(August 13, 2018)

We study the optical conductivity in A₃C₆₀ (A = K, Rb). The effects of the electron-phonon interaction is included to lowest order in the coupling strength λ. It is shown that this leads to a narrowing of the Drude peak by a factor 1 + λ and a transfer of weight to a mid-infrared peak at somewhat larger energies than the phonon energy. Although this goes in the right direction, it is not sufficient to describe experiment.

I. INTRODUCTION

The optical conductivity in A₃C₆₀ (A = K, Rb) has an unusual and interesting behaviour. The weight of the Drude peak is reduced by one order of magnitude relative to the weight for free electrons with the appropriate band mass. Much of the missing weight appears instead in a “mid-infrared” structure at about 0.06 eV. This suggests very strong interaction effects, e.g., electron-phonon or Coulomb interaction. The understanding of the optical absorption could therefore contribute much to the understanding also of other properties of A₃C₆₀.

A₃C₆₀ has orientational disorder, with the C₆₀ molecules taking, more or less randomly, one out of two preferential orientations. This orientational disorder leads to a substantial modification of the optical conductivity in one-particle calculations. For an ordered system, the Drude peak collapses to a δ-function, while the disorder leads to a broad Drude peak. The calculated optical conductivity furthermore shows a structure at somewhat larger energies than the experimental mid-infrared structure, although the structure is less pronounced and at higher energy than in the experimental spectrum. More serious is, however, that the weight and width of the Drude peak are much larger than the experimental results. Although it is hard to separate the theoretical results in a Drude and a mid-infrared structure, it may be estimated that the theoretical Drude width is more than a factor of ten too large.

The strong reduction of the Drude width suggests very strong renormalization effects, e.g., due to the electron-phonon or electron-electron interactions. The fullerenes have phonons with an energy of about 0.06 eV, which show a strong coupling to the electrons. Since these phonons may transfer weight from the Drude peak to a mid-infrared structure, we here study the effect of phonons.

We limit ourselves to calculating the electron self-energy to lowest order. This is sufficient if Migdal’s theorem is valid. It is, however, questionable if this is true for the fullerenes, and we should keep in mind that higher order effects may be important. To obtain the optical conductivity we calculate the current-current response function. We can neglect vertex corrections, since the electron self-energy is q-independent in our approach. The current-current response function is then reduced to a product of two electron Green’s functions.

We find that the electron-phonon coupling leads to a narrowing of the Drude peak by about a factor of 1/(1 + λ), where λ is the is the electron-phonon coupling constant. Although this goes in the right direction, it is by far not sufficient to explain the experimental data.

In Sec. II we present the formalism and the model. In Sec. III we show the results and in Sec. IV multiplet effects are briefly discussed. The results and other possible explanations of the narrow Drude peak are discussed in Sec. V.

II. FORMALISM AND MODEL

The optical conductivity is given by

\[ \text{Re} \sigma_{\alpha\beta}(\omega) = \text{Re} \lim_{\mathbf{q} \to 0} \frac{i}{\omega} \pi_{\alpha\beta}(\mathbf{q}, \omega) \]  

where

\[ \pi_{\alpha\beta}(\mathbf{q}, \omega) = -i \int_0^\infty dt e^{i\omega t} \langle 0 | j_{\alpha}^{\dagger}(\mathbf{q}, t) j_{\beta}(\mathbf{q}, 0) | 0 \rangle. \]

Here \( j \) is the current operator and \( | 0 \rangle \) is the ground-state. Below, we use a formalism where the electron self-energy is \( \mathbf{q} \)-independent. It can then be shown that the vertex corrections in the current-current response function vanish for \( \mathbf{q} \to 0 \), due to the odd parity of the current operator. We can then write the optical conductivity as a product of two Green’s functions, only keeping a simple bubble of dressed Green’s functions in the diagrammatic expansion of \( \sigma \). If we express the current operator as

\[ j_{\alpha} = \sum_{\sigma} \sum_{n'\sigma'} v_{nn'}^{\alpha} c_{n\sigma}^{\dagger} c_{n'\sigma'}. \]
the optical conductivity is given by

$$\text{Re} \sigma_{\alpha\beta} = \frac{2}{\omega} \text{Re} \sum_{n\alpha, m\beta} \sum_{n'm'} v_{nn'}^{\alpha*} v_{mm'}^{\beta} \times \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} G_{mm'}(\omega + \omega') G_{nn'}(\omega')$$

(4)

where $G$ is the electron Green’s function. This can be rewritten as

$$\text{Re} \sigma_{\alpha\beta} = \frac{2\pi}{\omega} \sum_{n\alpha, m\beta} \sum_{n'm'} v_{nn'}^{\alpha*} v_{mm'}^{\beta} \times \int_{-\infty}^{\infty} d\omega' A_{nm'}(\omega + \omega').A_{m'n}(\omega')[f(\omega') - f(\omega + \omega')],$$

(6)

where $A_{nm}(\omega) = \text{Im} G_{nm}(\omega - i0^+)/\pi$ and $f(\omega)$ is the Fermi function.

We consider the three $t_{1u}$ orbitals of $C_{60}$ which are connected by hopping matrix elements $t$

$$H_{1u} = \sum_{i\sigma} \sum_{\alpha} \varepsilon_{t_{1u}} n_{i\sigma} + \sum_{<ij>\sigma} t_{ijmm'} \psi_{i\sigma}^\dagger \psi_{j\sigma}^m$$

(7)

The orientational disorder has been built into the matrix elements $t_{ijmm'}$. Deshpande et al. have used a similar model for calculating the phonon self-energy. We want to describe the coupling to the intramolecular five-fold degenerate $H_3$ Jahn-Teller modes. Due to the intramolecular character, the coupling has a local form. To describe the electron-phonon interaction, we use the Hamiltonian

$$H_{1u-p} = \omega_{ph} \sum_{m=1}^{5} (b_m^\dagger b_m + \frac{1}{2})$$

(8)

$$+ \frac{g}{2} \sum_{m=1}^{5} \sum_{s=1}^{3} \sum_{i=1}^{3} V_{ij}^{(m)} \psi_{i\sigma}^\dagger \psi_{j\sigma}^m (b_m + b_m^\dagger),$$

(9)

where $\omega_{ph}$ is the phonon frequency, $b_m$ annihilates a phonon with quantum number $m$, $V_{ij}^{(m)}$ are dimensionless coupling constants given by symmetry and $g$ is an overall coupling strength. The electron-phonon coupling constant $\lambda$ is then given by

$$\lambda = \frac{5}{3} N(0) \frac{g^2}{\omega_{ph}},$$

(10)

where $N(0)$ is the density of states per spin at the Fermi energy.

We now construct a consistent current operator, essentially following Ref. 19. We write the density $\rho(i)$ at a site $i$ as

$$\rho(i) = \sum_{m\alpha} \psi_{i\alpha}^\dagger \psi_{i\alpha}^m.$$
weights and energies which are reduced by a factor Z. For \( \omega > 0 \) we then have

\[
\sigma_{\alpha \alpha}(\omega) \sim \lim_{\mathbf{q} \to 0} \frac{1}{\omega} \text{Im} \sum_n \sum_m \frac{|\langle n | \mathbf{j}_\alpha (\mathbf{q}) | m \rangle|^2}{\omega - \varepsilon_n + \varepsilon_m - i0^+}
\]

For zero frequency temperature, considered here. We can see, however, that influenced by the electron-phonon interaction at zero temperature, considered here. We can see, however, that the energy scale is reduced by a factor of Z, and that the weight of the Drude peak is reduced correspondingly. For larger frequencies these considerations are of course too simple, since we then have to consider the whole Green’s function including phonon satellites and not just the quasiparticle.

\[
\sigma_{\alpha \alpha}(\omega) = \sigma_{\alpha \alpha}^{(0)}(\omega/Z),
\]

where \( \sigma^{(0)} \) is the optical conductivity without the electron-phonon interaction. For zero frequency \( \sigma \) is unchanged, as it should, since the resistivity \( \sigma(0) \) is not influenced by the electron-phonon interaction at zero temperature, considered here. We can see, however, that the energy scale is reduced by a factor of Z, and that the weight of the Drude peak is reduced correspondingly. For larger frequencies these considerations are of course too simple, since we then have to consider the whole Green’s function including phonon satellites and not just the quasiparticle.

III. RESULTS

In Fig. 1 we show the optical conductivity for a phonon frequency \( \omega_{ph} = 0.15 \) eV and for different electron-phonon coupling constants \( \lambda \). The figure illustrates how the Drude peak becomes narrower and how weight is transferred to a mid-infrared peak due to the electron-phonon interaction.

From photoemission for a free C\(_{60}\) molecule\(^{12}\) and from neutron scattering\(^{13}\) it has been estimated that the strongest coupling is to the second lowest H\(_2\) mode at about 0.054 eV. From Raman scattering the strongest coupling was found for the lowest mode at about \( \omega_{ph} = 0.033 \) eV\(^{24}\). The value \( \omega_{ph} = 0.05 \) used in Fig. 2 should therefore be more realistic than the one in Fig. 1, and one might even argue for a still smaller value of \( \omega_{ph} \). This would then tend to give an energy of the mid-infrared structure of the right order of magnitude, although it is still larger than the experimentally observed value 0.06 eV. The electron-phonon coupling is of the order \( \lambda \sim 0.5 \)\(^{13}\). The width of the Drude peak is then reduced by a factor of 1.5-2. This reduction goes in the right direction, but it is much too small to explain experiment.

IV. MULTIPLET EFFECTS

An alternative mechanism for transferring weight from the Drude peak to the mid-infrared peak is provided by multiplet effects. Within the \( t_{1u} \) system, these are described by the exchange integral \( K \) between two \( t_{1u} \) orbitals and the difference \( \delta U \equiv U_{xx} - U_{xy} \) between the...
direct Coulomb integral for equal and unequal orbitals. Here we use \( 6U = 2K \). The \( C_{60} \) molecule has a ground-state with spin 3/2 and states with the spin 1/2 at 3K and 5K above the ground-state. The value of \( K \) has been estimated to be 0.05 eV and 0.024 eV. The unscreened value has been found to be \( K = 0.12 \) eV and within RPA screening \( K = 0.030 \) eV. The experience from atomic multiplets is that these are only weakly reduced (\( \sim 20\% \)) relatively to what is predicted by the unscreened Coulomb integrals, both for free atoms and for solids. We also find that to describe the multiplets in the \( h_u - t_{1u} \) exciton, unscreened integrals give a splitting of the right order of magnitude. Due to the lack of extensive experience for the large \( C_{60} \) molecule, we nevertheless consider the whole range of estimates for the multiplet integrals below. If the lower values of these estimates are used, the multiplet splitting is of the same order of magnitude as the energy of the mid-infrared structure, and it is then interesting to study to what extent these effects can explain this structure.

We have added a multiplet interaction to the Hamiltonian in Eq. \( (6) \)

\[
H_U = \frac{2}{3} \delta U \sum_{im} n_{im \sigma} n_{im \sigma'} - \frac{1}{3} \delta U \sum_{im} n_{i\sigma m} n_{i\sigma' m'} + \frac{1}{2} K \sum_{im \sigma m' \neq \sigma'} \psi_{i\sigma m}^\dagger \psi_{i\sigma' m'}^\dagger \psi_{i\sigma' m} \psi_{i\sigma m'}
\]

\( (20) \)

The simple Coulomb interaction

\[
H_U^0 = U \sum_{i \sigma m} n_{i\sigma m} n_{i\sigma' m'},
\]

\( (21) \)

should also be added but is not considered here, since in simple treatments it does not give a contribution to the mid-infrared structure.

We have estimated the self-energy to second order in \( \delta U \) and \( K \) and obtained

\[
\Sigma_{\text{Mult}}^{\text{Mult}} \sim \frac{K^2}{W}.
\]

\( (22) \)

This has to be compared with the self-energy due to the electron-phonon energy, which is of the order

\[
\Sigma_{\text{El}}^{\text{El-phon}} \sim \lambda \omega_{ph}.
\]

\( (23) \)

If we put \( K = 0.03 \) eV, \( W = 0.5 \) eV, \( \lambda = 1 \) and \( \omega_{ph} = 0.1 \) eV, we find that \( \Sigma_{\text{El-phon}} \) is about a factor of 35 larger than \( \Sigma_{\text{Mult}} \). This suggests that although the multiplet effects may transfer weight to the mid-infrared peak, the effect should be very small. If, on the other hand, we use a large value \( K = 0.15 \) eV for the multiplet integral, the second order self-energy due to the multiplet integrals becomes comparable to the electron-phonon contribution. In this case, however, the multiplet splitting is much larger than the energy of the mid-infrared peak. It therefore seems likely that the multiplet effects treated in second order theory cannot explain the energy and weight of the mid-infrared peak. We observe, however, the second order perturbation theory used here is not sufficient to describe the atomic limit, and that a better treatment conceivably could change the conclusions somewhat.

\[\textbf{V. DISCUSSION}\]

We have calculated the optical conductivity, including the effects of the lowest order self-energy diagram due to the electron-phonon interaction. This coupling reduces the width of the Drude peak and transfers weight to the mid-infrared structure at an energy somewhat larger than the phonon frequency. This leads to a mid-infrared structure with an energy of the right order of magnitude, but a bit too large. The reduction of the width of the Drude peak goes in the right direction, but it is much too small. We observe that the self-energy was calculated under the assumption that Migdal’s theorem is valid. Since Migdal’s theorem is questionable for these systems, higher order corrections could modify these conclusions.

It is interesting that Liechtenstein et al. found a rather narrow Drude peak (width \( \sim \) a few hundreds of an eV) in a one-particle calculation. As mentioned before, the \( C_{60} \) molecules in \( A_3C_{60} \) have primarily two different orientations. It has been found on theoretical grounds that it is energetically favorable if neighboring \( C_{60} \) molecules have different ("antiferromagnetic") orientations. The system can then be mapped onto a frustrated Ising model, for which the ground-state has a frustrated antiferromagnetic ordering. This ordering leads to a strong correlation in the mid-infrared peak mentioned above. Experimentally, a tendency to a short-ranged "antiferromagnetic" correlation has been found but under normal experimental conditions the samples are apparently cooled too fast to develop the long-ranged partial order assumed in Ref. 29. It therefore does not seem likely that the partial ordering assumed in Ref. 29 explains the narrow Drude peak in experimental samples used so far.

It is interesting to ask what other effects may contribute to the explanation of the optical conductivity. We have illustrated that multiplet effects are unlikely to explain the experimental results, at least if they are treated to lowest order. These systems have a strong coupling to a charge carrier plasmon at 0.5 eV due to the oscillations of the three \( t_{1u} \) electrons. In analogy with the coupling to the phonons, one may argue that the plasmons have a coupling constant \( \lambda_p \sim 2.5 \). Taking over the arguments from the electron-phonon coupling one might then expect a substantial narrowing from the coupling to the plasmons. This picture is, however, too simple, and a calculation of the electron self-energy in the so-called GW
approximation shows only a modest reduction of the band width. Actually, estimates of the specific heat do not show an enhancement compared with the result obtained from band structure calculations, apart from the enhancement expected from an electron-phonon interaction with a $\lambda \sim 0.5 - 1$. If these estimates are correct, they suggest that many-body interactions do not reduce the dispersion in $\text{Al}_2\text{Cu}$ ($A = $ K, Rb). This is also consistent with the susceptibility which shows a very weak temperature dependence, implying that there is no narrow peak in the density of states. We should then not expect an explanation of the narrow Drude peak in terms of a mechanism which reduces the dispersion beyond the reduction due to the electron-phonon interaction. Instead we should search for a mechanism which influences a two-particle spectrum, like the optical conductivity, without increasing the effective mass.
