Abstract
A recently introduced one-dimensional two-particle Bose–Hubbard model with a single impurity (Zhang et al 2012 Phys. Rev. Lett. 109 116405) is studied on finite lattices. The model possesses a discrete reflection symmetry and we demonstrate that all eigenstates odd under this symmetry can be obtained with a generalized Bethe ansatz if periodic boundary conditions (BC) are imposed. Furthermore, we provide numerical evidence that this holds true for open BC as well. The model exhibits backscattering at the impurity site—which usually destroys integrability—yet there exists an integrable subspace. We investigate the non-integrable even sector numerically and find a class of states which have almost the Bethe ansatz form. These weakly diffractive states correspond to a weak violation of the non-local Yang–Baxter relation which is satisfied in the odd sector. We introduce a method based on the Prony algorithm to check whether a numerically obtained wave function has the Bethe form or not, and if so, to extract its parameters. This technique is applicable to a wide variety of other lattice models.

1. Introduction

Exactly solvable models are always appreciated, not only because of the beauty they embody but also because of the pivotal role they can play. Among the exactly solvable models known so far, many are solved by the Bethe ansatz for the wave function [1]. A prerequisite for the consistency of this ansatz is the absence of diffraction [2], which was first explicitly pointed out by McGuire [3], and is formally characterized by the Yang–Baxter equation (YBE) [4, 5].

Recently, in an investigation motivated by atomic physics, the present authors discovered that a two-particle lattice model, whose continuum counterpart was previously claimed to be diffractive by McGuire [3], has eigenstates in the Bethe ansatz form although they do not span the whole Hilbert space [6, 7]. The model is very simple—it consists of two interacting identical bosons moving on a one-dimensional infinite lattice with a single site defect. The model possesses a reflection symmetry (parity) and the states odd under parity conform to the Bethe ansatz. Its original purpose was to investigate how the competition or cooperation between the interaction and the defect potential will affect the formation of bound states in the system, as interesting consequences are known in a similar object, i.e., the negative hydrogen ion H\(^-\) [8]. It turns out that the model can exhibit two kinds of exotic bound state, i.e., the bound state in the continuum [9] and the bound state at threshold [10–12].

It was convenient to consider the model on the infinite line because the bound state can be unambiguously discerned from the extended states belonging to the continuous spectrum. The Yang–Baxter relation is then sufficient to prove the validity of the Bethe ansatz in the odd subspace [7]. However, the situation is different on a finite lattice [13]. The boundary conditions (BC) impose now restrictions on the allowed momenta and as the impurity potential generates backscattered waves which in all known cases inevitably spoil integrability, it was not clear whether meaningful Bethe ansatz equations can be derived to determine the discrete spectrum and if so, whether their solutions span the full subspace with odd parity.

We shall address these questions in the following. Both can be answered in the affirmative for odd lattice size \(M\) and periodic BC. However, the framework of the Bethe ansatz has to be generalized to incorporate the non-trivial backscattering at the impurity. The standard approach (see e.g. [14]) defines the \(S\)-matrix as a relation between local amplitudes, whereas in our case the amplitudes have to be defined in a non-local way.

This paper is organized as follows. In section 2 we define the model and outline the formalism of the generalized Bethe ansatz. We show that it allows for a natural inclusion of the reflection (parity) symmetry and thus explains at the same time the integrability of the odd sector and the failure of the ansatz in the even sector. The representation of periodic BC in the formalism is discussed in some detail. We derive the Bethe ansatz equations for this case. The proof that their solutions span indeed the whole space is given in the appendix.

The partial solvability of this model contradicts common lore about the possibility to use the Bethe ansatz for systems with impurities which are neither located at the edges [15] nor have fine-tuned features which effectively remove the backscattering [16]. In the present case, our primary evidence comes from numerical data obtained by exact diagonalization. This is the subject of section 3. Here we study both open and periodic BC with three different methods to corroborate the fact that the odd sector is always integrable while the even sector is not. In particular, the Bethe ansatz checking method in section 3.2 allows us to confirm that all the eigenstates in the odd subspace have the Bethe form. On the other hand, the even sector exhibits eigenstates which are composed of only a few Fourier components and thus resemble Bethe states. These ‘weakly diffractive’ states are presented in section 3.3. We show in section 4 that some of them correspond to a weak violation of the generalized YBE, while the
ordinary YBE is strongly violated. Section 5 summarizes the results and lays out some directions for future work.

2. The model on a finite lattice

The model describes two spinless interacting bosons hopping on a lattice with a single site defect. On a one-dimensional lattice with an odd number \( M = 2M' + 1 \) sites, the Hamiltonian reads

\[
\hat{H} = \sum_{i=-M'}^{M'} \left[ -\left( \hat{a}_i^\dagger \hat{a}_{i+1} + \text{h.c.} \right) + \frac{U}{2} \hat{a}_i^\dagger \hat{a}_i \hat{a}_i^\dagger \hat{a}_i + V \hat{a}_0^\dagger \hat{a}_0 \right].
\]

We measure energy in units of the hopping integral; the parameters \( U \) and \( V \) are the strengths of on-site interaction and the defect potential at site 0, respectively. A crucial property of (1) is its invariance under the reflection \( \hat{P} \hat{a}_i \hat{P} = \hat{a}_{-i} \).

The Hamiltonian (1) conserves particle number and we work in the two-particle subspace. To set up the Bethe ansatz, we use the first quantized form of (1); the wave function reads

\[
\psi(x_1, x_2) = \sum \Delta \left[ \psi(x_1 + \Delta, x_2) + \psi(x_1, x_2 + \Delta) \right] + \left[ V(\delta_{x_1,0} + \delta_{x_2,0}) + U\delta_{x_1,x_2} \right] \psi(x_1, x_2).
\]

The group generated by \( \hat{P} \psi(x_1, x_2) = \psi(-x_1, -x_2) \) is \( \mathbb{Z}_2 \) and a state \( \psi(x_1, x_2) \) will be called even [odd] under parity if it satisfies \( \psi(x_1, x_2) = \psi(-x_1, -x_2) \).

2.1. Generalized Bethe ansatz

The one-dimensional elastic scattering between the particles (\( U \)) leaves the momenta pairwise invariant but the impurity potential \( V \) generates reflected waves with opposite momentum. Therefore only the absolute values of the momenta could serve as good quantum numbers. We try to generalize the Bethe ansatz, accounting for this simple type of diffraction through the introduction of an internal quantum number \( \sigma_j = \pm 1 \) for each particle which denotes the sign of the corresponding momentum. In this way the scattering phases in a system of spinless bosons are replaced by non-commutative \( S \)-matrices. The generalized ansatz reads,

\[
\psi(x_1, x_2) = S \sum_{R, n, \sigma_i} A_i^R e^{i[k_i n_{i+1} + k_{i+2} n_{i+2}]} \chi_R(x_1, x_2).
\]

The wavefunction is composed from plane waves defined in each region \( R = [ijk] \) with \( i, j, k \in \{0, 1, 2\} \) denoting the set \([x_1, x_2]\) in the \(x_1-x_2\) plane with

\[
[ijk] \iff x_i \leq x_j \leq x_k
\]

and \( x_0 = 0 \). \( \chi_R(x_1, x_2) \) is the characteristic function of region \( R \) and \( S \) symmetrizes the wave function with respect to \( x_1 \) and \( x_2 \). The pseudo-spin index \( \sigma_j \in \{+1, -1\} \) accounts for the possible backscattering at the impurity site. Due to the interactions at the boundaries of the regions \( R \), the amplitudes \( A_i^R \) are in general different in the six regions given by (4). For example, the amplitudes \( A_{[01]}^{[02]} \) and \( A_{[01]}^{[012]} \) are related by the \( \sigma_j \)-dependent scattering phase.
The scattering phases (5) are unimodular for real momenta $k_j$. On the other hand, the amplitudes $A_{+_+}^{[012]}, A_{++}^{[012]}$ are related to $A^{[012]}_{++}, A^{[021]}_{++}$ as

\[
\begin{pmatrix}
A_{++}^{[012]} \\
A_{++}^{[021]}
\end{pmatrix} = \begin{pmatrix}
1 + \frac{iV}{2s_1} & \frac{iV}{2s_1} \\
-iV & 1 - \frac{iV}{2s_1}
\end{pmatrix} \begin{pmatrix}
A^{[012]}_{++} \\
A^{[021]}_{++}
\end{pmatrix}.
\] (6)

The matrix appearing in (6) maps the amplitudes with particle 1 on the right of the impurity to the amplitudes corresponding to particle 1 being on the left of the impurity. This entails that it is not unitary but preserves instead the particle current across the impurity:

\[
\left|A_{++}^{[012]}\right|^2 - \left|A_{++}^{[021]}\right|^2 = \left|A_{+-}^{[012]}\right|^2 - \left|A_{+-}^{[021]}\right|^2.
\] (7)

This non-unitarity is the main obstacle to derive the Bethe ansatz equations even if the ansatz (3) should be consistent—which is not the case in general, the reason being the partial transmission/reflection generated by the impurity as exemplified in (6). It turns out that the parity symmetry of the model is able to restore integrability to a certain degree in the two-particle sector. To see that, it is mandatory to define the amplitude vectors in such a way that all S-matrices become unitary.

All scattering processes are necessarily unitary if considered not as a transfer from ‘right to left’ as in (6) but from ‘past to future’: one relates the set $A_{++}^{[012]}, A_{++}^{[021]}$ to the set $A_{++}^{[012]}, A_{++}^{[021]}$, i.e. the incoming to the outgoing waves,

\[
\begin{pmatrix}
A_{++}^{[012]} \\
A_{++}^{[021]}
\end{pmatrix} = \begin{pmatrix}
s_1 - \frac{iV}{2} & \frac{iV}{2} \\
-\frac{iV}{2} & s_1 - \frac{iV}{2}
\end{pmatrix} \begin{pmatrix}
A^{[012]}_{++} \\
A^{[021]}_{++}
\end{pmatrix}.
\] (8)

The matrix in (8) is unitary for real $k_1$ as it should be. However, it collects amplitudes belonging to different regions into a single vector, in contrast to (6). A consistent formalism has to express the scattering between particle 1 and 2 with non-local amplitudes as well which makes it convenient to split the regions [102] and [201] into two subregions (see figure 1),

\[
[102A] \leftrightarrow x_1 \leq 0 \leq x_2, \quad |x_1| \leq |x_2|,
\]

\[
[102B] \leftrightarrow x_1 \leq 0 \leq x_2, \quad |x_1| \geq |x_2|,
\]

\[
[201A] \leftrightarrow x_2 \leq 0 \leq x_1, \quad |x_1| \leq |x_2|,
\]

\[
[201B] \leftrightarrow x_2 \leq 0 \leq x_1, \quad |x_1| \geq |x_2|.
\] (9)

The interaction part of the Hamiltonian vanishes on the boundary between $[j0kA]$ and $[j0kB]$, so the corresponding amplitudes have to be the same. This will be guaranteed if the S-matrices are chosen correctly. We collect the local amplitudes $A_{s_1s_2}^R$ into the following eight four-vectors,
Figure 1. The eight regions of the $x_1$-$x_2$ plane used in the generalized Bethe ansatz. Regions $[102]$ and $[201]$ are split into two subregions although there is no interaction on the boundary between them (dashed line). This is the major difference between the formalism in this paper and the old formalism in [7].

$$A_1 = \left( A_{[012]}^{[102]} , A_{[201A]}^{[201A]} , A_{[1024]}^{[1024]} , A_{[210]}^{[210]} \right)^T,$$

$$A_2 = \left( A_{[012]}^{[102]} , A_{[201A]}^{[201A]} , A_{[1024]}^{[1024]} , A_{[210]}^{[210]} \right)^T,$$

$$A_3 = \left( A_{[021]}^{[102]} , A_{[201B]}^{[201B]} , A_{[1028]}^{[1028]} , A_{[120]}^{[120]} \right)^T,$$

$$A_4 = \left( A_{[021]}^{[102]} , A_{[201B]}^{[201B]} , A_{[1028]}^{[1028]} , A_{[120]}^{[120]} \right)^T,$$

$$A_5 = \left( A_{[012]}^{[102]} , A_{[201B]}^{[201B]} , A_{[1028]}^{[1028]} , A_{[120]}^{[120]} \right)^T,$$

$$A_6 = \left( A_{[012]}^{[102]} , A_{[201A]}^{[201A]} , A_{[1024]}^{[1024]} , A_{[210]}^{[210]} \right)^T,$$

$$A_7 = \left( A_{[021]}^{[102]} , A_{[201B]}^{[201B]} , A_{[1028]}^{[1028]} , A_{[120]}^{[120]} \right)^T,$$

$$A_8 = \left( A_{[021]}^{[102]} , A_{[201B]}^{[201B]} , A_{[1028]}^{[1028]} , A_{[120]}^{[120]} \right)^T. \quad (10)$$
The wavefunction reads in terms of the components $A_j^k$, $(j = 1 \ldots 8, k = 1 \ldots 4)$,

$$
\psi(x_1, x_2) = S \left\{ \sum_k \left[ A_k^j \chi_{A_j^j} + A_j^k \chi_{A_j^k} \right] e^{-i(k_1|x_1| + k_2|x_2|)} + \sum_k \left[ A_k^j \chi_{A_j^j} + A_j^k \chi_{A_j^k} \right] e^{i(k_1|x_1| - k_2|x_2|)} + \sum_k \left[ A_k^j \chi_{A_j^j} + A_j^k \chi_{A_j^k} \right] e^{i(k_1|x_1| + k_2|x_2|)} + \sum_k \left[ A_k^j \chi_{A_j^j} + A_j^k \chi_{A_j^k} \right] e^{-i(k_1|x_1| - k_2|x_2|)} \right\},
$$

(11)

where $\chi_{A_j^j} = \chi_{R(A_j^j)}(x_1, x_2)$ denotes the characteristic function of the region belonging to $A_j^j$. Note that the exponential factor is invariant under $\hat{P}$ and the same for all components $A_j^j$ of $A_j$. Moreover, we have for all $j = 1 \ldots 8$ the relation

$$
\hat{P} \left[ \chi_{A_j^j} \right](x_1, x_2) = \chi_{A_j^{j-1}}(x_1, x_2).
$$

(12)

It follows that

$$
\hat{P} \left[ \psi \left( x_1, x_2; \left\{ A_j^j \right\} \right) \right] = \psi \left( x_1, x_2; \left\{ A_j^{j-1} \right\} \right).
$$

(13)

which means that $\hat{P}$ acts on $\psi(x_1, x_2)$ by transforming each amplitude vector $A_j$ with the matrix $R_{ij} = \delta_{i,j-1}, k, l = 1, \ldots, 4$. The projection of $\psi(x_1, x_2)$ onto the even (odd) subspace is done by projecting the amplitudes $A_j$ onto the two-dimensional eigenspace of $\hat{R}$ with eigenvalue $+1$ ($-1$). The $S$-matrices $S(j, l) = S^{-1}(l, j)$ for $1 \leq j, k \leq 8$ connect ‘adjacent’

Figure 2. The eight amplitudes connected by $S$-matrices derived from the interaction terms in the Hamiltonian (2). The red lines correspond to the transfer of particle 1 (from amplitude 3 to 8), respectively, particle 2 (from amplitude 1 to 6) around the ring with periodic boundary conditions assumed.
The amplitudes $A_j = \hat{S}(j, j \pm 1)A_{j\pm1}$ ($8 + 1 = 1$ because $A_8$ is adjacent to $A_1$). $\hat{S}(2, 3)$, $\hat{S}(4, 5)$, $\hat{S}(6, 7)$, $\hat{S}(8, 1)$ correspond to an exchange of particle 1 with 2 and $\hat{S}(1, 2)$, $\hat{S}(5, 6)$ $[\hat{S}(3, 4), \hat{S}(7, 8)]$ to scattering of particle 1 [2] at the impurity, see figure 2.

The determination of the $S$-matrices from (2) is straightforward [7]. Defining

$$\alpha = \frac{s_1 - s_2 + i\frac{v}{2}}{s_1 - s_2 - i\frac{v}{2}}, \quad \beta = \frac{s_1 + s_2 + i\frac{v}{2}}{s_1 + s_2 - i\frac{v}{2}},$$

we find e.g. for $\hat{S}(1, 8)$,

$$\hat{S}(1, 8) = \begin{pmatrix} \alpha^{-1} & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & \alpha^{-1} \end{pmatrix},$$

and for $\hat{S}(2, 1)$,

$$\hat{S}(2, 1) = \frac{1}{s_1 + i\frac{v}{2}} \begin{pmatrix} -i\frac{v}{2} & 0 & s_1 & 0 \\ 0 & -i\frac{v}{2} & 0 & s_1 \\ s_1 & 0 & -i\frac{v}{2} & 0 \\ 0 & s_1 & 0 & -i\frac{v}{2} \end{pmatrix}.$$

Each amplitude can be obtained from any other by following a path connecting them on the circle depicted in figure 2. The ansatz (3), (11) will be consistent if the amplitudes $A_j$ are not overdetermined by the $S$-matrices. The amplitude $A_5$ is given by $A_1$ in two ways,

$$A_5 = \hat{S}(5, 4)\hat{S}(4, 3)\hat{S}(3, 2)\hat{S}(2, 1)A_1,$$

$$A_5 = \hat{S}(5, 6)\hat{S}(6, 7)\hat{S}(7, 8)\hat{S}(8, 1)A_1.$$  

Because of the relations

$$\hat{S}(8, 1) = \hat{S}(5, 4), \quad \hat{S}(7, 8) = \hat{S}(4, 3),$$

$$\hat{S}(6, 7) = \hat{S}(3, 2), \quad \hat{S}(5, 6) = \hat{S}(2, 1),$$

we obtain the analogue of the YBE,

$$\hat{S}(8, 1)\hat{S}(7, 8)\hat{S}(6, 7)\hat{S}(5, 6) = \hat{S}(5, 6)\hat{S}(6, 7)\hat{S}(7, 8)\hat{S}(8, 1).$$

This generalized consistency relation is quadrilinear instead of trilinear in the $S$-matrices. The reason is the existence of two different $S$-matrices describing the scattering between particle 1 and 2: although both $\hat{S}(1, 8)$ and $\hat{S}(7, 6)$ correspond to the exchange of the two particles, they are not identical; if we define $\hat{S}(1, 8) = \hat{S}_{12}$ and $\hat{S}(7, 6) = \hat{S}_{12}'$, together with $\hat{S}(8, 7) = \hat{S}_{20}$, $\hat{S}(1, 2) = \hat{S}_{10}$, we obtain the generalized YBE in the following, more familiar form,

$$\hat{S}_{10}\hat{S}_{12}'\hat{S}_{20}\hat{S}_{12} = \hat{S}_{12}\hat{S}_{20}\hat{S}_{12}'\hat{S}_{10}.$$  

This relation is formally equivalent to Sklyanin’s condition for integrable boundary terms [15]; the difference lies in the physical interpretation: in the systems considered by Sklyanin,
the particles are only reflected but not transmitted by the boundary potential (the amplitudes are local). Due to the parity invariance of (1), the $\hat{S}$-matrices are block-diagonal in the eigenbasis of $\hat{P}$. One finds for the even sector

$$\hat{S}^+_{10} = \frac{1}{s_1 - i\frac{\nu}{2}} \begin{pmatrix} i_{\frac{\nu}{2}} & s_1 \\ s_1 & i_{\frac{\nu}{2}} \end{pmatrix}, \quad \hat{S}^+_{12} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

and for the odd sector

$$\hat{S}^-_{10} = \frac{1}{s_1 - i\frac{\nu}{2}} \begin{pmatrix} -s_1 & i_{\frac{\nu}{2}} \\ i_{\frac{\nu}{2}} & -s_1 \end{pmatrix}, \quad \hat{S}^-_{12} = \begin{pmatrix} 1 & 0 \\ 0 & \beta \end{pmatrix},$$

$$\hat{S}^-_{20} = \frac{1}{s_2 - i\frac{\nu}{2}} \begin{pmatrix} i_{\frac{\nu}{2}} & s_2 \\ s_2 & i_{\frac{\nu}{2}} \end{pmatrix}, \quad \hat{S}^-_{12} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \alpha^{-1} \end{pmatrix}. \quad (22)$$

One checks now that (21) is violated for $s_1 s_2 U V \neq 0$ in the even sector but satisfied identically in $k_j$, $U$, $V$ in the odd sector. The ansatz (3) is therefore consistent for parity-odd states but fails in the even sector (see section 4).

2.2. Bethe ansatz equations

We confine the analysis from now on to the odd sector. The momenta $k_1$, $k_2$ are quantized by the BC. For periodic BC we have $\psi(x_1, x_2) = \psi(x_1 + M, x_2) = \psi(x_1, x_2 + M)$. Open BC correspond to $\psi(\pm (M' + 1), x_2) = \psi(x_1, \pm (M' + 1)) = 0$. We shall now demonstrate how periodic BC can be implemented within our non-local framework, leaving open BC for future study (they are treated numerically in section 3).

Because of the non-local nature of the amplitudes $A_j$, a given particle (say particle 1) moves in both directions simultaneously if the regions are connected via the $S$-matrices $\hat{S}(j_1, j_2)$. It is therefore convenient to treat each component $A^j_k$ separately, before projection onto the odd subspace. For example, the amplitude $A^{3}_1$ describes particle 1 with negative momentum $-k_1$ to the right of the impurity, $0 < x_1 < x_2 < M'$. $\hat{S}(2, 1)$ maps it to $A^{3}_1$ to the left of site 0. $\hat{S}(3, 2)$ corresponds to crossing the border between $[102\Lambda]$ and $[102\beta]$, leading to $A^{3}_3$, of course without changing the value of amplitude $A^{3}_1$. Now particle 1 is close to the left border of the system, periodicity for values $x_1 < -M'$ means proportionality of $A^{3}_3$ to $A^{3}_3$ with $0 < x_2 < x_1 < M'$. We have

$$\psi \propto A^{3}_3 e^{i(-k_1)(-M'-x)} = A^{3}_3 e^{i(-k_1)(M'-x+1)}, \quad (24)$$

or $A^{3}_3 = e^{i\text{M}A^{3}_3}$. Now the configuration of $A^{3}_3$ can be recognized as that of $A^{4}_1$, which is mapped by $\hat{S}(1, 8)$ back onto $A^{4}_1$. Similarly, $A^{3}_3$ describes a right-moving particle with positive momentum $k_1$, which is transferred by $\hat{S}(2, 1)$ to $A^{3}_1$, and in turn by $\hat{S}(3, 2)$ to $A^{3}_3$. This time the exchange between the two particles leads to a non-trivial phase factor, because the border between $[012]$ and $[021]$ is crossed. The regions $A^{3}_1$ and $A^{3}_3$ with $-M' < x_1 < 0 < x_2$ are related by periodicity as
meaning $A_3 = e^{ikM} A_3^1$, $A_3^1$ corresponds to $A_3^0$, mapped by $\hat{S}(1,8)$ onto the original amplitude $A_3^0$. The phase factor $e^{ikM}$ picked up during transfer from $A_3$ to $A_0$ (see the red arrows in figure 2) is independent from the sign of the momenta. Collecting all amplitudes and projecting onto the odd subspace, we conclude that the odd part of $A_1$ must be an eigenvector of

$$M_1 = \frac{1}{s_1 + i \frac{V}{2}} \begin{pmatrix} s_1 \beta^{-1} & i \frac{V}{2} \alpha^{-1} \\ i \frac{V}{2} \alpha^{-1} & s_1 \beta^{-1} \end{pmatrix}$$

(26)

with eigenvalue $e^{-ikM}$. In an analogous way, by transporting particle 2 around the ring, one obtains that the odd part of $A_1$ is an eigenvector of

$$M_2 = \frac{1}{s_2 + i \frac{V}{2}} \begin{pmatrix} s_2 \beta^{-1} & -i \frac{V}{2} \alpha^{-1} \\ -i \frac{V}{2} \alpha^{-1} & s_2 \beta^{-1} \end{pmatrix}$$

(27)

with eigenvalue $e^{-ikM}$. Indeed, $[M_1, M_2] = 0$, so both matrices are simultaneously diagonalizable. Moreover, they are unitary for real $k_1, k_2$. Let us denote their eigenbasis as $\{v_+ , v_- \}$. The corresponding eigenvalues of $\hat{M}_1$ and $\hat{M}_2$ read

$$\lambda_\pm^{(1)} = \frac{s_1 \left( s_1^2 - s_2^2 + \frac{U^2}{4} \right) \pm \left( U^2 - V^2 \right) \left( s_1^2 s_2^2 + \frac{V^2}{4} \left( s_1^2 + s_2^2 + \frac{U^2}{4} \right) \right)^{1/2}}{s_1 \left( s_1^2 - s_2^2 - \frac{U^2}{4} - \frac{UV}{2} \right) + i \left( \frac{V}{2} \left( s_1^2 - s_2^2 - \frac{U^2}{4} \right) + Us_1^2 \right)}$$

$$\lambda_\pm^{(2)} = \frac{s_2 \left( s_2^2 - s_1^2 + \frac{U^2}{4} \right) \pm \left( U^2 - V^2 \right) \left( s_1^2 s_2^2 + \frac{V^2}{4} \left( s_1^2 + s_2^2 + \frac{U^2}{4} \right) \right)^{1/2}}{s_2 \left( s_2^2 - s_1^2 - \frac{U^2}{4} - \frac{UV}{2} \right) + i \left( \frac{V}{2} \left( s_2^2 - s_1^2 - \frac{U^2}{4} \right) + Us_2^2 \right)}$$

(28)

One notes that the eigenvalue of $\hat{M}_2$ obtains from the corresponding eigenvalue of $\hat{M}_1$ by exchange of $k_1$ and $k_2$, as expected. If one writes

$$\lambda_\pm = \frac{a_j \pm ib}{c_j + id_j}$$

(29)

we have

$$a_j^2 + b^2 = c_j^2 + d_j^2,$$

(30)

which guarantees unimodularity of $\lambda_\pm^{(j)}$ for real $k_1, k_2$. The Bethe ansatz equations read

$$e^{-ikM} = \lambda_\pm^{(1)}(k_1, k_2), \quad e^{-ikM} = \lambda_\pm^{(2)}(k_1, k_2),$$

(31)

which are coupled equations for $k_1$ and $k_2$. In general both $v_+$ and $v_-$ yield solutions obtained from $\{\lambda_+^{(1)}, \lambda_+^{(2)}\}$ and $\{\lambda_-^{(1)}, \lambda_-^{(2)}\}$, respectively.

An interesting detail can be read off from (28) immediately: if $U = -V$ and $U > 0$ ($U < 0$) the eigenvalues $\lambda_\pm^{(1)}$ ($\lambda_\pm^{(2)}$) become 1 for all $k_1, k_2$. This means that all states in the
subspaces \( v \) (\( v_0 \)) have momenta quantized in multiples of \( \frac{2\pi}{M} \) as in the non-interacting system. The effects of the impurity and the interaction (being equal but with opposite sign) compensate each other in one of the invariant subspaces \( v \) and the particles behave in this subspace as if they were free bosons on a ring with \( M \) sites.

Although (31) has formally the same structure as the Bethe ansatz equations in the two-particle sector of known integrable systems, the right-hand sides are much more complicated, leading to more types of possible solutions. It turns out that there are not just real solutions and strings [14] but two additional types, which we shall discuss in detail in the next section, presenting a numerical analysis of the eigenstates.

### 3. Numerical analysis of three aspects

In this section we study the model via exact diagonalization on finite lattices, for both open and periodic BC. We shall use three methods to analyze the numerical data, corroborating the results of sections 2.1 and 2.2. Furthermore, they provide numerical evidence that the odd sector is integrable for open boundary conditions and even lattice size as well.

#### 3.1. Spectral graph

The first evidence that the odd-parity subspace is integrable while the even one is not comes from the behavior of the energy spectrum of the model as a function of \( V \) (or \( U \)).

In figure 3, we plot the spectrum of the model as a function of \( V \) in the odd and even parity subspaces and with open or periodic boundary conditions. We see that regardless of the boundary condition, levels in the odd subspace cross each other while levels in the even subspace repel each other. These two different behaviors strongly hint to the integrability of the odd subspace and the nonintegrability of the even subspace [17].

#### 3.2. Bethe-form checking

By full exact diagonalization of the Hamiltonian, we can obtain numerical values of all the eigenvalues and eigenstates of the model. A natural question is then whether it is possible to...
demonstrate that a wave function, whose value at each site \((x_1, x_2)\) is known, can or cannot be decomposed into the form of (3). To answer this question, first we note that, if the wave function has this form, its values on a line which lies entirely in a particular region (say, the line \(x_1 = 0, x_2 \geq 0\) in region \([0, 1]\)), is a superposition of at most four exponentials (if the four wave vectors \(\pm k_1, \pm k_2\) are all different, as is demonstrated below). Therefore, first we need to check whether the wave function evaluated on this line is a superposition of four exponentials.

3.2.1. Prony’s algorithm. Fortunately, there exists a beautiful algorithm, namely Prony’s algorithm [18], which can be used to check whether a function is a superposition of several exponentials and if it is, to extract the exponents. The logic of this algorithm is as follows. Let a function \(g_n\) defined on the integers be a superposition of four exponentials,

\[
g_n = w_1 e^{c_1 n} + w_2 e^{c_2 n} + w_3 e^{c_3 n} + w_4 e^{c_4 n},
\]

(32)

where the exponents \(c_i\)’s are assumed to be all different, and the \(w_i\)’s are all constant coefficients. Here we take four exponentials merely because of the context—the algorithm works for an arbitrary number of exponentials. Because the \(c_i\)’s are all different, the Vandermonde matrix

\[
K = \begin{pmatrix}
1 & e^{c_1} & e^{2c_1} & e^{3c_1} \\
1 & e^{c_2} & e^{2c_2} & e^{3c_2} \\
1 & e^{c_3} & e^{2c_3} & e^{3c_3} \\
1 & e^{c_4} & e^{2c_4} & e^{3c_4}
\end{pmatrix}
\]

(33)
is non-singular and the linear equation

\[
\begin{pmatrix}
1 & e^{c_1} & e^{2c_1} & e^{3c_1} \\
1 & e^{c_2} & e^{2c_2} & e^{3c_2} \\
1 & e^{c_3} & e^{2c_3} & e^{3c_3} \\
1 & e^{c_4} & e^{2c_4} & e^{3c_4}
\end{pmatrix}
\begin{pmatrix}
r_0 \\
r_1 \\
r_2 \\
r_3
\end{pmatrix}
= \begin{pmatrix}
e^{c_1} \\
e^{c_2} \\
e^{c_3} \\
e^{c_4}
\end{pmatrix}
\]

(34)

has a unique solution for the \(r_i\)’s. It is readily seen that this fact implies the linear iterative relation

\[
g_{n+4} = r_1 g_{n+3} + r_2 g_{n+2} + r_3 g_{n+1} + r_4 g_n,
\]

(35)

which holds regardless of the values of the \(w_i\)’s.

Now consider such a linear equation for the \(z_i\)’s (note that the \(4 \times 4\) matrix on the left hand side is a Hankel matrix),

\[
\begin{pmatrix}
g_n & g_{n+1} & g_{n+2} & g_{n+3} \\
g_{n+1} & g_{n+2} & g_{n+3} & g_{n+4} \\
g_{n+2} & g_{n+3} & g_{n+4} & g_{n+5} \\
g_{n+3} & g_{n+4} & g_{n+5} & g_{n+6}
\end{pmatrix}
\begin{pmatrix}
z_0 \\
z_1 \\
z_2 \\
z_3
\end{pmatrix}
= \begin{pmatrix}
g_{n+4} \\
g_{n+5} \\
g_{n+6} \\
g_{n+7}
\end{pmatrix}
\]

(36)

If the value of the function \(g\) is known at each integer \(n\), the \(4 \times 4\) matrix on the left-hand side and the \(4 \times 1\) vector on the right-hand side can be constructed, and the linear equation is well-posed. Now the point is that, in view of (35), the solution \((z_0, z_1, z_2, z_3)^T\) would be equal to \((r_0, r_1, r_2, r_3)^T\) if \(g\) has the form (32). That is, it is a constant vector independent of \(n\). This is a necessary condition for the function \(g\) to have the form (32).

Therefore, by constructing and solving the linear equation in (36) at different \(n\), and observing whether the solution varies with \(n\), one can determine whether a function \(g\) has the
form (32) or not. If it is, which means the values of the \( r \)'s have been determined, one has at least two options to determine the values of the \( c \)'s. One can either solve them inversely by using (34) as we will do below, or by diagonalizing the 4 × 4 transfer matrix in the following equation

\[
\begin{pmatrix}
    g_{n+4} \\
    g_{n+3} \\
    g_{n+2} \\
    g_{n+1}
\end{pmatrix} =
\begin{pmatrix}
    0 & 1 & 0 & 0 \\
    1 & 0 & 0 & 0 \\
    0 & 1 & 0 & 0 \\
    0 & 0 & 1 & 0
\end{pmatrix}
\begin{pmatrix}
    g_n \\
    g_{n+1} \\
    g_{n+2} \\
    g_{n+3}
\end{pmatrix}.
\]

which is a reformulation of the iterative relation (35).

Now let us come back to our problem. Suppose we take the line with \( x_1 = 0 \) and \( x_2 \geq 0 \), and consider the wave function on this line as a function of \( x_2 \). The range of \( x_2 \) depends on the boundary condition. In the case of open BC, we have to confine ourself to region [102] and \( x_2 \) can take values from 0 up to \( M' \); while in the case of periodic BC, we can advance into region [210] and \( x_2 \) can take values from 0 up to \( M - 1 \). We can then use Prony’s algorithm above to check whether the wave function has the Bethe ansatz form or not.

In our specific problem, the \( c \)'s are a permutation of \((i k_1, -i k_1, i k_2, -i k_2)\). It is tedious but straightforward to solve the \( r \)'s in (34) as

\[
\begin{align*}
    n_0 &= -1, \\
    n_1 &= e^{i k_1} + e^{-i k_1} + e^{i k_2} + e^{-i k_2} = -E(k_1, k_2), \\
    r_2 &= \left( e^{i k_1} + e^{-i k_1} \right) \left( e^{i k_2} + e^{-i k_2} \right) = 2,
\end{align*}
\]
The fact that \( r_1 = -r_1 \) regardless of the values of \( k_1, k_2 \) is a stringent condition for the wave function to have the Bethe form. Besides this condition, \( r_1 = -E \) is another very stringent one. Once these two conditions are verified, it is likely that the wave function has indeed the Bethe form. In figure 4, we show \( r_0 \) and \( -r_1 \) as functions of \( x_2 \) in different subspaces and under different boundary conditions. The lattice has \( M = 55 \) sites and the state in each panel is sampled unbiased as the one whose energy is the closest to \( 2 \). We see that, for the odd-parity states, \( r_0 \) and \( -r_1 \) are indeed independent of the position \( x_2 \) and take the values expected. On the contrary, for the even-parity states, they both fluctuate significantly, which rules out the possibility that the corresponding wave function has the Bethe form.

By (39) and (40), we can solve from the values of \( r_1, r_2 \) the values of \( \mu_{\pm j} = e^{ik_j} + e^{-ik_j} \) \((j = 1, 2)\), from which in turn we can solve the wave vectors \( k_1, k_2 \). Finally, we can plug \( k_1, k_2 \) into (3), solve for the amplitudes and compare the result with the one obtained by exact diagonalization. The inner product between them should be unity if they are the same.

We have carried out this algorithm on lattices with sizes between 15 and 31 and with both kinds of boundary condition. We used the multiple precision toolbox for MATLAB [19] to solve for the eigenstates and eigenvalues to high precisions (say, with 40–60 digits) and then analyzed the eigenvectors one by one by using Prony’s algorithm. In this way, we confirmed that all the odd-parity eigenstates have the form (3) while none of the even-parity eigenstates fit to it.

Here some remarks are necessary. First, we need high precisions for the eigenstates because—as we shall see in the following—some eigenstates decay exponentially in at least one direction. If the precision is not high enough, the true values of the \( g_i \)’s in (36) can be overwhelmed by the noise by orders of magnitude. Second, Prony’s algorithm is very sensitive to any perturbation to the wave function. Specifically, for the weakly diffractive states in figures 7 and 8 below, we get \( r_i \)’s as random as in figures 4(b) and (d). Therefore, the algorithm can only tell whether a state has exactly the Bethe form or not. It cannot distinguish weakly diffractive states from strongly diffractive states. Third, we see the algorithm as a layman’s tool for ruling out the integrability of a model. Instead of setting out with tedious analytic calculations, one can perform simple numerical diagonalizations and check the wave functions for Bethe form. Only if the result is positive, it is promising to continue with analytic analysis. In this way, we have confirmed that in a modified model, in which the dashed line in figure 1 has potential \( U \) as the other diagonal line (see [20] for a continuum variant of this model), about 7/8 of the energy eigenstates have the Bethe form; the others are diffractive and belong to the trivial representation of the symmetry group \( D_4 \) of the system.

3.2.2. Four main categories of states. Previously it was shown that the model on the infinite line has three continuum bands with different nature [6, 7]. It turns out that in correspondence there are three main categories of \((k_1, k_2)\)-pair in the odd sector, which are shown in the three panels of figure 5 separately and explained below (because the wave function is real, the \( r \)’s are real and thus \( \mu_{1,2} \) must be real simultaneously or complex conjugate to each other): (i) \( \mu_{1,2} \) are both real, and \( \max \{ |\mu_{1}|, |\mu_{2}| \} \leq 2 \). In this case, \( k_{1,2} \) are both real and we can always choose them as \( 0 \leq k_2 \leq k_1 \leq \pi \) (see figure 5(a)). The realness of \( k_{1,2} \) means that the two particles are both delocalized on the lattice and they are not bound to each other. This is the feature of the first-band states [6, 7]. (ii) \( \mu_{1,2} \) are both real, and \( \min \{ |\mu_{1}|, |\mu_{2}| \} \leq 2 < \max \{ |\mu_{1}|, |\mu_{2}| \} \). In this case, one wave vector is real while the other is complex (depending on the sign of \( V \), it can be purely imaginary or have a real part of
We observe that (see figure 5(b)), the magnitude of the imaginary part can be well approximated by
\[ \nu_{\text{imp}} = \text{asinh}(2) > 0. \]  
(42)

Here \( \nu_{\text{imp}} \) is the inverse of the localization length of the defect mode induced by the impurity.

This kind of \( k_1, k_2 \) indicates that one particle is localized by the impurity potential while the other is not, in accordance with the picture for the second band \([6, 7]\). (iii) \( \mu_{1, 2} \) are both complex, and \( \mu_1^* = \mu_2 \). As a result, \( k_{1,2} \) are complex and can be chosen in the form \( (k_1, k_2) = (k + i\nu, k - i\nu) \) with \( \nu > 0 \) and \( 0 < k < \pi \). It is observed that (see figure 5(c)), generally the relation
\[ \nu = \text{asinh}(U/(4\cos k)) \]  
(43)
holds approximately. This kind of complex \( k_1, k_2 \) with the relation (43) is what one expects for an interaction induced molecule state. Therefore, the corresponding state falls in the second band \([6, 7]\), where the two particles form a molecule and move on the lattice together. The approximate validity of (42), (43) is derived in the appendix using the Bethe ansatz equations (31). We have thus confirmed the existence of three distinct continuum bands from another perspective. Note that the number of states in the first band is of the order \( M^2 \), while those in the second and third bands are merely of the order \( M \). This is reasonable since in the latter two bands, always one degree of freedom is frozen. Besides the three primary categories above, there is yet a fourth possibility, i.e., (iv) \( \mu_{1,2} \) are both real, and \( |\mu_1|, |\mu_2| > 2 \). In this case, \( e_1^a \) and \( e_2^a \) are both real. This possibility is related to the two analytically solvable odd-parity bound states on an infinite lattice \([6, 7]\), which appear alternatively in the regions \( 0 < U/V < 1 \) and \( 1 < U/V < 2 \). In fact, by our analytic analysis before \([6, 7]\), these two bound states have the property of \( |\mu_1|, |\mu_2| > 2 \). Here it is observed that for given parameters \((V, U, M)\), this case occurs at most once. Moreover, due to the finiteness of the lattice size, the region where it occurs is a proper subset of the region \( 0 < U/V < 2 \). In figure 6, the region where the bound state exists is shown for a \( M = 31 \) lattice with open BC.

**Figure 5.** Classification of the wave vector pair \((k_1, k_2)\) for the odd-parity eigenstates in three primary categories. Each data point corresponds to a state. The parameters are \((V, U, M) = (-2, -1, 31)\) and the boundary condition is open. In (a), \( k_{1,2} \) are both real. The corresponding states belong to the first band. In (b), one wave vector is real while the other is purely imaginary, i.e., \((k_1, k_2) = (k, i\nu)\). The horizontal solid line indicates the value of \( \nu_{\text{imp}} \) (see equation (42)). The corresponding states belong to the second band. In (c), the two wave vectors are complex conjugates, i.e., \((k_1, k_2) = (k + i\nu, k - i\nu)\). The solid line indicates the function of (43). In (b) and (c), the deviations of the data points from the solid lines are too small to be visible on the current scale. By counting the number of states, we know that one state is missing on these three panels. It belongs to category (iv) and is a bound state in the continuum \([6, 7]\).
We prove in the Appendix for periodic boundary conditions that the first band contains
\( -\frac{M(M - 3)}{4} \) states, the second band \( M' \) states and the third band either \( M' \) or \( M' - 1 \) states, depending on the absence or presence of a bound state. Altogether this are \( -\frac{M(M^2 - 1)}{4} \) states, the full dimension of the odd subspace.

3.3. Momentum distribution

The ansatz wave function (3) in each region is a superposition of eight plane waves with symmetrically related wave vectors. To check whether an eigenstate indeed has this property or not, a natural idea is to do Fourier analysis and have a look at the momentum distribution of the wave function directly. Fortunately, this idea can be readily carried out in region [102], whose rectangular shape means that we have a set of plane waves as a complete orthonormal basis. We thus perform the (discrete) Fourier transform of the wave function in region [102] as follows:

\[
F(q_1, q_2) = \frac{1}{M' + 1} \sum_{x_1=-M'}^{0} \sum_{x_2=0}^{M'} \psi(x_1, x_2) e^{-i q_1 x_1 - i q_2 x_2} 
\]

where \( q_i = \frac{2\pi n_i}{M' + 1} \) \((i = 1, 2)\), with \( n_i = 0, 1, ..., M' \). Of course, \( q_i \) are defined only up to an integer multiple of \( 2\pi \). In the following, we will take them in the interval \([-\pi, \pi)\).

3.3.1. Weakly diffractive even-parity states. The simple Fourier analysis reveals interesting facts. For the odd-parity states, the eight plane waves are beautifully demonstrated in figures 7(a)–(c). In these three panels, we see eight sharp peaks symmetrically distributed\(^4\). From one peak, by inversion about the origin, reflection about the \( q_1, q_2 \) axes as well as the \( q_1 = \pm q_2 \) axes, we can get all the eight peaks. The Bethe form of the odd-parity states is thus vividly demonstrated. We have also depicted the wave functions in real space in figures 7(a')–(c'). They are apparently very regular.

\(^4\) The eight peaks are not as sharp as located on a single square, simply because the wave vectors \( k_{1,2} \) are generally not integer multiples of \( 2\pi/(M' + 1) \), as can be seen in figure 5(a).
For the even-parity states, something unexpected emerges. Because the YBE is violated for the even-parity states [7], diffraction is inevitable and the eight peaks are expected to disappear or at least be strongly smeared. However, for some states, they remain and are remarkably sharp. Two such states are shown in figures 7(d) and (g), with open and periodic BC, respectively. We see that the eight peaks look even sharper than their counterparts in figures 7(a)–(b), and they are symmetrically distributed as in the odd-parity case. Actually, in figures 7(d) and (g), the eight red squares contribute to 0.6609 and 0.6621 of the total weight of the corresponding wave function (in region [102]), respectively. Therefore, though the wave function (in region [102]) has not exactly the form (3) (as can be verified by using the Prony algorithm), it can be well approximated by it and is qualitatively close to it.

We call such a state a weakly diffractive state [21], since the diffraction-free picture survives to some extent and remains the most prominent feature of the wave function. Of course, not all even states are weakly diffractive. As shown in figures 7(e)–(f) and 7(h)–(i), some have a rather broad distribution in momentum space. In figures 7(e) and (h), the eight peaks are still prominent but the diffractive components are also apparent. In figures 7(f) and (i), the eight peaks are smeared out completely and the momentum components form four continuous arcs. Of course, the arcs are just the energy isolines of a free particle in a two dimensional square lattice because all scattering is elastic.

In figure 8, we show another three weakly diffractive states. The common feature of them is that there are not eight, but four peaks in the momentum distribution. One should note that in panel (b), two squares on opposite sides of the Brillouin zone should be identified.

Figure 7. The wave function in region [102] (see figure 1) in momentum space (left three columns, labeled as (a)–(i)), and the full wave function in real space (right three columns, labeled as (a′)–(i)′ in correspondence). In the left three columns, $|\Psi(q_1, q_2)|^2$ is shown and in the right three columns $|\psi(x_1, x_2)|^2$. In the first row, the three states have odd parity and the boundary condition is open in (a) and (b), while periodic in (c). In the second and third rows, the states have even parity, and the boundary condition is open and periodic, respectively. In all panels, $(V, U, M') = (-1, -1, 47)$. From (a) to (i), the energy $E$ of the corresponding state is 0.7020, 0.7994, 0.8600, −0.9580, −1.0134, −0.8033, 0.9193, 0.7093, and 0.6205, respectively.
The weakly diffractive states remind us of the quantum scar states appearing in some quantized classically chaotic billiards [22]. There, although most eigenstates manifest apparent chaotic features, some do exhibit very regular behavior.

4. The generalized YBE in the even sector

The weakly diffractive states in figures 7(d) and (g) can be understood by examining the generalized YBE (21) quantitatively. As mentioned in section 2.1, the generalized YBE (21) is violated in the even sector. We find explicitly for the difference

\[ \hat{S}_D = \hat{S}_{10} \hat{S}_{12} \hat{S}_{20} \hat{S}_{12} - \hat{S}_{12} \hat{S}_{20} \hat{S}_{12} \hat{S}_{10} \]  

(45)

the expression \((s_j = \sin k_j)\)

\[ \hat{S}_D = \frac{-2iUVs_1s_2\hat{\sigma}_z}{(s_1 - i\frac{U}{2})(s_2 - i\frac{U}{2})(s_1 - s_2 + i\frac{U}{2})(s_1 + s_2 - i\frac{U}{2})} \]  

(46)

where \(\hat{\sigma}_z\) is the usual Pauli matrix.

We see that \(\hat{S}_D\) vanishes if \(U\) or \(V\) vanishes. In the opposite limit of \(\max|U|, |V|\) = \(\infty\), \(\hat{S}_D\) vanishes again. Under these circumstances, the model is fully integrable. For finite \((U,V)\), \(\hat{S}_D\) vanishes also if \(\sin k_1 = 0\) or \(\sin k_2 = 0\). This case is forbidden in the ansatz (3) because the scattering at the impurity would lead to a vanishing wave function as \(e^{iks} = e^{-iks}\) for \(k = 0, \pi\). Therefore, there are no admissible even-parity Bethe states for one of the \(k\)'s being zero or \(\pi\). Nevertheless, there may be even-parity states composed of a set of plane waves with one component having very small \(k\)—the corresponding amplitudes would not become strongly attenuated during scattering because the YBE is only weakly violated. These amplitudes could constitute therefore the dominant component of the wave function and lead to the weakly diffractive states observed in figure 7. Indeed, the momentum distribution of the states in panels (d) and (g) of figure 7 has peaks at values of \(k_1\) (or \(k_2\)) close to 0 or \(\pm \pi\), respectively. The states in figures 8(a) and (b) can be understood as the extreme limits of the states in figures 7(d) and (g), respectively.

However, we note that the weakly diffractive state in figure 8(c) cannot be understood in this way. The state apparently has \(k_1 \approx k_2\), but \(\hat{S}_D\) does not vanish at \(k_1 = k_2\). The momenta \(k_j\) can never coincide in the Bethe ansatz for similar reasons as \(k_j = 0, \pi\) are forbidden. States
having approximately this property are not ruled out in the even sector and they do appear. Moreover, they are not confined to special values of $U, V$ and therefore there must be a general reason for their existence. At present, this poses an open problem.

Finally, let us note that the argument breaks down if one tries to use the standard formalism as was done in [7]. There the amplitudes were defined locally and the YBE has the trilinear form

$$\hat{S}_{12}\hat{S}_{10}\hat{S}_{20} = \hat{S}_{20}\hat{S}_{10}\hat{S}_{12}. \quad (47)$$

The kernel of the corresponding difference matrix $\hat{S}_D$ is the odd subspace [7], so the integrability condition is satisfied for odd states also in this formalism. However, if one projects $\hat{S}_D$ onto the even subspace, it never becomes zero, not even small, for $UV \neq 0$. Within this framework, all weakly diffractive states appear mysterious, as the YBE is always strongly violated.

5. Conclusions

We have studied a one-dimensional Bose–Hubbard model with a single defect in the two-particle sector on finite lattices both analytically and numerically. The system, though simple, shows a rich variety of properties and peculiar features, some of them appearing counter-intuitive. The impurity potential should render the model nonintegrable because incoming waves are partly transmitted and partly reflected at the central site. Nevertheless, half of the eigenstates have the Bethe ansatz form, i.e. they are characterized by only two wave numbers $k_1, k_2$. Similar to systems with boundary potentials, only the absolute values of $k_1, k_2$ are good quantum numbers. To analyze the eigenstates properly, the Bethe ansatz for spinless particles with scalar scattering phases has to be generalized by the introduction of non-commutative scattering matrices and non-local amplitudes. This formalism is adapted to incorporate the $\mathbb{Z}_2$-symmetry (parity), which is probably the source of the partial integrability of our model. Only odd-parity states conform to the Bethe ansatz, whereas the even-parity states show diffraction and avoided crossings, a hallmark of non-integrable systems.

We have derived the generalized Bethe ansatz equations and proven that their solutions span the complete odd subspace for periodic boundary conditions. Moreover we have studied the model numerically for periodic and open boundary conditions by using a novel technique to check for the presence of non-diffractive states after exact diagonalization. This technique is numerically exact and very general. It can be used in many situations if one suspects that a model may be (fully or partially) diffractionless but cannot be treated analytically. We have used the method to confirm full integrability in a variant of our model introduced by Longhi and Della Valle [23]—the infinite lattice is replaced by a semi-infinite one and the impurity sits at the end. Putting open boundary conditions at the other end, we have studied this system with the checking algorithm and find that all states have the Bethe form. This comes not unexpected, as many boundary potentials do not destroy integrability [15].

Furthermore, we have analyzed the numerically obtained eigenstates in both sectors via Fourier transform to extract the momentum distribution. This gives another (approximate) criterion to test whether a given state is close to the Bethe ansatz. We confirm in this way the integrable nature of the odd sector. In the even sector, another unexpected phenomenon appears: some of the states show a momentum distribution with eight strong peaks, very similar to what one would expect for a state in Bethe form. The peaks are located near $k = 0, \pi$, where the generalized Yang–Baxter relation is satisfied also in the even sector. Now the values $k = 0, \pi$ are forbidden within the Bethe ansatz formalism and we are confronted
with a novel object: eigenstates which have ‘almost’ the Bethe form and can therefore be
called ‘weakly’ diffractive. Interestingly, the standard approach employing local amplitudes
does not show this connection between a weakly violated Yang–Baxter relation and weakly
diffractive states, because the former is strongly violated for arbitrary momenta.

A natural direction of further research would be the question whether systems with an
integrable sector due to the presence of a non-local symmetry (in our case space inversion
with respect to the impurity site) exist also for more than two particles. The first candidate to
investigate would be the Lieb–Liniger model of spinless interacting bosons defined in the
continuum [24], where the bosons interact via a delta-potential with a single impurity.
Another system which could exhibit an integrable subspace is the translational invariant
Lieb–Liniger model of discernible particles with interactions breaking the permutation
symmetry. It has been studied for three particles in [21, 25]. Here, a preliminary investigation
indicates the presence of an integrable sector similar to our model. The next step would be to
study other observables like correlation functions [25, 26] and the interplay of both sectors in
the real-time dynamics [27].

Appendix. Proof of Completeness

We shall prove the full integrability of the sector with negative parity for odd lattice size $M$
and periodic boundary conditions by showing that the Bethe ansatz equations (31) have
$(M^2 - 1)/4$ distinct solutions. We are guided in this effort by the numerically obtained types
of possible eigenstates in section 3.2.2.

We begin by assuming both $k_1$ and $k_2$ real, corresponding to the
first band. Without loss of generality, we set $0 \leq k_2 < k_1$ and suppress the index $+/$. Taking the logarithm of (31), one obtains

\[
\begin{align*}
  k_1 &= \frac{2\pi}{M} m_1 - \arg\left(\lambda^{(1)}(k_1, k_2)\right), \\
  k_2 &= \frac{2\pi}{M} m_2 - \arg\left(\lambda^{(2)}(k_1, k_2)\right).
\end{align*}
\]

(\text{A.1}) (\text{A.2})

The integers $m_j$ are the quantum numbers of the solution. They range over the set
$0, 1, \ldots, M'$. The maximal number of solutions is obtained if each pair $0 \leq m_2 \leq m_1 \leq M'$
would correspond to an admissible solutions of (\text{A.1}), (\text{A.2}). Consider the function $\tilde{k}_j(m_1, k_2)$
obtained as solution of (\text{A.1}) for given $m_1$ and and arbitrary $k_2 \in [0, \pi]$. Because $-\pi \leq \arg(\lambda^{(1)}(k_1, k_2)) \leq \pi$, we have $[(2m_1 - 1)\pi/M \leq \tilde{k}_1(m_1, k_2) \leq (2m_1 + 1)\pi/M$ for $m_1 > 1$ and $0 \leq \tilde{k}_1(0, k_2) \leq \pi/M$ for $m_1 = 0$. Drawn in the $k_1/k_2$-plane, the $\tilde{k}_1(m_1, k_2)$ form
at most $M' + 1$ different lines located in the stripes $s(m_1) = \{k_1 \in I_{m_1}, k_2 \in [0, \pi]\}$ with
$I_{m_1} = [(2m_1 - 1)\pi/M, (2m_1 + 1)\pi/M]$ for $m_1 \geq 1$ and $I_0 = [0, \pi/M]$ for $m_1 = 0$. In the same
way, the $M' + 1$ graphs of the functions $\tilde{k}_2(m_2, k_1)$ occupy an orthogonal set of stripes in the
$k_1/k_2$-plane. Their crossing points correspond to a solution of the coupled equations (\text{A.1}) and
(\text{A.2}). Because of the symmetry $\lambda^{(1)}(k_2, k_1) = \lambda^{(2)}(k_1, k_2)$, it is clear that for $m_1 = m_2$ the
crossing point is located at $k_1 = k_2$. Now it is easy to see that the wavefunction (3) vanishes for $k_1 = k_2$ because the scattering phase $\alpha(k, k) = -1$, a feature shared by all models solvable by Bethe ansatz. Therefore the set $\{(m_1, m_2)\}$ with $m_1 = m_2$ has to be excluded from the list of possible quantum numbers. The variation of $\arg(\lambda^{(1)}(k_1, k_2))/M$ with $k_1$ for fixed $k_2$ is of order $M^{-2}$ in each stripe $s(m_1)$, therefore there is exactly one solution of (A.1) for all $k_2$ if $\arg(\lambda^{(1)}(k_1, k_2))$ is continuous as function of $k_1$ in $I_{m_1}$ and large $M$. If $\lambda^{(1)}(k_1, k_2)$ passes through $-1$, its argument changes discontinuously from $\pm \pi + \pi$ to $\pm \pi$. If such a jump is located at $k_1^0 \in I_{m_1}$, a simple geometrical argument shows that it depends on the sign of $\lambda^{(1)}(k_1, k_2)/\alpha_1$ which can be assumed to be constant throughout the interval $I_{m_1}$ for sufficiently large $M$ whether a solution exist or not. If $-\lambda^{(1)}(k_1, k_2)/\alpha_1 > 0$, there is no solution to (A.1) (arg($\lambda^{(1)}(k_1)$) jumps from $-\pi$ to $\pi$) and if $-\lambda^{(1)}(k_1, k_2)/\alpha_1 < 0$ we have two solutions (arg($\lambda^{(1)}(k_1)$) jumps from $\pi$ to $-\pi$). Now arg($\lambda^{(1)}(k_1)$) is symmetric with respect to $\pi/2$, depending on $k_1$ only through $\sin k_1$, therefore $\lambda^{(1)}(k_1, k_2)/\alpha_1 = -\lambda^{(1)}(k_1, k_2)/\alpha_1|_{k_1^0}$ holds. If the interval $I_{m_1}$ contains no solutions because of a discontinuity at $k_1^0$, the interval $I_{m_1}$ containing $\pi - k_1^0$ will contain two solutions. This argument is valid for all $1 \leq m_1 < M'$, which means that the sum of the number of solutions in intervals $I_1 \ldots I_{(M-3)/2}$ equals $(M - 3)/2$. The intervals $I_0$ and $I_M$ require a separate treatment because $\lambda^{(1)}(0, k_2) = \lambda^{(1)}(\pi, k_2) = \mp \text{sign}(V)$ and $-\lambda^{(1)}(k_1)$ is either zero or $\pm \pi$ at these points. If it is zero, the interval $I_0$ contains no solution and $I_M$ contains one solution. If $-\lambda^{(1)}(0, k_2) = \pi$, $I_0$ contains one solution and $I_M$ none. For $-\lambda^{(1)}(0, k_2) = -\pi$ the situation is reversed. We conclude that the total number of solutions to (A.1) for fixed $k_2$ equals $M'$. The solutions to (A.1), (A.2) pertaining to $\nu_+$, respectively $\nu_-$, are parametrized by the quantum numbers $(m_1, m_2)$ with $m_2 < m_1$ and $m_1, m_2$ may take $M'$ different values. This leads altogether to $2(M - 1)(M - 3)/8$ solutions in the first band. Figure A1 shows an example for $M = 11$.

**Figure A1.** Graphical solutions of (A.1), (A.2) for $U = 3$, $V = -2$ and $M = 11$. The blue (red) lines correspond to $\nu_+$ ($\nu_-$). Dashed lines denote the values $k_j = 2m_j \pi/M$ obtained for the non-interacting model.
Compared with the total number \( M^2 - 1 \) of states in the sector with negative parity, \( M^2 - 1 \) states are missing. These are states with complex momenta and are located in the second and third band.

From (28) one sees that \( \lambda_{\pm}^{(2)}(k_1, k_2) \) may stay unimodular if \( k_1 \sin \nu_1 \) is purely imaginary, as then \( a_1, b_1, c_2, d_2 \) remain real and unimodularity follows from (30). States of this form constitute the second band. This entails either

\[
\nu = \nu_1 \quad \text{or} \quad \nu = \pi - \nu_1
\]

with \( \nu_1 \) real. In the first case, \( \nu = \nu_1 = i \sinh \nu_1 \), (31) for \( k_1 \) reads then

\[
\lambda_{\pm}^{(1)}(\nu, \nu_1) = \nu \pm e^{M \nu_1},
\]

i.e. \( \lambda_{\pm}^{(1)}(\nu, \nu_1) \) becomes exponentially large in \( M \) for \( \nu > 0 \). This means \( \nu \sim -\sinh(0.75) \approx 0.6931 \), as expected for a bound state at the impurity site corresponding to the lower edge of the free band. For \( \nu > 0 \), a solution exists if \( \nu = -\sinh \nu_1 \), the second case above. To proceed, we calculate the numerator of \( \lambda_{\pm}^{(1)}(\nu, \nu_1) \) for \( \nu \sim -\sinh (V/2), V < 0 \) (first case),

\[
a_1 \pm ib \sim \frac{|V|}{2} \left( \frac{U^2 - V^2}{4} - s_1^2 \pm \left| s_2^2 - \frac{U^2 - V^2}{4} \right| \right)
\]  \hspace{1cm} (A.3)

It follows that for \( s_2^2 > (U^2 - V^2)/4 \) the numerator of \( \lambda_{\pm}^{(1)}(\nu, \nu_1) \) vanishes as well as the denominator at \( \nu = \sinh(V/2) \) excluding \( \nu_1 \). Similarly, for \( s_2^2 < (U^2 - V^2)/4, \nu_1 \) is excluded: for all values of the parameters \( U, V \) and \( k_2 \) only one of the vectors \( \nu_1 \) may contribute to a state in the second band. The same conclusion holds for \( \nu \sim \sinh(V/2), V > 0 \). Let \( \nu_2(k_2) \) denote the solution of \( e^{M \nu_2} = \lambda_{\pm}^{(1)}(\nu, k_2) \) for the appropriate \( \nu_2 \) as function of \( k_2 \in [0, \pi] \). For large \( M \), \( \nu_2(k_2) \) will lie in a bounded interval \( I_\nu \) close to the limiting value \( \sinh(V/2) \). The equation for \( k_2 \) reads as before

\[
k_2 = \frac{2\pi}{M} \frac{M}{m - \arg(\lambda_{\pm}^{(1)}(\nu, k_2))}
\]  \hspace{1cm} (A.4)

We obtain again \( M' + 1 \) stripes \( k_2 \in I_\nu \). The same argument as above (which was independent from the value of \( k_2 \), whose role is now played by \( \nu \)) shows that \( M' \) solutions of (A.4) exist as function of \( \nu \). Because \( \nu_2(k_2) \) is bounded for \( 0 \leq k_2 \leq \pi \), there exist always \( M' \)
crossing points as admissible solutions of (31). Figure A2 presents an example of the case $U = -2, V = 1$, in which all solutions belong to $v_s$.

The third band is composed of states with complex conjugated momenta $\nu = k_0 - i\nu, k_2 = k_0 + i\nu$. This type is well-known as ‘string solution’ in most integrable systems. In our case, it is not obvious that the above ansatz is consistent given the complicated form of $\lambda_\pm(j)$ in (28). From (31) follows that $\lambda(1, 1) = \pm \lambda(2, -1)$, which can be checked using $s_2 = s_1^*$ and the identity (30). The ansatz is therefore consistent. Taking $\nu > 0$, the denominator of $\lambda(1, 1)$ must tend to zero for $M \to \infty$, leading now to the relation $k_0 \sinh \nu \sim -U/4$. This means that $k_0 < \pi/2$ for $U < 0$ and $k_0 > \pi/2$ for $U > 0$. The numerator of $\lambda(1, 1)$ reads then

$$a_1 \pm ib \sim \left( \sin^2 k_0 \cosh \nu + \frac{U^2}{16}\right)[-iU \pm |U|].$$

(A.5)

For $U < 0$, the numerator of $\lambda(1, 1)$ vanishes, lifting the divergence, and for $U > 0$, the numerator of $\lambda(1, 1)$ is zero. Again only one of the $v_s$ yields solutions of (31), similar to the second band. The function $\tilde{\nu}(k_0)$ is now defined only in one of the intervals $I_\nu = [0, \pi/2]$ ($U < 0$) and $I_\nu = [\pi/2, \pi]$ ($U > 0$). To determine $k_0$ we consider

$$\lambda(1)(k_0, \nu)\lambda(2)(k_0, \nu) = e^{-2ik_0 M}$$

(A.6)

from which we obtain

$$k_0 = \frac{\pi M}{M} - \frac{\arg(\lambda(1)\lambda(2))}{2M}. \tag{A.7}$$

Now the $M' + 1$ stripes have width $\pi/M$ and are located in $I_\nu$ or $I_\nu$. One may again infer that there are $M'$ admissible solutions $\tilde{k}_0(\nu)$ and therefore at most $M'$ crossing points with the function $\tilde{\nu}(k_0)$. However, because the latter is not bounded in $k_0$, diverging in the vicinity of $k_0 = \pi/2$, it is not clear whether the third band contains indeed $M'$ solutions or only $M' = 1$. 

Figure A3. Graphical solution of (31) for the states in the third (molecule) band and parameters $U = -2, V = 1$ and $M = 11$. In this case no bound state exists in the infinite system and the third band contains $M' = 5$ states belonging to $v_s$. Dashed lines denote the values $k_0 = m\pi/M$. 

J. Phys. A: Math. Theor. 47 (2014) 465303 D Braak et al

22
Figure A3 shows an example where the former is the case—for parameters at which no bound state exists in the infinite system.

From the analysis in [7] we know that at most one bound state may appear in the infinite system. This cannot change in the finite case (i.e. there can be no more bound states for finite $M$ than for $M \to \infty$). This means that at most one state from the third band can become a bound state in certain parameter ranges, which depend for finite $M$ not only on $U$, $V$ but also on $M$ as seen in figure 6.

It follows that the Bethe ansatz equations have at least $(M^2 - 1)/4 - 1$ solutions in the three bands considered. The missing state is a bound state where both $\sin k_1$ and $\sin k_2$ are purely imaginary. This state exists only for negative $U$, $V$ with $|U| < 2|V|$. A more detailed analysis could reveal the exact conditions (including the dependence on $M$) under which a molecule state from the third band transforms into a bound state. Here we have confined ourselves to the proof that all states in the sector with negative parity are solutions of (31).
