ABSTRACT

Objective: Lipid peroxides and their reactive aldehyde derivatives (LPPs) have been linked to obesity-related pathologies, but whether they have a causal role has remained unclear. Glutathione peroxidase 4 (GPx4) is a selenoenzyme that selectively neutralizes lipid hydroperoxides, and human gpx4 gene variants have been associated with obesity and cardiovascular disease in epidemiological studies. This study tested the hypothesis that LPPs underlie cardio-metabolic derangements in obesity using a high fat, high sucrose (HFHS) diet in gpx4 haploinsufficient mice (GPx4+/−) and in samples of human myocardium.

Methods: Wild-type (WT) and GPx4+/− mice were fed either a standard chow (CNTL) or HFHS diet for 24 weeks, with metabolic and cardiovascular parameters measured throughout. Biochemical and immuno-histological analysis was performed in heart and liver at termination of study, and mitochondrial function was analyzed in heart. Biochemical analysis was also performed on samples of human atrial myocardium from a cohort of 103 patients undergoing elective heart surgery.

Results: Following HFHS diet, WT mice displayed moderate increases in 4-hydroxynonenal (HNE)-adducts and carbonyl stress, and a 1.5-fold increase in GPx4 enzyme in both liver and heart, while gpx4 haploinsufficient (GPx4+/−) mice had marked carbonyl stress in these organs accompanied by exacerbated glucose intolerance, dyslipidemia, and liver steatosis. Although normotensive, cardiac hypertrophy was evident with obesity, and cardiac fibrosis more pronounced in obese GPx4+/− mice. Mitochondrial dysfunction manifesting as decreased fat oxidation capacity and increased reactive oxygen species was also present in obese GPx4+/− mice but not WT hearts, along with up-regulation of pro-inflammatory and pro-fibrotic genes. Patients with diabetes and hyperglycemia exhibited significantly less GPx4 enzyme and greater HNE-adducts in their hearts, compared with age-matched non-diabetic patients.

Conclusion: These findings suggest LPPs are key factors underlying cardio-metabolic derangements that occur with obesity and that GPx4 serves a critical role as an adaptive countermeasure.

1. INTRODUCTION

The prevalence of obesity is rapidly spreading throughout the world with over 28% of adults having a body mass index (BMI) of ≥25 kg/m² [1,2]. In addition to the increased risk for type 2 diabetes, a growing number of studies have reported a high prevalence of cardiomyopathy in obese patients (~40% by some estimates) [3], with ‘preclinical’ myocardial damage [4] and diastolic dysfunction already

2. RESULTS

2.1. GPx4 deficiency in obesity leads to enhanced lipid peroxidation and carbonyl stress in liver, exacerbatating insulin resistance and steatosis

To test our hypothesis that LPPs underlie obesity-related pathologies we used a GPx4-deficient (GPx4<sup>−/−</sup>) mouse model. GPx4<sup>−/−</sup> mice are phenotypically indistinguishable from WT in the absence of an exogenous stressor but more susceptible to damage from radiation and environmental toxins [43,44]. The rationale for using this mouse model was that it mimics the effect of previously identified gpx4 gene variants on GPx4 enzyme levels and activity in human cells [36,38,45]. Following HFHS diet no significant differences in adiposity or weight gain were observed between WT and GPx4<sup>−/−</sup> mice, although obese GPx4<sup>−/−</sup> mice had substantial dyslipidemia and fasting hyperglycemia with HFHS diet (Table 1). Whole body energy expenditure, determined by VO2 and VCO2 using indirect calorimetry, was not different between WT and GPx4<sup>−/−</sup> mice, either with CNTL or HFHS diet (data not shown). Glucose intolerance was exacerbated in the GPx4<sup>−/−</sup> mice compared with WT (Figure 1A), although serum insulin levels were increased with HFHS diet to equal extent regardless of genotype (Figure 1B). GPx4 enzyme levels in liver of WT mice increased significantly as a result of HFHS diet, although GPx4<sup>−/−</sup> mice contain significantly less enzyme than WT (Figure 1C and Supplemental Figure 1A). In parallel with the increase in GPx4, levels of HNE-adducts in liver increased in WT with HFHS diet but were significantly more pronounced in GPx4<sup>−/−</sup> mice compared with WT. To determine whether the increased lipid peroxidation in the GPx4<sup>−/−</sup> mice corresponded to a more severe liver pathology following HFHS diet, liver triglycerides and collagen were measured by oil red O and picrosirius red staining, respectively. GPx4<sup>−/−</sup> mice displayed greater liver steatosis (Figure 1D) and fibrosis (Figure 1E) than WT mice following HFHS diet.

2.2. Cardiac structural remodeling and fibrosis are exacerbated by GPx4 deficiency in obesity

Previous studies have shown that HFHS diet-induced obesity causes significant cardiac hypertrophy and left ventricular (LV) diastolic dysfunction in rodent models [46–48]. Here, HFHS diet caused an increase in cardiac mass to a similar extent between WT and GPx4<sup>−/−</sup> mice (Figure 2A,E). However, compared with WT, GPx4<sup>−/−</sup> mice display significantly greater cardiomyocyte diameter (Figure 2E,F) and fibrosis (Figure 2B,C) following HFHS diet. Obese mice also have increased levels of serum brain natriuretic peptide (BNP, Figure 2G), indicative of ventricular wall stress. This evidence of cardiomyopathy exists in the absence of any changes in LV systolic function (Figure 2H), blood pressure (Figure 2I) or heart rate (Figure 2J) in the mice following

### Table 1 – Body composition and metabolic parameters.

HFHS diet, indicating that any cardiomyopathy which might be present in these mice is not due to increased afterload.

Recently, in two independent experimental models of cardiac hypertrophy it was observed that GPx4 and Thioredoxin Reductase (TxnRd) were the only antioxidant seleno-enzymes to increase in the heart, suggesting that they are critical for cardiac compensatory response to hypertrophic stimuli [49,50]. A significant increase in GPx4 mRNA (Figure 3A) and enzyme content (Figure 3B and Supplemental Figure 2A) in myocardium of WT mice with HFHS diet was observed. Conversely, GPx4−/− mice had lower levels of mRNA that did not correspond to any significant change in GPx4 enzyme levels following HFHS diet. Levels of HNE-adducts (Figure 3C) and protein carbonyls (Figure 3D) do increase moderately in WT hearts with HFHS diet, although GPx4 deficiency leads to a striking increase in this protein carbonylation with obesity. To determine if GPx4 deficiency and augmented carbonyl stress in obesity triggered a compensatory redox adaptive response in the heart, expression of a number of antioxidant genes were examined. GPx4−/− mice were found to have increased expression of several antioxidant genes following HFHS diet (Figure 3D).

2.3. GPx4 deficiency causes mitochondrial abnormalities and up-regulation of cardiac inflammation and fibrosis signaling pathways with obesity

Mitochondrial dysfunction, as characterized by decreased ATP and/or respiration combined with increased ROS, has been linked to several obesity-related pathologies, including insulin resistance and cardiomyopathy, and recent studies have implicated a role for mitochondrial protein carbonylation in mediating this dysfunction [51–53]. Parameters of mitochondrial function in permeabilized LV myofibers were examined to assess the relationship between GPx4 deficiency, carbonyl stress, and mitochondria in the obese myocardium. GPx4 enzyme content was measured in the mitochondrial fraction isolated from whole hearts. GPx4 increased in cardiac mitochondria of WT mice with HFHS diet, while total levels of GPx4 were lower and remained that way following HFHS diet in the GPx4−/− mice (Figure 4A and Supplemental Figure 2A).

It was expected that mitochondrial GPx4 deficiency would potentially lead to a greater degree of mitochondrial membrane lipid peroxidation and reactive aldehyde formation. Here, the amount of mitochondrial HNE-adducts were greater in GPx4−/− hearts than WT, and the HFHS diet increased the relative amount of these adducts in both WT and GPx4−/− mice (Figure 4B and Supplemental Figure 2B). These increased HNE-adducts may have functional consequences since recent studies have documented that mitochondrial HNE-adducts correspond to decreased oxidative phosphorylation in diabetic heart mitochondria [74,75]. Moreover, another report highlights the importance of mitochondrial fatty acid β-oxidation as a metabolic ‘sink’ for HNE [72]. In WT hearts, both basal and maximal ADP-stimulated palmitoyl-L-carnitine supported respiration was markedly increased following HFHS diet, while these rates were unchanged with HFHS diet in the GPx4−/− mice (Figure 4B).

In a previous study we reported that the selenoenzyme thioredoxin reductase-2 (TxnRd2) increased in rat heart with HFHS diet [54], corresponding to a decreased rate of mitochondrial H2O2 emission in the obese rat heart. Other groups have also reported decreased mitochondrial ROS with obesity/diabetes in mouse [55] and rat models [56]. Given our previous findings, combined with the fact that TxnRd2 expression was increased in GPx4−/− hearts with HFHS diet (Figure 3E), we sought to ascertain whether a similar adaptation in redox buffering was occurring in cardiac mitochondria of these mice. Here, using paired H2O2 emission experiments in the absence and presence of the TxnRd2 inhibitor auranothin, a dramatic (~4-fold) increase in total H2O2 emission was observed in permeabilized
myofibers prepared from obese GPx4^+/− mice fed HFHS diet, while a decrease in this ROS emission was observed in the obese WT mice following HFHS diet (Figure 4C). Auranofin exposure significantly increased the rate of mitochondrial ROS in the obese WT mice but not obese GPx4^+/− mice.

Chronic, low-grade inflammation in the obese heart is known to cause proinflammatory and hypertrophic signaling. Although it has been difficult to fully ascertain the exact nature of the relationship between inflammation and cardiac remodeling, some investigators have proposed that activation of the receptor for advanced glycation end products (RAGE) may play a role. RAGE belongs to a family of pattern recognition receptors for AGE and has been studied extensively in the context of diabetes-related pathologies [57,58]. Increased expression of RAGE is present in the hearts of obese GPx4^+/− mice (Figure 5A), and this is consistent with the increased carbonyl stress present in these hearts since reactive aldehydes such as HNE are known to potentiate AGE formation [59]. Activation of RAGE has been shown to induce chronic activation of nuclear factor kappa-light-chain-enhancer of activated B cells (NFκB), which, in turn, activates further inflammatory pathways. Furthermore, there is extensive crosstalk between the RAGE and Transforming Growth Factor-Beta (TGF-β) family of proteins [60–62]. Notably, the hearts of obese GPx4^+/− mice also displayed greater proinflammatory cytokine expression and genes involved in fibrosis and hypertrophy compared with WT following HFHS diet, while only a modest increase in a few select genes was observed with HFHS diet in WT hearts (Figure 5A & B).

2.4. Cardiac GPx4 deficiency is associated with increased HNE-adducts and relative risk (RR) for diabetes in humans

Next, we sought to determine whether there is an association between GPx4 and lipid-derived carbonyl stress in human heart and, also, to examine whether there is a connection between these parameters and human metabolic disease. In a small pilot study of ~20 patients, we previously reported greater levels of HNE-protein adducts in the hearts of hyperglycemic type 2 diabetic patients, and these increased HNE-adducts were accompanied by depletion of cardiac glutathione and increased mitochondrial ROS production [63]. Here, using samples of atrial myocardium obtained from patients (n = 103) undergoing elective cardiac surgery (Table 2), we observed that diabetic patients had significantly less cardiac GPx4 than non-diabetic patients (Figure 6A), and this corresponded with greater levels of HNE-adducts in the diabetic hearts (Figure 6B). A multivariable regression analysis was performed on quartiles of cardiac GPx4 and tertiles of HNE-adducts, and cardiac GPx4 was found to be negatively associated while HNE-adducts positively associated with RR for diabetes in these patients (Table 3). To determine if hyperglycemia was associated with cardiac GPx4 or HNE-adducts in these patients, a multiple linear regression model was applied, adjusting for sex. No significant association between cardiac GPx4 or HNE-adduct levels and HbA1c was observed in these patients (Table 3 and Supplemental Figure 1).

Similar to what was observed with the WT-HFHS mice, cardiac GPx4 content was positively correlated with cardiac HNE-adducts in these patients (Figure 6C), suggesting that GPx4 is an adaptive response of

the tissue to persistent oxidative stress. Interestingly, the ratio of HNE-adducts/GPx4 was much higher in diabetic than non-diabetic hearts (Figure 6D), indicating that the GPx4 adaptive response has been overwhelmed or compromised in these patients.

3. DISCUSSION

Only an increased understanding of the mechanisms underlying obesity-related pathologies will enable physicians to better manage diseases associated with this emerging epidemic. Lipid peroxides and their reactive aldehyde derivatives have been postulated to play a causal role in obesity-related cardio-metabolic diseases, and emerging epidemiologic data has reported a link between polymorphisms and metabolic parameters with HFHS diet implies that lipid peroxides and their LPP derivatives are a distinctive form of oxidative stress that must overwhelm in an obese individual and HNE-adducts increase (along with numerous other LPPs that were not measured in this study). The consequence of this is increased inflammation, mitochondrial dysfunction (and likely potentiation of mitochondrial ROS), and the broad cardio-metabolic pathologies that are known to follow (e.g., diabetes, cardiomyopathy, liver disease).

These findings stand in contrast to preceding studies of diet-induced obesity in antioxidant-deficient models. One recent study of high-fat-fed GPx1-deficient mice (whole body GPx1<sup>−/−</sup>) found that systemic oxidative stress increased with obesity as expected, but these mice were actually protected from insulin resistance and liver steatosis [98]. In a study using high fat diet in SOD2<sup>−/−</sup> mice (also exhibiting greater oxidative stress), insulin sensitivity was again unchanged with obesity, although a modest effect on pancreatic β-cell release of insulin was observed [99]. Another intriguing study used high fat diet in a glutathione-deficient (Gclc<sup>−/−</sup>/−) mouse model. The authors found that despite a huge increase in systemic oxidative stress with the diet, these mice could be protected from increased adiposity, insulin resistance and steatosis, possibly due to an increase in basal energy expenditure [100]. Given these recent findings, the fact that GPx4 haploinsufficiency alone can induce such a damaging effect on cardio-metabolic parameters with HFHS diet implies that lipid peroxides and their LPP derivatives are a distinctive form of oxidative stress that must play a very prominent etiological role in obesity-related cardio-metabolic diseases.

Deleterious effects of lipid-derived aldehydes in biological systems have been well known for many years. For example, nuclearophilic attack of cysteine residues by aldehydes has negative ramifications on metabolic pathways in the cell [14,64]. A recent mass spectrometric analysis of cysteine oxidation status in hearts from mice fed a diabeticogenic diet for 8 months showed that ~40% of total oxidized cysteines are mitochondrial in origin [65]. Proteomic analysis of mitochondria from diabetic rat hearts reveals an increased formation of carbonyl adducts (e.g., HNE, MDA) with complexes of the electron transport chain and respiratory complexes, and these adducts correspond to a reduction in enzyme activity [18]. Our data suggest that GPx4 protects against cardiac mitochondrial dysfunction with obesity as the obese GPx4<sup>−/−</sup> mice had very high levels of carbonyl stress in their hearts (Figure 5), particularly HNE-adducts in the cardiac mitochondria (Figure 4B), accompanied by mitochondrial dysfunction, as compared with obese WT mice. Several studies have shown that GPx4 preserves ATP production and attenuates cytochrome c release in the mitochondria under oxidative stress [66–68]. Cardiac-specific overexpression of mitochondrial GPx4 is protective in models of cardiac ischemia/reperfusion injury and in a streptozotocin (STZ)-induced diabetes model [69,70]. GPx4 exists as both short (i.e., mitochondrial-localized) and long (i.e., cytosolic-localized) isoforms, yet only deletion of the former is lethal in mice [67]. Thioridoxin Reductase is the only

other essential selenoenzyme identified to date, and this enzyme also has both mitochondrial (TxnRd2) and cytosolic (TxnRd1) isoforms [71]. In the present study, increased mitochondrial H₂O₂ emission was observed in hearts of lean GPx4⁺/⁻/⁻ mice following the inhibition of TxnRd2 with auranofin (Figure 4C), although auranofin did not significantly affect the rate in the obese GPx4⁺/⁻/⁻/⁻ mice (which was already much greater than all other groups). This suggests that mitochondrial lipid peroxide-scavenging with GPx4 and the thioredoxin redox couple are both important adaptive responses of cardiac mitochondria in obesity-related cardiac hypertrophy and that TxnRd2 cannot appropriately compensate for GPx4 deficiency within cardiac mitochondria if animals are obese.

A recent study showed that fatty acid β-oxidation is a novel HNE clearance pathway in heart [72]. Considering the diminished rates of maximal palmitoyl carnitine-supported respiration observed in the obese GPx4⁺/⁻/⁻/⁻ hearts, it is plausible that the elevated carbonyl stress observed in the hearts of these mice is a result of both increased mitochondrial ROS production (which initiates more lipid peroxidation) as well as a disruption of aldehyde detoxification pathways. The decreased GPx4 and correspondingly increased HNE-adducts seen here in myocardium of diabetic patients support our previous observations of decreased palmitoyl-L-carnitine supported respiration and increased mitochondrial ROS in diabetic human hearts [42,73]. A link between mitochondrial HNE-adduct formation and decreased oxidative phosphorylation in diabetic heart mitochondria has recently been made [74,75], and our findings suggest that GPx4 deficiency may underlie these oxidative modifications. High variability in dietary fat may also be a contributor to the greater levels of cardiac HNE-adducts in the diabetic patients, as it has been reported that diets consisting of high fat mixed with carbohydrate, or high fat alone, can lead to drastically

Sample size N = 103 for GPx4, N = 61 for HNE-adduct.

Figure 6: GPx4 content and HNE-adducts in human myocardium. Total GPx4 enzyme content A and HNE-adducts B are shown in atrial myocardium obtained from non-diabetic and diabetic patients undergoing elective heart surgery. Shown in C is association between HNE-adducts and GPx4 enzyme in these heart samples, and the ratio of HNE-adduct to GPx4 enzyme are depicted in D. Each symbol corresponds to one individual patient (N = 103, see Table 2 for demographics and clinical variables). P-value computed using Friedman’s nonparametric test for central tendency, adjusting for sex.
different outcomes in HNE accumulation in oxidative tissues [101]. Other studies directed at examining the role that alternative aldehyde-producing (e.g., monoamine oxidase) and detoxifying enzymes (e.g., aldehyde dehydrogenases) may have in pathologies of obese/diabetic hearts may also be useful [64]. In addition, an improved understanding of the regulation of selenocysteine status may serve as a major clue to uncovering the mechanisms that govern the progression to mal-adaptive remodeling in hearts of patients with metabolic disease. Epidemiological studies of Keshan’s disease, a cardiomyopathy endemic to regions of China, confirm that the heart is highly susceptible to injury resulting from disturbances to selenocysteine enzymes. Cardiomyopathy in Keshan’s disease manifests as acute cardiac fibrosis and mitochondrial dysfunction [76], a phenotype that is strikingly similar to the GPx4−/− mice in the present study.

Aside from measurements of liver steatosis and serum lipids, our study did not explore the potential contribution of altered lipid metabolism that might exist in these mice. Lipotoxicity is a consistent feature of cardio-metabolic disease in both humans and animal models of obesity [77–82] and therefore may contribute to the severe liver and cardiac pathology observed in the obese GPx4−/− mice. The obese GPx4−/− mice do not possess significantly greater adiposity than obese WT, as determined by % body fat. However, we cannot exclude that there may have been differences in adipose distribution between groups. It is also known that GPx4 directly modulates the lipoxigenase and cyclooxygenase II enzyme systems, and, when viewed in this context, the increased cardiac inflammation present in obese GPx4−/− mice supports a potential role for prostaglandins and other oxidized lipids in mediating the severe metabolic pathologies in this model. Thus, we cannot exclude the contribution of these mediators in the obese GPx4−/− mice. Other studies have documented that proteolysis and autophagy become compromised with carbonyl stress, and the diminished activity of these cellular processes may also explain the more severe phenotype observed in the obese GPx4−/− hearts [83,84]. None of these alternative pathways were explored in the present study. It is anticipated that these findings will serve to lay a foundation for future mechanistic studies directed at understanding how LPPs contribute to obesity-related pathologies and the adaptive role of GPx4. Considering that the most severe effects observed in the obese GPx4−/− mice were evident in oxidative tissues (i.e., liver, heart, muscle), it will be very important in future studies to identify the cell- and tissue-specific role of GPx4 in mediating lipid peroxidation and carbonyl stress with obesity. Furthermore, our findings have clinical implications as they suggest that patients exhibiting decreased GPx4 expression and activity might be predisposed to obesity-related cardio-metabolic diseases. Indeed, clinical studies and human cell models have shown that GPx4 expression and activity vary widely in response to environmental and nutritional cues [38,45,85–88]. Finally, although our understanding of the role of lipid-derived aldehydes and carbonyl stress in the etiology of obesity-related diseases is in its infancy, it is important to recognize that compounds that scavenge HNE and other lipid-derived aldehydes specifically, such as histidine-containing dipeptides, may be very useful in this regard [89,90,102] and have experienced some success in pre-clinical testing and even clinical trials [91–93]. Thus, further research into novel therapeutics targeting carbonyl stress will be important for mitigating the numerous cardio-metabolic diseases that accompany this rising epidemic of obesity.

### 4. METHODS

#### 4.1. Mouse model and study design

Animal care and experimental procedures were performed with approval from the Institutional Animal Care and Use Committee of East Carolina University and were in compliance with the National Institutes of Health’s Guide for Care and Use of Laboratory Animals. C57BL6/J female mice (Jackson Laboratory) were crossed to male GPx4+/− mice and pups were genotyped by polymerase chain reaction (PCR) using primers described in [43]. At 8–12 weeks, WT and GPx4+/− male and female age-matched littermates (n = 6) were randomly assigned to groups and individually housed. Mice were fed either control (CNTL-TD110367) or high fat high sucrose (HFFS-TD110365) diet from Harlan-Teklad Laboratories (Madison, WI) ad libitum for 25 weeks. The composition of this diet was a special formulation consisting of mixed saturated and n-6 PUFA (44.6% kcal/g fat), with high sucrose (34% kcal/g) content [54]. Mice were housed at controlled temperature and a 12h light/dark cycle was maintained. At the end of the diet period, all live animal metabolic and echocardiographic measurements were made 1–2 weeks prior to tissue collection to allow for a ‘wash-out period’ to minimize artifact attributable to additional stress that may have been introduced by these procedures.

#### 4.2. Patient enrollment and myocardial tissue collection

The Institutional Review Board of the Brody School of Medicine at East Carolina University approved all aspects of this study. Adult patients undergoing primary, non-emergent elective coronary artery bypass graft (CABG) or CABG/valve surgery between January 2011 and December 2014 were enrolled for this study. Demographic and clinical variables for these patients, including preoperative cardiovascular and metabolic drugs, are listed in Table 2 according to diabetes status. Those having prior cardiac surgery, history of arrhythmia, or severely enlarged atria (≥4.0 cm) were excluded from the study. Atrial appendage biopsies were obtained from each patient as previously described [94], directly prior to institution of cardiopulmonary bypass. Myocardium was dissected from the endocardial side of the biopsy, rinsed briefly and frozen in liquid N2. All samples were rapidly processed this way to minimize protein and mRNA degradation across patients.

#### 4.3. Metabolic parameters

Body weight of the mice was recorded on a weekly basis throughout HFFS diet. Body composition was analyzed by nuclear-MRI (EchoMRI

---

### Table 3 – Multivariable analysis of GPx4 and HNE-adducts in human heart.

| GPx4 content (µg/ml) | Diabetes | No diabetes | RR (95% CI)a |
|----------------------|----------|-------------|--------------|
| Mean ± SD            | 6.2 ± 4.2| 8.7 ± 5.9   | P = 0.034b   |
| Median (IQR)         | 6.0 (5.2)| 6.7 (6.6)   |              |
| Q1 (<3.9)            | 17 (35)  | 9 (17)      | 1.0 Referent |
| Q2 (>3.9–6.3)        | 10 (20)  | 15 (29)     | 0.65 (0.37–1.1) |
| Q3 (>6.3–9.4)        | 13 (27)  | 13 (24)     | 0.74 (0.47–1.2) |
| Q4 (>9.4)            | 9 (18)   | 17 (31)     | 0.58 (0.31–1.1) |

HNE content (mM)

| Mean ± SD            | 18 ± 8.3 | 14 ± 9.8   | P = 0.028c   |
| Median (IQR)         | 16 (11)  | 11 (12)    |              |

a Relative Risk (RR) and 95% Confidence Interval (CI), adjusted for sex.

b P-value computed using Friedman’s Nonparametric test for central tendency, adjusting for sex.

c P-value computed using the likelihood ratio trend test, adjusting for sex.
Mice were anesthetized with isoflurane. Liver and cardiac histology long- and short-axis views were captured in M-mode and recordings assessed cardiac function and structural parameters using a 30 MHz transducer (Vevo 2100, VisualSonics, Toronto, ON) to approximately the same time every day. Also at this time, high-acclimatization cycles, with duration no longer than 10 min, at recorded. A single recording was an average of 10 measurements after Cary, NC). Mice were acclimated to the procedure for 3 days, and the At end of the diet intervention, blood pressure was determined by non-poprotein (HDL), and triglycerides (TG) were analyzed using UniCel DxC 700 Echo Medical Systems, Houston, TX). An oral glucose tolerance Original article

4.4. Assessment of cardiovascular function
At the end of the diet intervention, blood pressure was determined by non-invasive tail-cuff plethysmography (SCI1000, Hatters Instruments, Cary, NC). Mice were acclimated to the procedure for 3 days, and the average of blood pressure readings made over 3 consecutive days was recorded. A single recording was an average of 10 measurements after 5 acclimatization cycles, with duration no longer than 10 min, at approximately the same time every day. Also at this time, high-resolution echocardiography was performed on fully conscious mice using a 30 MHz transducer (Vevo 2100, VisualSonics, Toronto, ON) to assess cardiac function and structural parameters in vivo. Parasternal long- and short-axis views were captured in M-mode and recordings analyzed using system software.

4.5. Liver and cardiac histology
Mice were anesthetized with isoflurane. Hearts (n = 2/group) were stopped with KCl, fixed in Zinc Fixative then embedded in paraffin. Next, they were cut cross-sectionally, stained in Hematoxylin and eosin or picrosirus red (collagen), then viewed under polarized light. Livers from these animals were fixed, embedded and stained in a similar fashion, with the exception that oil red O was used for liver triglycerides. Images of each heart were captured at 20X. The cardiomyocyte diameter of 8–10 myocytes from 5 captured images per animal was analyzed using Image J (http://imagej.nih.gov/ij/) by an individual blinded to the treatment group.

4.6. Preparation of permeabilized cardiac myofibers and mitochondrial function measurements
All procedures for these measurements have been described in detail by our group previously [42,54,73,95]. The mice were anesthetized with isoflurane and rapidly euthanized by pneumothorax. Blood was collected for serum analysis via cardiac puncture. Whole hearts were dissected, weighed, and a small portion of the left ventricle (LV) was cut for preparation of permeabilized myocytes (~30 mg) and placed in Buffer X containing (in mM): 7.23 K3EGTA, 2.77 CaK2EGTA, 20 Imidazole, 20 Taurine, 5.7 ATP, 14.3 Phosphocreatine, 6.56 MgCl2-6H2O and 50 MES (pH 7.1, 295 mOsm). Of the remaining LV/septum, cardiac tissue was homogenized in TEET Buffer (10 mM Tris, 1 mM EDTA, 0.5% Triton X-100, pH 7.4, 295 mOsm) and remained in Buffer Z with 20uM Blebbistatin at a rotator at 4°C until analysis (~1.5 h). Fibers were then transferred to an Orobos O2K (Orobos Instruments, Innsbruck, Austria) where respiration was recorded in Buffer Z containing (in mM): 110 K-MES, 35 KCl, 1 EGTA, 5 K2HPO4, 3 MgCl2-6H2O, and 5 mg/ml BSA (pH 7.4, 295 mOsm) and remained in Buffer Z with 20uM Blebbistatin, 20 mM Creatine at 30 °C. Respiration (OCR) measurements were performed following addition of 125pmol/mg palmitoyl-carnitine, 2 mM Malate +100 µM ADP, 5 mM glucose and 1 U/ml hexokinase (i.e., phosphorylating state) followed by sequential addition of 5 mM glutamate then 5 mM succinate. Once mitochondrial experiments completed, fibers were collected, rinsed in ddH2O to remove excess salts, and lyophilized (Labconco, Kansas City, MO). Fibers were then weighted on a microbalance (Mettler Toledo, Denver, CO) and mitochondrial JO2 (oxygen consumption rate) and ΔΨm (pH gradient) were normalized to dry weight.

4.7. Real-time qPCR of gene expression
Cardiac samples (~10 mg) were homogenized in glass grinders (Kimble Chase, Vineland, NJ) then subjected to Proteinase K digestion. All materials used in RNA extraction were provided in RNaseasy Fibrous Tissue Mini Kit (Qiagen Inc, Valencia, CA cat# 74704). Reverse Transcription was performed using the iScript ™ cDNA Kit (Biorad Laboratories, Hercules, CA cat# 170–8891). The SsoAdvanced ™ SYBER Green reaction cocktail was used in the amplification and detection of DNA in RT-PCR. All protocols were performed according to product specifications unless otherwise stated. Cycle threshold (C(t)) values were converted to relative gene expression levels using the 2-ΔΔC(t) method and normalized to the level of 18S ribosomal RNA. Data are reported as fold-change in gene expression (arbitrary units) ± S.E.M. relative to WT-CNTL mice (n = 4–5 per group). The sequences and references for the primers used in qRT-PCR are listed in Supplemental Table 1.

4.8. Mitochondria isolation
The technique applied has been modified from methods previously described [96,97]. Briefly, ~100 mg of cardiac tissue was excised and added to a petri dish with ice. The tissue was minced for 4–5 min, until it could pass through a pipette, and subjected to a brief (2 min) trypsin incubation. The mixture was transferred to a 50 mL conical tube and allowed to settle. The supernatant was removed and discarded. The remaining mixture was resuspended in 3 mL of Mitochondria Isolation Medium (MIM) (300 mM Sucrose, 10 mM NaHEPES, 0.2 mM EDTA) with BSA, then transferred to a pre-chilled Dounce homogenizer and slowly homogenized for a total of 10–12 counts. The homogenate was then subjected to a series of differential centrifugation steps. The fractions of isolated mitochondria obtained (mixed subsarcolemmal and intermyofilibrillar) were resuspended in a small volume of MIM + BSA and frozen at ~80°C for biochemical analysis.

4.9. Immunoblot and enzyme-linked immunosorbent assay (ELISA)
Cardiac tissue was homogenized in TEET Buffer (10 mM Tris, 1 mM EDTA, 1 mM EGTA + 0.5% Triton X-100), then loaded on 4–20% prefcast polyacrylamide SDS gel (Biorad, Hercules, CA) under reducing conditions. Protein was transferred to PVDF membranes (Millipore, Bellerica, CA) and incubated with primary antibodies for GPX4 and α-tubulin (Abcam, Cambridge, UK), COX IV and β-actin (Cell Signaling Technology, Danvers MA), and HNE-adduct (Percpio Biosciences). Membranes were incubated using infrared fluorophore-conjugated secondary antibodies (LiCor Biosciences, Lincoln, NE), scanned using Odyssey Cx Infrared Imaging System (Li-Cor) and analyzed by densitometry using Image J (NIH). The absolute quantities of GPX4 and HNE-modified protein adducts in human cardiac tissue was determined by a quantitative ELISA approach developed in our lab, as described previously [54]. Fixed concentrations of HNE-adducts were made by incubating 4-hydroxynonenal (Cayman Chemical, Ann Arbor, MI) with BSA. A standard curve of both recombinant GPX4 (AbFrontier, Seoul, Korea) and HNE-modified BSA were then incubated on
immunolon-coated 96-well assay plate (Fisher Scientific) along with diluted cardiac protein. Samples were incubated overnight at 4 °C, and subsequently washed with PBS + 0.05% Tween-20 and blocked for 2 h with BSA or NB4025 (NOF America, White Plains, NY) at 37 °C. Samples were then incubated with primary antibodies for GPx4 and HNE adduct for 2 h at 37 °C. Samples were washed with PBS + 0.05% Tween-20 and incubated with HRP-conjugated secondary antibody for 2 h at 27 °C. Following this incubation, samples were washed as before and incubated with Amplex Red (10 μM). Concentrations of GPx4 and HNE-adducts in the samples were determined by fitting to the standard curve within each plate and normalized to total protein concentration.

4.10. Hydrazide labeling of carbonyl-modified proteins

Hydrazide Cy5.5 dye (GE Healthcare Bio-Sciences, Pittsburgh, PA) was diluted in dimethyl sulfoxide (DMSO) at a stock concentration 1 mg/ml. Tissue was homogenized under an anaerobic chamber (Coy Laboratory Products, Grass Lake, MI) in 10 mM sodium phosphate buffer, containing 0.1% Triton X-100, and de-gassed using dry vacuum pump (Welch No. 25228—01, Monroe, LA). Dye was added to half of the homogenate (1:10). The samples were left under anaerobic conditions for 2 h and incubated overnight on orbital shaker at 4 °C. The other aliquot of tissue homogenate was subjected to quantified protein concentration. Portions of the labeled cardiac tissue homogenate were subjected to SDS-PAGE on 10% SDS polyacrylamide gel. The gels were scanned using Odyssey Cx Infrared Imaging System (Li-Cor) and Cy5.5-labeled proteins were analyzed by densitometry using Image J (NIH).

4.11. Statistical analysis

All animal data are presented as mean ± SEM. Statistical analysis of mouse model variables were performed with GraphPad Prism (GraphPad Prism, La Jolla, Ca.). One way ANOVA was performed on continuous variables followed by Newman–Keuls post test, with α < 0.05 considered statistically significant. In the human data analysis, categorical variables are presented as frequency and percentage and continuous variables were presented as mean ± standard deviation, median, and interquartile range. Fisher exact and Chi (2) procedures were used to compute statistical significance of group comparisons for categorical variables. Deuchler-Willcoxon was used for continuous variables. Biochemical variables were divided into quartiles (GPx4) or tertiles (HNE) and analyzed using a robust Poisson regression model (with relative risk as the measure of association). Missing values for all clinical and biochemical variable were imputed using the iterative expectation-maximization (EM) algorithm as described in a recent study [94]. Variables that were statistically significant in the univariable analysis were included into the multivariable analysis. P-value was computed using Friedman’s Nonparametric test for central tendency while adjusting for age. P-trend was computed using likelihood ratio trend test, adjusting for age and sex. Statistical significance was defined as P < 0.05. SAS Version 9.3 was used for all analyses of human biochemical and clinical variables.

FUNDING

This research was supported in part by National Institutes of Health grant 1R01HL122863 to E.J.A.

CONFLICT OF INTEREST

The authors have no conflict of interest to declare.

ACKNOWLEDGMENTS

This authors would like to thank Amy Bullock for assistance with animal care and breeding and Joany Oswald Zary for assistance with histology.
