on the proton’s fluctuating shape at high energy (small x), which is an important input for calculations of observables in p+p and p+A collisions. These include in particular azimuthal anisotropy coefficients, which in case of strong final state effects are highly sensitive to the initial shape of the proton. We will investigate in the future if the fluctuating effects are highly sensitive to the initial shape of the proton shape constrained in this work is indeed compatible with experimental data on anisotropic flow in p+Pb collisions at the LHC and p+Au collisions at RHIC.

Appendix A: Phenomenological corrections

As discussed already in Sec. III, the phenomenological corrections, and especially the skewedness correction, are numerically important. To demonstrate this, we show in Fig. 15 the effect of the skewedness and real part corrections on the coherent diffractive ρ production cross section at different values of Q^2. The corrections are calculated separately for transversally and longitudinally polarized photons. The effect of the skewedness correction (see Eq. (18)) is quantified in the IPSat model without fluctuations by the ratio of the diffractive production cross section with and without taking the skewedness correction into account. The real part correction is quantified by the factor (1 + β^2) from Eq. (16), again calculated in the IPSat model without fluctuations.

As the corrections depend slightly on |t|, the results shown in Fig. 15 are the average correction factors at |t| < 0.5 GeV^2. We observe that especially at high Q^2, where the gluon density rises most rapidly, the skewedness correction becomes very large, of the order of 50%. For J/Ψ photoproduction in the same kinematics (as shown in Fig. 10) the skewedness correction is ≈ 43% and the real part correction ≈ 11%.

FIG. 15: Average effect of the skewedness and real part corrections at |t| < 0.5 GeV^2 to the coherent ρ production cross section calculated from the IPSat model without fluctuations at ⟨W⟩ = 75 GeV.

FIG. 16: Dependence of coherent (thick lines) and incoherent (thin lines) diffractive J/Ψ production cross section at ⟨W⟩ = 75 GeV on the number of constituent quarks (hot spots) N_q. The bands show statistical errors of the calculation.

Appendix B: Dependence on the number of constituent quarks

We study the dependence of the effect of geometric fluctuations on the number of hot spots (N_q in Eq. (21)). Numbers larger than 3 can be interpreted as the three constituent quarks plus large x sea-quarks or gluons, which are emitted from the large-x valence quarks (see also Ref. [113, 114]). This change does not affect the coherent cross section, as the average proton density profile remains approximately the same. However, it results in a smoother proton on average and thus one would ex-
fluctuations and comparable incoherent cross section is obtained at large $|t|$. $Q_s$ fluctuations are not included in this analysis.

Appendix C: Dependence on the infrared cutoff in the IP-Glasma model

Because it affects the average proton size and overall normalization of the gluon distribution, the infrared cutoff parameter $m$, introduced for the IP-Glasma model in Eq. (14), is expected to have an effect on both the coherent and incoherent cross sections. To study the sensitivity on this parameter, we show in Fig. 17 the coherent and incoherent cross section calculated with $m$ ranging from 0.2 GeV to 0.6 GeV. As could be expected, the results are most sensitive to the infrared cutoff in the small-$|t|$ region, while for $|t| \gtrsim 1$ GeV$^2$ its effect becomes negligible. The dependence on $m$ at small momentum can be understood as follows: Smaller masses allow for longer Coulomb tails, making the proton effectively larger, leading to steeper coherent $|t|$ spectra. The fact that for smaller $m$ the proton becomes more dense at large impact parameters also increases the overall normalization of both the coherent and incoherent cross sections. We note that the ratio of the incoherent and the coherent cross section is almost independent of $m$ [15].
