ABSTRACT

Detection of the radiation emitted from the first galaxies at $z \geq 10$ will be made possible in the next decade, with the launch of the James Webb Space Telescope (JWST). We carry out cosmological radiation hydrodynamics simulations of Population III (Pop III) starbursts in a $10^8 M_\odot$ dwarf galaxy at $z \sim 12.5$. For different star formation efficiencies and stellar initial mass functions (IMFs), we calculate the luminosities and equivalent widths (EWs) of the recombination lines H$\alpha$, Ly$\alpha$ and He II$\lambda$1640, under the simple assumption that the stellar population does not evolve over the first $\sim 3$ Myr of the starburst. Although only $\lesssim 40$ per cent of the gas in the central 100 pc of the galaxy is photoionized, we find that photoheating by massive stars causes a strong dynamical response, which results in a weak correlation between luminosity emitted in hydrogen recombination lines and the total mass in stars. However, owing to the low escape fraction of He II-ionizing photons, the luminosity emitted in He II$\lambda$1640 is much more strongly correlated with the total stellar mass. The ratio of the luminosity in He II$\lambda$1640 to that in Ly$\alpha$ or H$\alpha$ is a complex function of the density field and the star formation rate, but is found to be a good indicator of the IMF in many cases. The ratio of observable fluxes is $F_{\lambda 1640}/F_{H\alpha} \sim 1$ for clusters of 100 $M_\odot$ Pop III stars and $F_{\lambda 1640}/F_{H\alpha} \sim 0.1$ for clusters of 25 $M_\odot$ Pop III stars. The EW of the He II$\lambda$1640 emission line is the most reliable IMF indicator, its value varying between $\sim 20$ and $\sim 200$ AA for a massive and very massive Pop III IMF, respectively. Even the bright, initial stages of Pop III starbursts in the first dwarf galaxies will likely not be directly detectable by the JWST, except in cases where the flux from these galaxies is strongly magnified through gravitational lensing. Instead, the JWST may discover already more massive, and hence more chemically evolved, galaxies in which primordial star formation has largely ceased, or is contaminated with more normal, Pop I/II, star formation.

Key words: H II regions – galaxies: formation – cosmology: theory – early Universe – ultraviolet: galaxies.

1 INTRODUCTION

The epoch of the first galaxies marked a fundamental transition in the Universe, ending the Cosmic Dark Ages, beginning the process of reionization, and witnessing the rapid proliferation of star formation and black hole (BH) growth (e.g. Barkana & Loeb 2001; Bromm & Larson 2004). While the theory of primordial star forma-

on early cosmic evolution. The current theoretical consensus posits that the first stars, which formed in isolation in dark matter (DM) minihaloes, likely had masses of the order of $10^6 M_\odot$ (Bromm, Coppi & Larson 1999, 2002; Abel, Bryan & Norman 2002; Yoshida et al. 2006; McKee & Tan 2008; Yoshida, Omukai & Hernquist 2008). In the first galaxies, which form in DM haloes with masses $\gtrsim 10^9 M_\odot$ (Greif et al. 2008; Wise, Turk & Abel 2008), there is no such theoretical consensus on the IMF, as the initial conditions of the star-forming gas are uncertain (see Jappsen et al. 2009a,b). A large fraction of these first galaxies are likely to already host Population II (Pop II) star formation, due to previous metal enrichment (Johnson, Greif & Bromm 2008; see also Clark, Glover & Klessen 2008; Trenti & Stiavelli 2009). However, clusters of primordial stars likely form in some fraction of the first galaxies, owing to either inhomogeneities in the Lyman–Werner (LW) background which can suppress star formation where galaxies are strongly clustered (Dijkstra et al. 2008; see also Ahn et al. 2009) or to the direct collapse of the first stars to BHs, thereby locking up the metals produced in their cores (e.g. Heger et al. 2003).

Due to the hard spectra of massive metal-free stars, strong nebular emission in helium recombination lines has been suggested as an observable indicator of a population of such stars (e.g. Bromm, Kudritzki & Loeb 2001; Oh, Haiman & Rees 2001; Tumlinson, Giroux & Shull 2001; Schaerer 2002). In particular, a high ratio of the luminosity emitted in HeII $\lambda 1640$ to that emitted in Ly$\alpha$ or He I may be a signature of a galaxy hosting massive Pop III star formation, and has already served as the basis for searches for such galaxies (e.g. Dawson et al. 2004; Nagao et al. 2005, 2008). In addition, high equivalent widths (EWs) of Ly$\alpha$ and HeII $\lambda 1640$ are expected to characterize galaxies undergoing a Pop III starburst (e.g. Schaerer 2003). While no definitive detections of such galaxies have been achieved to date, observations of galaxies at $3 \lesssim z \lesssim 6.5$ with large Ly$\alpha$ EW and strong HeII $\lambda 1640$ emission may indicate that some galaxies host Pop III star formation even at such relatively low redshift (see Jimenez & Haiman 2006; Dijkstra & Wyithe 2007).

Previous analytical calculations of the recombination radiation expected from the first galaxies have been carried out under a number of idealized assumptions, namely of a static, uniform density field and of the formation of a static Strömgren sphere. Taking a complementary approach, we study here the properties of the recombination radiation emitted by the first galaxies with a focus on how the dynamical evolution of the galaxy affects the properties of this radiation. We present high-resolution cosmological radiation hydrodynamics simulations of the production of nebular emission from a cluster of primordial stars formed within the first galaxies. We resolve the H II and He II regions generated by the stellar cluster, thereby arriving at improved predictions for the emission properties of the first galaxies, which will be tested by the JWST.

Our paper is organized as follows. In Section 2, we describe our simulations and the methods used in their analysis; in Section 3 our results are presented, along with the implications for both IMF and star formation rate (SFR) indicators; in Section 4, we summarize and give our conclusions.

## 2 METHODOLOGY

We carry out radiation hydrodynamics simulations which track the impact of the radiation from Pop III stellar clusters forming promptly within a dwarf galaxy at $z \sim 12.5$. In this section, we describe the simulations and the calculations carried out in analysing their outcomes.

### 2.1 The simulations

As with previous work, for our three-dimensional numerical simulations, we employ the parallel version of GADGET (version 1), which includes a tree (hierarchical) gravity solver combined with the smoothed particle hydrodynamics (SPH) method for tracking the evolution of gas (Springel, Yoshida & White 2001; Springel & Hernquist 2002). Along with H$_2$, H$^+$, H, H$^-$, e$^-$, He, He$^+$ and He$^{++}$, we have included the five deuterium species D, D$^+$, D$^-$, HD and HD$^+$, using the same chemical network as in Johnson & Bromm (2006, 2007).

For our simulation of the assembly of a dwarf galaxy at $z \sim 12.5$, we have employed multigrid initial conditions which offer higher resolution in the region where the galaxy forms (e.g. Kawata & Gibson 2003). We initialize the simulation according to the Λ cold dark matter power spectrum at $z = 100$, adopting the cosmological parameters $\Omega_m = 1 - \Omega_\Lambda = 0.3, \Omega_\Lambda = 0.045, h = 0.7$ and $\sigma_8 = 0.9$, close to the values measured by the Wilkinson Microwave Anisotropy Probe in its first year (Spergel et al. 2003). Here, we use a periodic box with a comoving size $L = 1 h^{-1}$ Mpc for the parent grid. Our simulations use $N_{\text{gal}} = N_{\text{SPH}} = 1.05 \times 10^6$ particles for DM and gas, where the SPH particle mass is $m_{\text{SPH}} \sim 120 M_\odot$ in the region with the highest resolution. For further details on the technique employed to generate our multigrid initial conditions see Greif et al. (2008). The maximum gas density that we resolve is $n_{\text{gas}} \sim 10^3$ cm$^{-3}$, while gas at higher densities is accreted on to sink particles, as described in Johnson, Greif & Bromm (2007). We have also included the effect of a LW background radiation field, at a level of $J_{\text{LW}} = 0.04 \times 10^{-21}$ erg s$^{-1}$ cm$^{-2}$ Hz$^{-1}$ sr$^{-1}$, just as in Johnson et al. (2008).

To capture the effects of the ionizing radiation emitted by a single Pop III stellar cluster within the dwarf galaxy, we approximate the cluster as a point source located at the centre of the most massive DM halo in our simulation box at $z = 12.7$. The projected gas temperature in the entire simulation box at this redshift is shown in Fig. 1 (left-hand panel); the right-hand panel shows the temperature

![Figure 1. The projected gas temperature at $z = 12.7$, just before the stellar cluster turns on. Shown at the left-hand panel is the entire 1.4 Mpc (comoving) simulation box. The region of highest resolution is in the centre of our multigrid simulation box; magnified at the right-hand panel is the central $\sim 10$ kpc (physical), where the $\sim 10^3 M_\odot$ DM halo hosting the stellar cluster is located. Note that the gas is heated to $\geq 10^4$ K when passing through the virialization shock.](https://academic.oup.com/mnras/article-abstract/399/1/37/1085724)
in the region of the host halo at the centre of the box, which has a virial mass of $9 \times 10^7 M_\odot$, characteristic of the first galaxies. At each time-step, we find the boundaries of both the H II and He II regions generated by the stellar cluster using a ray-tracing technique that improves our earlier implementation (Johnson et al. 2007).

The procedure used to calculate the Strömgren sphere around the stellar cluster for a given time-step $\Delta t$ is similar to the ray-tracing scheme used in Johnson et al. (2007). We create a spherical grid centred at the location of the cluster, consisting of $\sim 1.2 \times 10^6$ rays and 1000 linearly spaced radial bins. We resolve the central kiloparsec around the source, roughly the virial radius of the host halo, with 250 radial bins, while the remaining 750 bins are linearly spaced out to $\sim 20$ kpc.

In a single, parallelized loop, the Cartesian coordinates of all particles are converted to spherical coordinates, such that their density and chemical abundances may be mapped to the bins corresponding to their radius, azimuth and zenith, denoted by $r, \theta$, and $\phi$, respectively. To avoid missing dense clumps, particles contribute to bins independent of distance, but proportional to their density squared. Once this preliminary step is complete, it is straightforward to solve the ionization front equation along each ray,

$$n_r \frac{dr}{dt} = \frac{Q_{\text{ion}}}{4\pi} - q_{\text{ion}} \int_0^{r_1} n_r n_\ast r^2 dr,$$

where $r_1$ denotes the position of the ionization front, $Q_{\text{ion}}$ the number of ionizing photons emitted per second by the stellar cluster, $q_{\text{ion}}$ the case B recombination coefficient, and $n_r, n_\ast$, and $n_\ast$ the number densities of non-ionized particles, electrons and ionized particles, respectively. The numbers of H II, He I and He II-ionizing photons are $Q_{\text{ion}} = N_\ast q_{\text{ion}}$, where $N_\ast$ is the number of stars in the cluster (here, we assume that all have the same mass) and $q_{\text{ion}}$ is the number of ionizing photons emitted by a single star, given by

$$q_{\text{ion}} = \frac{n L_\ast}{\sigma_{\text{eff}} T_{\text{eff}}^4} \int_{\text{in}} B_v \frac{hv}{h^2} dv,$$

where $\sigma$ is the Stefan–Boltzmann constant, $v_{\text{min}}$ denotes the minimum frequency corresponding to the ionization thresholds of H II, He I and He II, and we assume that massive Pop III stars emit a blackbody spectrum $B_v$ (in erg s$^{-1}$ cm$^{-2}$ Hz$^{-1}$ sr$^{-1}$) with an effective temperature $T_{\text{eff}}$ and a luminosity $L_\ast$ (e.g. Schaerer 2002).

To obtain a discretization of the ionization front equation, we replace the integral on the right-hand side of equation (1) by a discrete sum,

$$\int_0^{r_1} n_r n_\ast r^2 dr = \sum_i n_{e,i} n_{\ast,i} r_{i,r}^2 \Delta r,$$

where $\Delta r$ is the radial extent of the individual bins. Similarly, the left-hand side of equation (1), which models the propagation of the ionization front into neutral gas, is discretized by

$$n_r \frac{dr}{dt} = \frac{1}{\Delta t} \sum_i n_{e,i} r_{i,r}^2 \Delta r,$$

where $\Delta t$ is the current time-step and the summation is over radial bins starting with the bin lying immediately outside of $r_{i,r}$, the position of the ionization front at the end of the previous time-step, and ending with the bin lying at the new position of the ionization front. We perform the above steps separately for the H II and He II regions, since they require distinct heating and ionization rates.

We have chosen the size of the bins that are used in our ray-tracing routine to roughly match the volume of gas represented by a single SPH particle within the $\sim 1$ kpc virial radius of the halo hosting the stellar cluster, such that the boundaries of the photoionized regions are maximally resolved while also reliably conserving ionizing photons. However, in some cases it may occur that the mass contained in a bin is smaller than that of the SPH particle contained within it, such that ionizing the entire SPH particle involves ionizing more gas than is contained in the bin. In turn, this can lead to an overestimate of the number of recombinations. While this effect is minor in our simulations, in the calculations presented below we enforce that the total number of recombinations does not exceed the total number of ionizing photons available.

We carry out four simulations, each with a different combination of IMF and total cluster mass. For the IMF, we assume for simplicity, and in light of the still complete uncertainty regarding its detailed shape, that the cluster consists either entirely of 25 or 100 M$\odot$ Pop III stars. These choices are meant to bracket the expected characteristic mass for Pop III stars formed in the first galaxies, which depending on the cooling properties of the gas may be Pop III.2 stars with masses of order 10 M$\odot$ or, possibly, Pop III.1 stars with masses perhaps an order of magnitude higher (Johnson & Bromm 2006; Greif et al. 2008; McKee & Tan 2008; but see Jappsen et al. 2009). For each of these IMFs, we vary the total stellar mass in the cluster, choosing either $2.5 \times 10^5$ M$\odot$ or $2.5 \times 10^7$ M$\odot$ for the total mass in stars. These choices correspond to $\sim 1$ and $\sim 10$ per cent, respectively, of the cold gas available for star formation within the central few parsecs of such a primordial dwarf galaxy (see Wise et al. 2008; Regan & Haehnelt 2009). We calculate the ionizing flux from each of these clusters, assuming blackbody stellar spectra at $7 \times 10^4$ and $10^5$ K and bolometric luminosities of $6 \times 10^5$ and $10^6$ L$\odot$, for the 25 and 100 M$\odot$ stars, respectively, appropriate for metal-free stars on the main sequence (Marigo et al. 2001).

For simplicity, we have chosen to keep the input stellar spectra constant in time over the course of the simulations. Accordingly, we run the simulations only for 3 Myr, which is roughly the hydrogen-burning time-scale of a 100 M$\odot$ primordial star, and about half that of a 25 M$\odot$ primordial star. We note that while the H II-ionizing flux from 100 M$\odot$ primordial stars is roughly constant over this time-scale, the He II-ionizing flux decreases by a factor of $\sim 2$ by a stellar age of 2 Myr, and by a much larger factor near the end of hydrogen-burning as the star evolves to the red (e.g. Marigo et al. 2001; Schaerer 2002). We note, however, that stellar models accounting for the effects of rotation yield less precipitous drops in the emitted ionizing flux with time, as fast rotation, especially of low-metallicity stars, can keep the stars on bluer evolutionary tracks (e.g. Yoon & Langer 2005; Woosley & Heger 2006; Vázquez et al. 2007); indeed, Pop III stars may have been fast rotators (see Chiappini et al. 2008). None the less, the results that we derive pertaining to He II recombination emission from clusters of 100 M$\odot$ stars may be, strictly speaking, only reliable for stellar ages $\lesssim 2$ Myr. An in-depth study of the impact that stellar evolution has on the emission properties of primordial galaxies is given in Schaerer (2002); in the present work, we take a complementary approach and instead focus on how the emission properties are affected by the hydrodynamic evolution of the gas in the first galaxies.

We make the related simplifying assumption that the stellar cluster forms instantaneously. This is valid if the time-scale for star formation $t_{SF}$ is much shorter than the lifetime of the stars that we consider or $t_{SF} \ll 3$ Myr. If we assume that stars form on the order of the free-fall time $t_{ff}$, and take it that the star cluster forms within the central $\sim 1$ pc of the halo (see e.g. Wise et al. 2008; Regan & Haehnelt 2009), then we find $t_{SF} \sim 5 \times 10^5$ yr, for which our assumption is marginally valid. We note that more work is needed to accurately determine the star formation time-scale in the...
Deriving the observational signature.

2.2.1 Escape fraction of ionizing photons

Photons which escape the host halo from which they are emitted proceed to reionize the intergalactic medium (IGM), where densities are generally very low, yielding long recombination times. Ionizing photons which do not escape the host halo are, however, available to ionize dense gas which recombines quickly, leading to appreciable emission in recombination lines. Therefore, the luminosity of a galaxy in recombination radiation is intimately related to the escape fraction of ionizing photons. The escape fraction of ionizing photons from the halo hosting the stellar cluster is given by subtracting the number of recombinations \( Q_{\text{rec}} \) per second within the virial radius from the total number of ionizing photons emitted by the cluster:

\[
f_{\text{esc}} = \left( Q_{\text{ion}} - Q_{\text{rec}} \right) \left( Q_{\text{ion}} \right)^{-1},
\]

again with \( Q_{\text{ion}} = N_s q_{\text{ion}} \). This equation is valid under the assumption that within the host halo the number of ionizing photons which fail to escape is balanced by the number of recombinations within the halo. This is a reasonable assumption, since the number of atoms which become ionized within the host halo is far less than the total number of recombinations that occur in the halo, the ionization of previously neutral gas being the only other sink for ionizing photons within the halo. The number of recombinations is given as

\[
Q_{\text{rec}} = \sum_i Q_i \frac{m_i}{\rho_i} \frac{\rho_i}{\mu_{\text{H}}} f_{\text{esc}} f_{\text{HII}},
\]

where \( Q_i \) is the case B recombination coefficient for hydrogen, \( m_i \) is the mass of a hydrogen atom, while \( m_i, \mu_i \), and \( \rho_i \) are the total mass, mean molecular weight and mass density of the \( i \th \) SPH particle, respectively. For each SPH particle, \( f_{\text{HII}} \) and \( f_{\text{esc}} \) denote the fraction of nuclei in H II and the fraction of free electrons, respectively.

Here, the summation is over all SPH particles within the virial radius of the host halo or within a physical distance of \( \sim 1 \) kpc from the central stellar cluster. We calculate the escape fractions of both H II-ionizing and He II-ionizing photons. These quantities are generally not equal, and they each contribute to determining the radiative signature of the initial starbursts in the first galaxies.

2.2.2 Luminosity in recombination lines

For each of our simulations, we compute the luminosity emitted from photoionized regions in each of three recombination lines: \( H\alpha \), Lya and He II \( \lambda 1640 \). These luminosities are calculated by again summing up the contributions from all SPH particles within the virial radius, where virtually all of the recombination line luminosity emerges, as follows:

\[
L_{\text{H\alpha}} = \sum_i f_{\text{H\alpha}} \frac{m_i}{\rho_i} \frac{\rho_i}{\mu_{\text{H}}} f_{\text{esc}} f_{\text{HII}},
\]

\[
L_{\lambda 1640} = \sum_i f_{\lambda 1640} \frac{m_i}{\rho_i} \frac{\rho_i}{\mu_{\text{H}}} f_{\text{esc}} f_{\text{HeIII}},
\]

where the \( j \) are the temperature-dependent emission coefficients for the lines (Osterbrock & Ferland 2006), and \( f_{\text{HeIII}} \) is the fraction of helium nuclei in He III for each SPH particle.

Given the luminosity in a recombination line over an area of the sky, we may compute the flux in that line, as observed at \( z = 0 \) with a spectral resolution \( R = \lambda / \Delta \lambda \), where \( \lambda \) is the wavelength at which the emission line is observed (e.g. Oh et al. 2001). While Lya photons are scattered out of the line of sight in the IGM prior to reionization (Loeb & Rybicki 1999), a process which we do treat in the present calculations, H\alpha and He II \( \lambda 1640 \) photons will not suffer such severe attenuation. Assuming that the line is unresolved, the monochromatic flux in H\alpha, for example, is

\[
f_{\text{H\alpha}} \approx 20 \text{nJy} \left( \frac{L_{\text{H\alpha}}}{10^{40} \text{erg s}^{-1}} \right) \left( \frac{1 + z}{10} \right)^{-1} \left( \frac{R}{1000} \right),
\]

where \( L_{\text{H\alpha}} \) is the luminosity in H\alpha along the line of sight through the emitting galaxy, \( D_{\lambda}(z) \) is the luminosity distance at redshift \( z (\sim 10^2 \) Gpc at \( z = 10 \)), and \( \lambda_{\text{H\alpha}} \) is the rest-frame wavelength of the line, 656.3 nm. If the galaxy is spatially unresolved, appearing as a point source, we may simply substitute \( L_{\text{H\alpha}} \) for \( f_{\text{H\alpha}} \) in equation (10), to compute the total flux from the galaxy. In terms of total (integrated) line flux, we have the equivalent expression:

\[
F_{\text{H\alpha}} = \frac{L_{\text{H\alpha}}}{4\pi D_{\lambda}^2(z)} \sim 10^{-20} \text{erg s}^{-1} \text{cm}^{-2} \left( \frac{L_{\text{H\alpha}}}{10^{40} \text{erg s}^{-1}} \right) \left( \frac{1 + z}{10} \right)^{-2}.
\]

2.2.3 Recombination line equivalent widths

Another observable quantity obtained from our simulations is the rest-frame EW of recombination lines. We calculate the EWs of the three recombination lines considered, following Schaerer (2002),

\[
W_{\text{H\alpha}} = \frac{L_{\text{H\alpha}}}{L_{\lambda,\text{neb}} + L_{\lambda,\ast}}
\]

\[
W_{\text{Lya}} = \frac{L_{\text{Lya}}}{L_{\lambda,\text{neb}} + L_{\lambda,\ast}}
\]

\[
W_{\lambda 1640} = \frac{L_{\lambda 1640}}{L_{\lambda,\text{neb}} + L_{\lambda,\ast}}
\]

where the monochromatic continuum luminosity, evaluated at the wavelength of the line, is the sum of the nebular emission \( L_{\lambda,\text{neb}} \) and the stellar emission \( L_{\lambda,\ast} \). The nebular continuum luminosity is given by

\[
L_{\lambda,\text{neb}} = \frac{c}{\lambda^2} \frac{\gamma_{\lambda\text{neb}} Q_{\text{rec}}}{\alpha_{\text{H}}},
\]

where \( \lambda \) is the wavelength in question, and \( Q_{\text{rec}} \) is again the total number of recombinations per second in the halo. The continuous emission coefficient \( \gamma_{\lambda\text{neb}} \) accounts for free–free, free–bound and two-photon continuum emission, as described in Schaerer (2002).
The stellar continuum luminosity is calculated assuming a blackbody stellar spectrum and is given by

$$L_{\lambda,*} = \frac{N_*}{\lambda^5} \frac{8\pi^2 \hbar c^2 R_*^2}{\exp(hc/\lambda k_B T_{\text{eff}}) - 1}, \quad (15)$$

where $N_*$ is the number of stars in the cluster, $T_{\text{eff}}$ is the effective surface temperature of a star, and $R_*$ is the stellar radius.

3 RESULTS AND IMPLICATIONS

We next discuss the observable characteristics of primordial dwarf galaxies. In particular, we evaluate the utility of indicators for the SFR and the stellar IMF in such galaxies.

3.1 Evolution of gas inside the galaxy

With the ignition of a stellar cluster at the centre of the host halo, the gas surrounding the cluster is photoheated, raising its pressure and leading to its outward expansion. In turn, the overall recombination rate in the host halo drops, allowing the expansion of the H II region to continue for a constant rate of ionizing photon production. Fig. 2 shows the growth of the H II region and the concomitant expansion of the gas in the centre of the host halo for the more massive 100 M\(_{\odot}\) cluster. The H II region breaks out of the host halo within the first \(\sim 1\) Myr, and after 3 Myr it extends to \(\lesssim 7\) physical kpc, only slightly larger than the size of the H II region created by a single massive Pop III star in a minihalo (e.g. Alvarez, Bromm & Shaprio 2006).

![Figure 2. The density-weighted temperature (left-hand column), density-weighted H II fraction (middle column) and number density (right-hand column), each averaged along the line of sight, of the gas surrounding the more massive 100 M\(_{\odot}\) star cluster, shown at three different times from the prompt formation of the cluster: 500 000 yr (top row), 1 Myr (middle row) and 3 Myr (bottom row). The H II region grows as the density of the gas in the centre of the host halo gradually drops in response to the intense photoheating. Note the different length scale of each column, given at the top in physical units; the density is shown only within the central region of the host halo.](https://academic.oup.com/mnras/article-abstract/399/1/37/1085724)

Figure 3. The mass fraction of enclosed gas which is photoionized, \(f_{\text{ion}}\), as a function of the distance from the central star cluster, after 3 Myr of photoheating. Each line corresponds to a different choice of IMF and total mass in stars, as labelled. The ionized fraction begins to drop at \(\gtrsim 300\) pc mostly due to two minihaloes at \(\sim 400\) and \(\sim 500\) pc, shown in Fig. 2 (right-hand panels), which remain shielded from the ionizing radiation and are thus largely neutral. Within \(\sim 100\) pc, there is a large fraction of gas which remains un-ionized at densities \(\gtrsim 100\) cm\(^{-3}\). This gas will likely collapse to form stars, despite the strong radiative feedback from the central stellar cluster.

While the gas surrounding the formation sites of the first stars in minihaloes is easily photoevacuated by a single massive Pop III star (e.g. Kitayama et al. 2004; Whalen, Abel & Norman 2004), the deeper gravitational potential well of the DM haloes hosting the first galaxies allows for the retention of gas even under intense photoheating; indeed, this is one criterion used to define the first galaxies (e.g. Read, Pontzen & Viel 2006; Johnson et al. 2008; Greif et al. 2008).

As shown in Fig. 3, a substantial portion of the gas in the galaxy, even within \(\sim 100\) pc of the stellar cluster, remains neutral after 3 Myr. This gas is shielded from the ionizing radiation, causing the ionization front (I-front) to propagate outward anisotropically in the inhomogeneous cosmological density field (see also e.g. Shapiro, Iliev & Raga 2004; Abel, Wise & Bryan 2006; Alvarez et al. 2006). Even for the case of the highest ionizing flux, the fraction of ionized gas within the central \(\sim 100\) pc is \(\lesssim 0.4\), leaving the majority of the high density gas neutral. While the photodissociating radiation from the initial stellar cluster will slow the collapse of this primordial gas (e.g. Susa & Umemura 2006; Ahn & Shapiro 2007; Whalen et al. 2008), some fraction of it will likely be converted into stars once the most massive stars in the cluster have died out. Indeed, the shocks engendered by the supernovae that mark the end of their lives may expedite the collapse of the gas (e.g. Mackey, Bromm & Hernquist 2003; Salvaterra, Ferrara & Schneider 2004; Machida et al. 2005; Greif et al. 2007; Sakuma & Susa 2009). The incomplete ionization of the central gas confirms that the masses that we have chosen for the clusters are not overly large, as there is still some neutral gas available for subsequent star formation regardless of the radiative feedback.

The gas that is photoionized, however, is gradually expelled from the centre of the halo, and after 3 Myr of photoheating the density of the photoionized gas within \(\sim 20\) pc of the cluster drops to \(\lesssim 10\) cm\(^{-3}\) for the more massive cluster of 100 M\(_{\odot}\) stars shown in Fig. 2. For our other choices of IMF and total cluster mass the...
dynamical response is less dramatic, as the ionizing flux is weaker; for example, after 3 Myr the density of the central photoionized gas is \( \lesssim 50 \, \text{cm}^{-3} \) for the less massive cluster of 25 \( M_\odot \). The varying degree to which photoheating dynamically impacts the host halo leads to important differences in the properties of the emitted radiation.

Although the limited resolution of our simulations allows only to track the expansion of the H\( \text{II} \) region from an initial physical size of \( \gtrsim 10 \, \text{pc} \), we expect that after roughly a sound-crossing time of the central unresolved \( \sim 10 \, \text{pc} \), or after the first few \( 10^5 \, \text{yr} \), the evolution of the H\( \text{II} \) region is reliably resolved. It should thus be noted that the breakout of the H\( \text{II} \) region may be delayed by order of magnitude compared to our simulations. We note that in the Milky Way the expansion of the photoheated gas in an H\( \text{II} \) region may be slowed due to turbulent pressure confinement (e.g. Xie, Mundy & Vogel 1996; Mac Low, Toraskar & Oishi 2007), resulting in ultra-compact H\( \text{II} \) regions persisting for \( \gtrsim 10^7 \, \text{yr} \) (Wood & Churchwell 1989), much longer than the sound-crossing time-scale for such regions. As turbulence begins to play an important role in the formation of the first galaxies (Greif et al. 2008; Wise et al. 2008), the initial evolution of H\( \text{II} \) regions therein may be similarly confined. This possibility notwithstanding, we expect that the spatial resolution that we do achieve suffices to track changes in the luminosity emitted in recombination lines and in the escape fraction of ionizing radiation, which we discuss in the remainder of this section.

### 3.2 Star formation rate indicators

The luminosity emitted in recombination lines, such as H\( \alpha \), has been found to scale remarkably well with the SFR of galaxies at low redshift (e.g. Kennicutt 1983; but see Pfenn-Altzenburg, Weidner & Kroupa 2007). The SFR obtained using such relations relies on some knowledge of the IMF of the stars which are forming, as well as on the escape fraction of ionizing radiation. Fig. 4 shows our calculations of the escape fraction \( f_{\text{escH}\alpha} \) of H\( \alpha \)-ionizing photons for each of our choices of IMF and total mass in stars, and Fig. 5 shows the escape fraction \( f_{\text{escHe}\alpha} \) of He\( \alpha \)-ionizing photons. The corresponding luminosities emitted in H\( \alpha \), Ly\( \alpha \) and He\( \alpha \) are presented in Fig. 6.

As shown in Fig. 4, there is a clear trend towards higher H\( \alpha \)-ionizing photon escape fractions for more massive stellar clusters, with the majority of the ionizing photons escaping from clusters with the larger total stellar mass. The escape fraction is not, however, independent of IMF; for a given total mass in stars, the escape fraction can differ by a wide margin. Both the variability in the escape fraction with time and the range of values that we find are in rough agreement with other recent calculations of the escape fraction of ionizing photons from dwarf galaxies at \( z \gtrsim 10 \) (Wise & Cen 2009; Razoumov & Sommer-Larsen 2009). For a recent calculation of the escape fraction of ionizing photons from more massive galaxies, see Gnedin, Kravtsov & Chen (2008).

The breakout of the H\( \alpha \) region generated by the less massive 100 \( M_\odot \) star cluster occurs after \( \sim 1 \, \text{Myr} \), leading to an escape fraction \( \gtrsim 0.5 \) after 2 Myr. In contrast, the H\( \alpha \) region of the equally massive 25 \( M_\odot \) star cluster remains confined to the host halo for \( \gtrsim 3 \, \text{Myr} \), contributing no ionizing photons to the IGM. The progress of the initial stages of hydrogen reionization, likely driven by star formation in the first galaxies (e.g. Loeb 2008), may thus depend on whether these galaxies hosted massive (\( \gtrsim 10 \, M_\odot \)) or very massive stars (\( \gtrsim 100 \, M_\odot \)) (see also Choudhury & Ferrara 2007).

The evolution of the H\( \alpha \)-ionizing photon escape fraction is reflected in the evolution of the luminosity of hydrogen recombination lines, as shown in Fig. 6. Comparing the panels on the left-hand side to those on the right-hand side, the luminosity in the Ly\( \alpha \) and H\( \alpha \) lines, while generally higher for larger total mass in stars, does not scale with the total mass in stars. Indeed, owing to the increase in the escape fraction of ionizing photons, after \( \sim 1 \, \text{Myr} \) the luminosity in hydrogen recombination lines from the clusters with greater total stellar mass drops below that of the clusters with lower total stellar mass, for a given IMF. Overall, because of the temporal
Figure 6. The luminosity of the galaxy, as a function of the time from the prompt formation of the cluster, in three recombination lines: Lyα (dotted black), Hα (solid red) and He II λ1640 (dashed black). The four panels correspond to our four different choices of IMF and total mass in stars; these are, clockwise from top left: twenty-five 100 M⊙ stars, two hundred fifty 100 M⊙ stars, one thousand 25 M⊙ stars and one hundred 25 M⊙ stars. The luminosities generally decrease with time, as the photoheating acts to decrease the density of the ionized gas, lowering the recombination rate. Note the different evolution of the He II λ1640 luminosity as compared to that of the hydrogen recombination lines, owing to the lower escape fraction of He II-ionizing photons (see Fig. 5).

Figure 7. The rest-frame EWs, \( W^0 = W/(1 + z) \), where \( W \) is the observed EW, as a function of time, of the same three recombination lines shown in Fig. 6. For comparison, in each panel we plot the observed EWs of galaxies from two different surveys: the dotted line at 400 Å denotes the median EW of Lyα emitters detected at \( z = 4.5 \) in the LALA survey (Malhotra & Rhoads 2002), while the dotted line at 145 Å denotes the average EW of the six Lyα emitters at \( z \geq 6 \) detected in the Subaru deep field (Nagao et al. 2007). Note that the Lyα EWs that we compute are upper limits, as scattering in a neutral IGM has not been accounted for.

3.3 Initial mass function indicators

The luminosity emitted from a galaxy in recombination lines depends not only on the stellar IMF, but also on the density field of the galaxy and the escape fraction of ionizing photons. Therefore, the utility of recombination line strengths as IMF indicators hinges on an understanding of the dynamical evolution of the photoionized gas, especially for the case of starbursts in the first dwarf galaxies, in which such dynamical effects can be most pronounced.

For the starbursts that we simulate here, the luminosity of the He II λ1640 emission line relative to the hydrogen recombination lines can be read from Fig. 6, while the EWs of these lines are presented in Fig. 7. Comparing the top panels of Fig. 6 to the bottom panels, it is evident that the ratio of the luminosity emitted in He II λ1640 to that in Hα (or Lyα) can be very different depending on the IMF. Fig. 7 shows that there is a similar distinction in the ratios of the EWs. For the 100 M⊙ star clusters, the luminosity in He II λ1640 is comparable to that in Hα, while for the 25 M⊙ star clusters the luminosity in He II λ1640 is up to an order of magnitude lower than that in Hα. However, as the escape fraction of H I-ionizing photons increases with time for the more massive 25 M⊙ stellar cluster, the luminosities in these two lines become comparable, revealing that there is some ambiguity in the use of this ratio of line luminosities as an indicator of the IMF of young (\( \lesssim 3 \) Myr) stellar clusters. Thus, in some cases dynamical effects may compromise the use of this line ratio in distinguishing between clusters of Pop III.1 and Pop III.2 stars, with typical masses of order 100 and 10 M⊙, respectively.

The ratio of the observed fluxes in He II λ1640 and Hα, as calculated using equation (10), is displayed in Fig. 8. In this figure, it is clear that this line ratio is sensitive to the IMF, although it is not a constant for each cluster. Instead, for clusters in which the escape
fraction of H I-ionizing photons increases with time dramatically, while the escape fraction of He II-ionizing photons remains roughly constant, this line ratio varies with the flux observed in Hα. While the ratio of the fluxes is a somewhat ambiguous IMF indicator, the clusters with the more top-heavy IMF do consistently exhibit larger ratios of He II λ1640 to Hα. Nagao et al. (2005) present a search for He II λ1640 emission from a strong Lyα emitter at z = 6.33, finding an upper limit for the ratio of He II λ1640 to Lyα. Assuming a standard value of 0.07 for the ratio of luminosity in Hα to that in Lyα (Osterbrock & Ferland 2006), we show in Fig. 8 the upper limit that these authors report (see also Dawson et al. 2004). Although a weak upper limit, it is clear that observations with only slightly greater sensitivity will allow to differentiate between the flux ratios predicted here for massive and very massive Pop III IMFs.

Comparing the EW of Hα in the four panels of Fig. 7, it is clear that it is not strongly dependent on the IMF or on the total mass in stars, varying by at most a factor of three between each of the cases. While showing more variation between the four cases, the EW of Lyα also shows considerable ambiguity as an IMF indicator, its maximum value varying by about a factor of 3 between each of the four cases. This insensitivity of the Lyα EW to the IMF arises from two effects. First, the stellar continuum luminosity Lλ increases in a similar manner as the number of ionizing photons from the massive (25 M⊙) IMF to the very massive IMF (100 M⊙). This acts to keep the EW, roughly the ratio of the two, relatively constant. Secondly, while the luminosity in Lyα decreases with the increasing escape fraction of ionizing photons for the more massive clusters, the continuum luminosity remains largely unchanged, leading to a decrease in the EW with time for these clusters. We note that the Lyα EWs presented here are only upper limits, as we have not accounted for scattering of Lyα photons in the IGM (see e.g. Dijkstra et al. 2007).

The EW of He II λ1640 is a more definitive indicator of IMF, being higher for the clusters of 100 M⊙ stars than for the clusters of 25 M⊙ stars, regardless of the total mass in stars or of the age of the cluster (up to ≥3 Myr). As with the utility of He II λ1640 as a SFR indicator, this largely follows from the generally low escape fraction of He II-ionizing photons.

For comparison with observed galaxies, we plot in Fig. 7 the two observational results: the median Lyα EW of galaxies detected in the Large Area Lyman Alpha (LALA) survey, W1640 ~ 400 Å, and the average EW of six galaxies observed at z ≥ 6 in the Subaru deep field, ~145 Å (Nagao et al. 2007). The large LALA EWs are comparable to that we find for primordial dwarf galaxies, although the LALA galaxies likely do not host Pop III star formation (but see Jimenez & Haiman 2006). The detection of an EW of the He II λ1640 line ≥10 Å would be a stronger indication of a galaxy hosting primordial star formation, as shown in Fig. 7, although none has been found as of yet. We note that observed Lyman break galaxies at z ~ 3 have been found to have He II λ1640 EWs of ~2 Å (Shapley et al. 2003), consistent with what is expected for Wolf–Rayet stars formed in starbursts (see Schaerer & Vacca 1998; Brinchmann, Pettini & Charlot 2008).

### 3.4 Detectability of recombination radiation

In Fig. 9, we present our predictions for the observable recombination line fluxes, for each of the stellar clusters that we simulate. Fig. 10 shows the surface brightness in Hα as observed on the sky, for the two more massive stellar clusters, which each have a total mass in stars of 2.5 × 10⁵ M⊙. The fluxes in each plot, largely determined by our choices for the total stellar mass, are calculated using equation (10). While the larger H II region generated by the more massive stars encompasses more dense gas, creating more widely distributed emission in Hα, as shown in Fig. 10, the highest flux per square arcsecond is in the central region of the halo hosting the less massive stars. This is due again to the less dramatic dynamical response of the gas to photoheating, leading to higher densities, and thus higher recombination rates. Due to this effect, the highest

**Figure 8.** The ratio of the integrated fluxes in He II λ1640 and Hα, Fλ1640/FHa, as a function of time, for each of the four clusters simulated here, as labelled. The dashed horizontal line denotes the upper limit of this ratio for the strong Lyα emitter SDF J132440.6+273607 at z = 6.33, as reported by Nagao et al. (2005). Similar upper limits for Lyα emitters at z = 4.5 have been reported by Dawson et al. (2004).

**Figure 9.** The observed fluxes, f, as a function of time, of the same three recombination lines shown in Fig. 6, for the galaxy we simulate at z ~ 12.5. The fluxes are normalized to what would be observed with a spectroscopic resolution of R = 1000, and are computed using equation (10) assuming that the galaxy appears as an unresolved point source. Note that the flux in Lyα is an upper limit, as the present calculation does not take into account scattering in a neutral IGM.
fluxes are generated just after the birth of a stellar cluster, as shown in Fig. 9, when the density of the photoionized gas is still high, not having had time to expand in response to the concomitant heating. Indeed, Fig. 9 shows that the flux in H$\alpha$ from the more massive 25 M$_{\odot}$ star cluster may reach $\gtrsim 10 \times (R/1000)$ nJy before the breakout of the HII region. Catching the first galaxies when still in the earliest stages of their initial starbursts, within the first few $10^5$ yr, is thus likely to provide one of the best chances for observations of purely primordial stellar populations in the early Universe.

Aboard the JWST, the H$\alpha$ line would be observed with the Mid-Infrared Instrument (MIRI). Its pixel size of $\gtrsim 0.1$ arcsec would not resolve the brightest portions of the galaxies that we simulate, which, as shown in Fig. 10, are of order 0.01 arcsec. With a resolution capability of $R = 3000$, the MIRI has a sensitivity of $\gtrsim 200$ nJy for a signal to noise of 10, in exposures of $\sim 10^5$ s (see Panagia 2004), making it unable to detect even the brightest galaxies that we simulate, the flux in H$\alpha$ of these being $\lesssim 20$ nJy for $R = 3000$.

With a greater sensitivity of $\lesssim 100$ nJy (Panagia 2004), the Near Infrared Spectrograph (NIRSpec) operates in the wavelength range 0.7–5 $\mu$m, allowing it to possibly detect Ly$\alpha$ out to $z \sim 40$ and He II $\lambda 1640$ out to $z \sim 30$. However, the flux in He II $\lambda 1640$ is always below that in H$\alpha$ and, hence, is too low to be detected. The Ly$\alpha$ line, with the highest flux of the three recombination lines shown in Fig. 9, is also not directly detectable, with a flux falling well below the $\sim 100$ nJy sensitivity limit of NIRSpec. Furthermore, although the luminosity in Ly$\alpha$ is always intrinsically higher than that in H$\alpha$, before reionization the observable flux in Ly$\alpha$ may be dramatically decreased due to scattering in the neutral IGM (e.g. Dijkstra et al. 2007). Because we do not account for this effect in the present calculations, the Ly$\alpha$ fluxes presented here are only upper limits.

The Near Infrared Camera (NIRCam) aboard the JWST, which will be used to conduct deep surveys designed to detect the first galaxies, will be capable of detecting point source fluxes as low as $\sim 3.5$ nJy at a signal to noise of 10 for a $10^5$ s exposure (e.g. Gardner et al. 2006). With a resolution of $\gtrsim 0.03$ arcsec pixel$^{-1}$, the NIRCam would also not quite resolve the galaxies that we simulate. We can evaluate the possibility that NIRCam may detect them as point sources, however, by estimating the continuum flux of the galaxies as observed at $\sim 2 \mu$m. As can be read from Figs 6 and 7, the continuum flux, $\propto L_{\lambda 1640}/W_{\lambda 1640}$, varies only by a factor of a few between Ly$\alpha$ and He II $\lambda 1640$. Thus, for simplicity we assume that the continuum is roughly flat and calculate the specific continuum flux, as observed at $z = 0$, as

$$f_{\text{cont}} \sim \frac{L_{\lambda 1640}}{4\pi c D_L^2(z)} \frac{\lambda^2_{\lambda 1640}(1+z)}{W_{\lambda 1640}^0},$$

where $W_{\lambda 1640}^0$ is the EW in the rest frame of the galaxy, as defined in equation (9). This flux is well below the sensitivity limit of the NIRCam, and so we conclude that detection of the continuum radiation from the galaxies we simulate would also be undetectable. We note, however, that under favourable circumstances, gravitationally lensed emission from a primordial galaxy undergoing an only slightly more luminous starburst may be detectable with the JWST, given that lensing can boost the flux by a factor of order 10 (e.g.Refsdal 1964; Stark et al. 2007).

The first dwarf galaxies could be more luminous than we find here if the efficiency of star formation $\epsilon_{SF}$, defined as the fraction of the total baryonic mass in the galaxy contained in stars, is larger than what we have assumed in our simulations, where our choices for the total mass in stars correspond to modest values of $\epsilon_{SF} \sim 10^{-3}$–$10^{-4}$. A larger efficiency ($\epsilon_{SF} \sim 10^{-4}$), for the top-heavy IMFs considered here, would yield a cluster observable by NIRCam (e.g. Gardner et al. 2006). However, as we have demonstrated, the much higher ionizing flux from a $\sim 10^6$ M$_{\odot}$ cluster of massive primordial stars
would induce a strong hydrodynamic response which would lead to a rapid decline in the luminosity emitted in recombination radiation. Thus, even if such clusters can be identified by their continuum emission, the detection of recombination radiation, and with it information about the stellar IMF, may be beyond the capabilities of the JWST. Furthermore, the formation of such a massive cluster of primordial stars may face an impediment due to the strong radiative feedback within the cluster itself. Recent simulations of clustered star formation in the present-day Universe suggest that radiative feedback influences the fragmentation behaviour of the gas and possibly lowers the overall star formation efficiency (see Krumholz, Klein & McKee 2007; Bate 2009). However, the situation is by no means clear (e.g. Dale et al. 2005; Dale, Clark & Bonnell 2007).

It is possible that more massive (10^9–10^10 M_☉) primordial galaxies form at z ≥ 12, or form at lower redshift, making their detection feasible. However, such more massive, and therefore more luminous, galaxies are likely to also be more chemically evolved, and so may already be dominated by Pop II star formation. Thus, it may be that the galaxies which host pure Pop III starbursts, such as those we study here, will remain out of reach of even the JWST, although this critically depends on the poorly constrained process of metal enrichment in the early Universe (see e.g. Pan & Scalo 2007; Tornatore, Ferrara & Schneider 2007; Cen & Riquelme 2008; Johnson, Greif & Bromm 2008). We emphasize, however, that the dynamical effects studied here are likely to play a role even in the more luminous galaxies that will be detected, and are important to take into account in evaluating observations meant to constrain the SFR or the IMF.

4 SUMMARY AND CONCLUSIONS

We have presented calculations of the properties of the recombination radiation emitted from a primordial dwarf galaxy at z ~ 12.5, during the initial stages of a starburst. Our cosmological radiation-hydrodynamical simulations allow us to track the detailed dynamical evolution of the emitting gas in the central regions of the galaxy, and thus to study its effect on the emerging radiation. The goal of this study has been to determine the observable signatures of the initial starbursts in the first galaxies. In particular, we have aimed to find reliable indicators of the SFR and of the stellar IMF.

Owing to the escape of H{i}-ionizing photons into the IGM, we find only a weak correlation between the total mass in stars and the luminosity in hydrogen recombination lines. This suggests that Lyα and Hα, despite the high luminosity in these lines, may not serve as strong indicators of the SFR, unlike in the low-redshift Universe (e.g. Kennicutt 1983). The He II λ1640 line may be a more effective SFR indicator, as the luminosity in this line scales more closely with the total mass in stars, due to the lower escape fraction of He ii-ionizing photons.

We confirm that the ratio of He II λ1640 to either Lyα or Hα can be used as an IMF indicator, although its utility is compromised in some cases by the unequal escape fractions of H{i} and He ii-ionizing photons. The most robust IMF indicator, in terms of distinguishing between populations of massive (≥ 10 M_☉) and very massive (≥ 100 M_☉) Pop III stars, is the EW of He ii λ1640, as it is consistently higher for the more massive stars regardless of the total mass in stars. We note that while in principle the radiation emitted by a central accreting BH in a primordial dwarf galaxy could introduce complications for using He II λ1640 as IMF indicator (e.g. Tumlinson et al. 2001), recent work suggests that BH accretion is inefficient in the early Universe (e.g. Johnson et al. 2007; Pelupessy, Di Matteo & Ciardi 2007; Alvarez, Wise & Abel 2008; Milosavljević et al. 2008; Milosavljević, Couch & Bromm 2009). Such miniquasar activity may thus not result in appreciable observable radiation for the first ~10^8 yr.

In cases where the gas in primordial dwarf galaxies is unable to cool efficiently due to the photodissociation of H_2, it has been argued that, instead of a stellar cluster, a BH with mass ≥ 10^4 M_☉ may form by direct collapse (see Bromm & Loeb 2003; Lodato & Natarajan 2006; Begelman, Volonteri & Rees 2006; Spaans & Silk 2006; Regan & Haehnelt 2009). The fraction of dwarf galaxies that host the formation of such BHs is likely quite small, since the photodissociating flux required to suppress fragmentation is very high, well above the cosmological average at z ≥ 10 (Dijkstra et al. 2008). In the present work, we have chosen to focus on the presumably more common case that a stellar cluster forms (but see Begelman & Shlosman 2009). We do note, however, that such stellar mergers within dense clusters, such as those we consider here, may lead to the formation of ~10^3 M_☉ BHs (Omukai, Schneider & Haiman 2008; Devecchi & Volonteri 2009).

In terms of the detectability of the recombination radiation from the first galaxies, we have shown that due to the dynamical response of the gas to photoheating, a top-heavy IMF or a high star formation efficiency can be self-defeating, leading to a decrease in the line luminosity of the galaxy. We conclude that the detection of purely primordial dwarf galaxies at z ≥ 10 is likely to be beyond the capabilities of the JWST, although their detection may be just possible if the galaxies are strongly lensed. More luminous, 10^8–10^10 M_☉ (total mass), galaxies may thus be detected by the JWST; however, such more massive galaxies are likely to be already chemically enriched due to previous episodes of star formation in their progenitors. These systems are then expected to host Pop II star formation, or a composite of Pop II and Pop III, depending on the still poorly understood mixing of heavy elements in the first galaxies (e.g. Karlsson, Johnson & Bromm 2008).

Our results demonstrate how the radiation emitted from the first galaxies depends on the hydrodynamic effects of the photomization from clusters of massive stars. This is complementary to the results of previous studies (e.g. Schaerer 2002, 2003), which highlight the evolution of the emitted radiation owing to the aging of a stellar population. Clearly, both effects must be considered in future work.

The initial starbursts of the first galaxies may constitute the formation sites of the only metal-free stellar clusters in the Universe, since after the first several Myr supernova feedback can quickly enrich the galaxy with metals (e.g. Mori, Ferrara & Madau 2002; Kitayama & Yoshida 2005; but see Tornatore et al. 2007; Cen & Riquelme 2008). Also, a large fraction of the first dwarf galaxies, with masses of order 10^8 M_☉, may already form from metal-enriched gas (Johnson et al. 2008; see also Omukai et al. 2008); it is an important open question what fraction of dwarf galaxies forming at z ≥ 10 are primordial when they begin forming stars. Future observations of those first dwarf galaxies that do host primordial star formation offer one of the few opportunities for constraining the primordial IMF.
