Abstract. Since 2000, and for the following 20 years, hydrological data of the Mediterranean Sea, with a particular focus on the western and central Mediterranean sub-basins, have been acquired to study the hydrodynamics at both coastal and open sea scales. In total, 1468 hydrological casts were realized in 29 oceanographic cruises planned due to scientific purposes linked with funding research projects but were also sometimes driven by sea conditions and type of vessel. After accurate quality assurance and control, following standard procedures, all hydrological data were included in four online public open-access repositories in SEANOE (SEA scienTitic Open data Edition), available from https://doi.org/10.17882/87567 (Ribotti et al., 2022). Hydrological and dissolved oxygen data are always present in all of the datasets, whereas pH, fluorescence, turbidity, and chromophoric dissolved organic matter (CDOM) are available just for some cruises. Samplings were carried out mainly along transects, with some repetition over the years. The results of two data analyses, i.e., staircase systems in the Tyrrhenian Sea and spreading of the Western Mediterranean Transient, are mentioned.

1 Introduction

The Mediterranean basin is an east–west-oriented, semi-enclosed sea connected with the North Atlantic Ocean through the narrow and shallow Strait of Gibraltar. Its circulation, although characterized by complex patterns, can simply be described as made of three main active overturning circulation cells, i.e., a shallow one and two deep ones (Tanhua et al., 2013). The Mediterranean Sea is one of the few basins in the world where deep convection and water mass formation take place (Siedler et al., 2001, p. 422). Morphology, climatology, and hydrodynamics, with also reduced timescales in the turnover of most of the oceanographic processes of the global ocean, make the Mediterranean Sea a “small and accessible ocean”, where changes can be more easily studied (Bethoux et al., 1999).

Within this context, the Italian National Research Council in Oristano and La Spezia (hereafter CNR), organized over 29 scientific cruises in 21 years in the Mediterranean, mostly in the western Mediterranean and the Strait of Sicily, with a particular focus on the acquisition of vertical profiles of temperature, salinity, dissolved oxygen, fluorescence, and, more recently, pH and turbidity. The cruises were always planned based on funding projects’ objectives, but then further activities linked to other research interests and/or scientific collaborations were added. Therefore, for each cruise and dataset there is a duality between “fit for purpose”, i.e., the projects that prompted us to organize the campaigns, and “fit for use”, i.e., the possibility of reusing the data for purposes other than the original aims, such as data also acquired in areas outside of the projects’ interest. This duality was also behind the sampling plan that could be on a regular or mostly regular grid (cruises 2000–2004 and 2014), which is generally suitable for calibrating and validating ocean numerical models, and/or along transects (after 2004) for studies on general or local circulation, and, if there was some repetition...

The paper is organized as follows: in Sect. 2 (methods),
cruises, vessels, and data are described, as well as the qual-
y assurance and check procedures applied to the datasets.

Subsequently, two examples of their use are given in Sect. 3,

where the results obtained from data analyses on the dif-

usion of the Western Mediterranean Transient are given and a

still-open issue on the thermohaline staircases in the Western

Mediterranean is described.

2 Methods

Over 29 oceanographic cruises were realized in the Mediter-
ranean basin between May 2000 and October 2020 (Table 1
and Fig. 1) by the CNR in Oristano jointly with the CNR in
Spezia, except for the years 2016 and 2019 when no cruises

were carried out. The strict collaboration, from 2000 till
2018, with the CNR institute in La Spezia, which has much
longer experience with ocean cruises and studies, has off-
ered the choice of some sampling plans like the transects in
the Strait of Sicily and Corsica Channel, where they moored
deep oceanographic chains for tens of years.

In total, 1468 hydrological vertical profiles were acquired
in 21 years in the Mediterranean Sea, covering areas span-
ning from the Strait of Gibraltar in the western sub-basin to
the south of Crete in the eastern part of the Mediterranean
Sea.

In addition to the projects’ objectives and further research
interests, two more aspects have influenced, even heavily
in the last 4 years, data acquisition, i.e., sea conditions and

type of vessel (described in the next subsection). Until 2017
(Table 1), the availability of large research CNR vessels
like Urania and Minerva Uno allowed working throughout
the Mediterranean and in less than optimal sea conditions,
whereas, since 2018, the available research vessels have not
been suitable for working in rough sea conditions in the open
sea.

2.1 Research vessels and projects

Different research vessels (R/Vs) were used during several

measuring campaigns, each one with characteristics and fa-

cilities that influenced both sampling plans and data acquisi-

tion. Between May 2000 and December 2017, the CNR used
two multidisciplinary research vessels designed in Italy that

permitted researchers to work all over the Mediterranean and

in all seasons. These vessels are the 61.30 m long R/V

Urania (2000–2014) and the 47.66 m long R/V

Minerva Uno (2015–2017). During these years, the cruises allowed us to

acquire data to study the local (e.g., the Sea of Sardinia till

2004) and the general circulation all over the Mediterranean,

to maintain deep-ocean bottom-moored infrastructures in the

Corsican and Sardinian channels and the Strait of Sicily, and
to acquire data to calibrate and validate numerical models at
different spatial scales. In 2016, no cruise was planned.

In March 2010, the 42.35 m long R/V

Maria Grazia was used just for the cruise of Bonifacio2010-Cor, for a project
in the Strait of Bonifacio area, where an oceanographic and

oil spill prediction system based on numerical models was

realized for the local coast guard.

During the years 2018–2020, the 35.7 m long R/V

G. Dal-
aporta, a coastal vessel particularly suitable for activities re-
lated to scientific fishing and marine biology, was used in
research projects mainly focused on coastal measurements
and the launch/rescue of Lagrangian surface drifters in south-
ern Sicily and Sardinia. In 2019, the 8 d long cruise

SeriousGame2014-2, performed in the Tuscan Archipelago,
Table 1. List of cruises carried out from 2000 to 2020. Areas with at least three casts are listed. Ocean parameters are listed with acronyms, so P stands for pressure, C for conductivity, T for temperature, O for dissolved oxygen, F for fluorescence, Tu for turbidity, CD for CDOM (chromophoric dissolved organic matter), and pH is just pH.

in the northern Tyrrhenian Sea. Data were acquired to test one of the limited ocean forecast models for the oil spill fate (Gonnelli et al., 2016; Sorgente et al., 2016), which is part of the wider Mediterranean decision support system (Zodiatis et al., 2016).

2.2 Sensors and data

For all the adopted vessels, the hydrological instruments were mounted on a General Oceanics Rosette system with $24 \times 12$ L Niskin bottles for water column samples collection ($2 \times 10$ L during the cruise of Bonificacio2010-Cor). This system was equipped with a SBE911 plus CTD (conductivity, temperature, and depth) probe (Sea-Bird Scientific, hereafter SBE Sci.), which sampled the hydrological parameters along the vertical at 24 Hz and with a lowering speed of 1 m s$^{-1}$. With the CTD, the data of water conductivity were measured by a SBE 4 sensor, with a resolution of $3 \times 10^{-4}$ S m$^{-1}$, the water temperature was measured by means of a SBE 3F thermometer, with a resolution of 0.00015 °C/bit at $-1$ °C or 0.00018 °C/bit at 31 °C, and the dissolved oxygen (DO) was measured by means of a SBE 13, with a resolution of 4.3 µM, from Medgoos1 to 4, and then using a SBE 43 polarographic membrane sensor with a range of 120 % of surface saturation and an accuracy of $\pm 2\%$ for saturation. The chlorophyll a fluorescence was reported as a relative fluorescence unit (Chl a), by means of a Sea Tech fluorometer with energy emitted by the flash lamp of 0.25 J for flash, with a temperature range between 0 and 25 °C and a resolution of 0.15 g L$^{-1}$.

Since the cruise of Medgoos12, in April 2006, the Chelsea Aqua 3 fluorometer has been used, whereas, due to sensor malfunction, no fluorescence data were collected during the Medgoos11 and the two cruises of Bonificacio2010-Sic and Bonificacio2010-Cor. Turbidity was acquired only during Bonificacio2011 by a Seapoint turbidity meter and by a WET Labs Environmental Characterization Optics (ECO)-NTU during Piattaforme2018 and Ichnussa2017. The pH/reduction sensor (SBE 27) was available only during the cruise of Piattaforme2018, but it had been calibrated 1 year before. During cruises from Medgoos5 to Medgoos7, temperature data were checked on board at defined depths against inverted thermometers, i.e., model RTM 4002 by Sensoren Instrumente Systeme GmbH (SiS), installed in correspondence with the Niskin bottles numbered 1, 3, 5, and 7 of the Rosette sampler.

Since the cruise of Medgoos2 in March–April 2001 (see Table 1), redundant or secondary sensors have always been used for a data quality assessment (as defined in Bushnell et al., 2019) for measurements of temperature, salinity, and dissolved oxygen (this is from Medgoos5 in October 2022: Table 1). These secondary sensors were used to evaluate the stability of primary ones on board and during the following visual data quality check.

Pre-cruise and post-cruise calibrations of first and redundant sensors of temperature, salinity, and dissolved oxygen were performed by CNR technicians at the NATO Centre for Maritime Research and Experimentation (CMRE) in La Spezia (Italy). These two calibrations permitted us to obtain a slope correction, used in the configuration file of the SBE Seasoft™ suite of programs, improving the data quality. The post-cruise calibration was not performed on data acquired during the cruise of Piattaforme2018. After their acquisition, data were pre-processed by the SBE Data Processing™ software with the updated configuration file to correct coarse errors. Data from the redundant sensor were used instead of the primary data in case of malfunction (Ribotti et al., 2020).

But, despite their double calibrations, during a cruise all sensors can drift, thereby reducing their data quality. For conductivity and dissolved oxygen sensors, their stability was checked through onboard comparisons with data from water samples. On board R/V Urania (2000–2014) and R/V Minerva Uno (2015–2017), salinity was checked against the onboard analyses of water, sampled at pre-defined depths, by a Guildline™ Autosal 8400B Laboratory Salinometer, while on the other vessels all samples were analyzed once back at CNR (Ribotti et al., 2020). The same applied for dissolved oxygen measurements that were checked onboard against the Winkler titration method (Winkler, 1888) and analyzed through the program tiamo™ 2.0 by Metromh.

Finally, Chl a, pH, and turbidity data were not calibrated. The pressure sensor is usually stable, and so it is not calibrated but, in case of malfunction, it was sent to SBE Sci. in the USA to be revised.

During all cruises, dissolved inorganic nutrients were also acquired from water samples, and analyses were carried out once back in the laboratory. Data from Medgoos8 in May 2004 and Ichnussa2017 in October–November 2017 are available online (Belgacem et al., 2019) and described, in their quality check procedures, in Belgacem et al. (2020).

Furthermore, in the framework of the MEDESS4MS project (see info at https://keep.eu/, last access: 5 September 2022), on 17 and 21 May 2014, two daily cruises, SeriousGame2014-1 and SeriousGame2014-2, were jointly held by the CNR in Oristano, the CNR in Ancona, and the Italian Coast Guard. The two surveys covered, with 45 casts each, about 880 km$^2$ of a shelf on a 5 x 5 km in latitude and longitude spatial grid of an area located north of Elba island in the Tuscan Archipelago in the northern Tyrrhenian Sea. The CTD probe was a Seabird SBE 19 plus v2 equipped with sensors of pressure, temperature, conductivity, SBE 63 for dissolved oxygen, a WET Labs FLNTU for fluorescence and turbidity (NTU), and chlorophyll a (µg L$^{-1}$) and, just during the second cruise, a Turner Cyclops sensor for the chromophoric dissolved organic matter (CDOM in parts per billion, ppb, of quinine sulfate, QS). The probe was calibrated on 29 January 2013 at SBE Sci. in the USA, but not before and after the two cruises, so the data were just quality
checked and processed by the SBE Data Processing™ software to correct the coarse errors.

All CTD data listed in Table 1 are available in the SEANOE (SEA ScienNitific Open data Edition) data repository (Ribotti et al., 2019a, b, c, 2022), where each dataset is identified per cruise and provided in the Ocean Data View (ODV: Schlitzer, 2022) ASCII file format, with missing values set to \(-1 \times 10^{10}\).

Methodologies before, during, and after any acquisition, instruments, and personnel changed a little during the 21 years of CTD acquisitions, apart from during the two coastal cruises of SeriousGame2014-1 and SeriousGame2014-2 in 2014, due to different adopted instruments. This makes the data in the datasets highly coherent and comparable.

3 Data analyses

In 21 years, projects and scientific interests led to the choice of areas and sampling plans that could change in relation to vessel characteristics and sea conditions. Nevertheless, repetitions of casts were realized, like in the Sea of Sardinia, where the same sampling strategy was repeated for seven cruises in 5 years, or the sampling transects between Sardinia and the Balearic Islands, across the Strait of Sicily and the Corsica Channel, and along the western Mediterranean (see in Table 1), mainly for oceanographic studies like circulation, hydrology, and their variabilities. In the following subsections, a process and an oceanographic event, observed from the data described in this paper, are mentioned to suggest further scientific research interests and opportunities for using these data.

In the first subsection, we show the step structures observed during the first four Medgoos cruises between 2000 and 2002 in the Sea of Sardinia but also during other cruises in the western Mediterranean. In the following subsection, we describe studies on the Western Mediterranean Transient that were detected in the datasets acquired between 2005 and 2017.

3.1 Step structures in the deep Sea of Sardinia

The first seven cruises named Medgoos have been organized to cover the Sea of Sardinia either partially or totally. Casts were realized on a regular 25 km grid from the shelf to the abyssal plain, which are some hundreds of kilometers from the coast. The integration of numerical models’ solutions and satellite images permitted the study of the circulation in the Sea of Sardinia (Ribotti et al., 2004; Puillat et al., 2006). It is mainly characterized by fresher modified Atlantic Water (AW) in the upper 200 m, warmer and saltier Levantine Intermediate Water (LIW) below and till 800 m depth, moving northward along the Sardinian slope, and the Western Mediterranean Deep Water (WMDW) between 800 m and the abyssal plain. Due to baroclinic instabilities of the Algerian Current, surface and intermediate waters are dynamically affected by the presence of deep anticyclonic Algerian eddies (AEs) along the Sardinian coast, involving surface and intermediate waters till 1500 m depth (Puillat et al., 2006) and reaching a latitude around 40° N (Puillat et al., 2002; Pessini et al., 2020). Waters are also affected by the Sardinian eddies, formed by the interaction of the westward flux of LIW and Tyrrenian Deep Water (TDW) coming from the Tyrrenian Sea with the Algerian gyres at the southwestern Sardinian corner, which influence the circulation of intermediate and deep circulation (Testor and Gascard, 2005; Testor et al., 2005). Cruises of Medgoos2, Medgoos4, and Medgoos7 (in March 2001, May 2002, and January 2004, respectively; see Table 1) covered the whole Sea of Sardinia, permitting us to investigate some hydrological profiles from March 2001 and repeat some casts hundreds of kilometers from Sardinia. AEs were observed during the first two cruises in the southern central part of the Sea of Sardinia (Puillat et al., 2006), while in January 2004 the area was eddy free. The profiles from these three cruises showed step structures at latitudes between 40.5 and 41.5° N offshore of northwestern Sardinia at depths between 500 and 1400 m. Following the method proposed by Durante et al. (2019) to investigate the staircase systems in the central Tyrrenian Sea, the analysis of data collected during Medgoos cruises always revealed a five- to nine-step structure, with interfaces 50–110 m thick, located between intermediate and deep waters, as depicted by the profiles of absolute salinity and conservative temperature reported in Fig. 2.

During the first cruise conducted in March 2001, the staircase structure was less evident than in 2002 and 2004. Each step is defined by a layer with values of the stability ratio \(R_p\) and of the Turner angle \(Tu\) finger regime, both defined in Durante et al. (2019), which comprised between 1 and 1.7 (1 < \(R_p\) < 1.7) and between 45 and 90° (45° < \(Tu\) < 90°), respectively. Following Durante et al. (2019), these staircase systems can be defined with rough profiles, representing instabilities in the convective layer, and characterized by a reduced number of thick steps alternated by rough interfaces. The ranges of the differences in the temperature and salinity at the interface of each step ranged between 1 \(\times 10^{-2}\) and 1.5 \(\times 10^{-1}\) °C and between 1 \(\times 10^{-2}\) and 9 \(\times 10^{-3}\) PSU (Practical Salinity Unit), respectively, with an interface thickness varying between 9 and 40 m. These values are comparable with those observed in the Tyrrenian Sea by Zodiatis and Gasparini (1996), with the difference that the central Tyrrenian Sea is a low-energy area in terms of water currents, whereas the northern Sea of Sardinia is at the limits of the passage of deep anticyclonic eddies moving anti-clockwise in the Algerian sub-basin and generating intense currents (Pessini et al., 2018, 2020).

Staircase systems were also found in the central Algero-Provençal Basin during the Bonifacio2011 (November 2011) and Ichnussa2012 (January 2012) cruises and were well iden-
Figure 2. Some of the steps observed offshore of northwestern Sardinia, between 500 and 1500 m, through the profiles of absolute salinity and conservative temperature at the interface of intermediate–deep waters in the period of March 2001–January 2004.

These staircases are organized in seven- to nine-step structures, with interfaces 60–110 m thick and $R_p$ and $T_u$ comparable with those observed offshore of northwestern Sardinia. These systems were detected in sampling stations located in the central Provençal sub-basin and in the central part of the transect between the Menorca island in the Balearic Islands and Oristano in Sardinia, along a latitude at around 40°N. They are similar to those described by Fuda et al. (2000), who observed them between 500 and 1400 m depths from CTD and expendable bathythermograph (XBT) profiles acquired in February 1994 in the open Algerian area.

The features of these dynamical structures confirm that they are related to salt fingering that originated in the presence of intermediate waters, both when close to the continental slopes (NW Sardinia) and when in the middle of the Algero-Provençal area. In both cases, their presence is probably dependent on the absence of eddies that, if deep, can erode the step structure, which is in agreement with what observed in June 2017 by Taillandier et al. (2020) in the Algerian Basin along the 38°N parallel. Finally, during the 12 cruises between March 2003 (Medgoos6) and December 2015 (Ichnussa2015), the 3550 m deep cast number 51 in the central Tyrrhenian Sea was repeated to study the staircase system previously mentioned and recently well described by Durante et al. (2019).
3.2 Deep changes in the western Mediterranean sub-basin

In the Mediterranean, the deep circulation is organized in two deep cells, located in the western and eastern sub-basin, respectively, and is constituted by denser waters than those above whose thermohaline features can differ between the two sub-basins (Malanotte-Rizzoli et al., 1997; Sparnocchia et al., 1999; Wu et al., 2000; Bethoux et al., 2002; Rixen et al., 2005; Marty and Chiavéri, 2010; Bensi et al., 2013; Ingrosso et al., 2017; Send and Testor, 2017).

Between October 2004 (Medgoos9) and 2017 (Ichnussa2017), 15 cruises covered some deep sub-basins of the western and central Mediterranean, from the Strait of Sicily and the Tyrrhenian Sea over to the Strait of Gibraltar, with hydrological casts (see Table 1). These data, apart from the shallow cruise Bonifacio2010-Cor and the two SeriousGame cruises in 2014, have permitted us to follow the spreading of the new Western Mediterranean Deep Waters (nWMDW) in the western Mediterranean sub-basins since its formation in 2005 (Schroeder et al., 2008), revealing over a decade of great thermohaline variability. During winter 2004/2005, above the northwestern Mediterranean area, a little rain with intense and persistent northerly winds brought a massive heat loss in the Gulf of Lions, the highest since 1948, that led to an increase in surface salinity (Font et al., 2007). In the same years, the propagation of the Eastern Mediterranean Transient, from the eastern to the western basin of the Mediterranean, led to maximum values of temperature and salinity in the intermediate layers (Gasparini et al., 2005; López-Jurado et al., 2005; Schroeder et al., 2006; Margirier et al., 2020). The concomitance of these meteorological and oceanographic processes has created the perfect conditions for the formation of warmer and saltier deep waters than the pre-existing ones (Herrmann et al., 2010; López-Jurado et al., 2005), which then occupy the deepest layer close to the bottom and are known as the Western Mediterranean Transient (WMT; López-Jurado et al., 2005; Schroeder et al., 2008; Briand, 2009; Zunino et al., 2012). After the first event of 2004/2005, WMT continued with large volumes of nWMDW formed in winter 2005/2006 (Medgoos10 and Medgoos13 in Fig. 4), while in the following winters of 2006/2007 and 2007/2008, no deep water production occurred due to a mild cold season. But deep convection started again in winter 2008/2009 and in the following (i.e., 2009/2010, 2010/2011, and 2011/2012) winters, due to particularly cold weather, as in 2011/2012, in the Mediterranean Sea. In 2012, and at the bottom of the Gulf of Lions, the nWMDW had a potential temperature of 12.905 °C, a salinity of 38.508 and a maximum density of 29.134 kg m−3 (Durrieu de Madron et al., 2017).
Figure 4. Deep sections (over 2000 m depth) of potential temperature (°C) and practical salinity (dimensionless) along a transect at 37–37.5° N between the eastern entrance to the Alboran Sea (0° E) and the western entrance to the Sardinian Channel (8.5° E) during the cruises Medgoos9 (a and b; October 2004) before the Western Mediterranean Transient (WMT), Medgoos10 (c and d; May–June 2005), and Medgoos13 (e and f; October 2006) with the filling of the Algerian sub-basin by the WMT.

Figure 5. Potential temperature and practical salinity (θS), with the potential density anomaly (σθ; kg m⁻³) of the casts along the transect of Fig. 4 during the cruises Medgoos9 (a; October 2004) before the WMT, Medgoos10 (b; May–June 2005), and Medgoos13 (c; October 2006) with the typical hooks and inversions of the new deep water characteristics.

https://doi.org/10.5194/essd-14-4187-2022 Earth Syst. Sci. Data, 14, 4187–4199, 2022
A mere 6 years earlier, and at the bottom of the Algerian Basin (Medgoos13 in 2006), values were lower, with 12.845 °C, 38.465, and 29.115 kg m⁻³ of potential temperature, salinity, and density, respectively, as shown in Figs. 4e and f and 5c.

Every winter, new warmer, saltier, and denser deep waters formed, moving to a continuous increase in the heat and salt content in the deep layer, making the deep temperature–salinity (θS) diagrams more and more complex (Schroeder et al., 2016). The replacement of the old deep waters near the bottom by new ones is visible as a creep close to the bottom in 2005 and becoming 600 m thick in 2006, almost 1000 m thick in 2008, over 1200 m in 2010, 1400 m in 2013, and ≥ 1500 m in 2015. Since 2010, the signal of the WMT has been found also in the Tyrrenhenian Sea, after having overpassed the Sardinian Trough, connecting the Algerian sub-basin with the Tyrrenhenian one along the axis of the Sardinian Channel. The WMT changed the structure and properties of the deep layers in the western Mediterranean, which is recognizable by the hooks and inversions in characteristic θS diagrams (in Fig. 5, in comparison with Medgoos9 data prior to the WMT). This set of CTDs acquired during over a decade (2004–2017) can contribute to the understanding of the temporal and spatial evolution of the thermohaline variability in the western Mediterranean Sea. The thermohaline circulation of the Mediterranean Sea, through the Mediterranean Outflow Water (MOW), has a particular impact on the North Atlantic circulation and the Atlantic Meridional Overturning Circulation (AMOC) due to its high salinity, as rebuilt in paleoceanographic studies (Roegner et al., 2012; van Dijk et al., 2018; Ausín et al., 2020; Mesa-Fernández et al., 2022).

4 Data availability

The four datasets described in this study are publicly available and available free of charge from the SEANOE data repository as Ribotti et al. (2019a, b, c) at https://doi.org/10.17882/59867, https://doi.org/10.17882/59777, and https://doi.org/10.17882/70340, respectively, and as Ribotti et al. (2022) at https://doi.org/10.17882/87567. The presented datasets are composed of CTD data in Ocean Data View (ODV) .txt spreadsheet files, with one for each cruise (Schlitzer, 2022).

5 Discussion and conclusion

Over 1468 hydrological vertical profiles were acquired during 29 oceanographic cruises in 21 years in the Mediterranean Sea, with a particular focus on the western and central Mediterranean sub-basins, between May 2000 and October 2020. Each cruise was mainly led by the project objectives funding the research but also by scientific interests at different spatial (coastal or offshore) and temporal (from days to years) scales. The use and reuse of data with time was mainly driven by the following issues: solution of marine environmental problems, studies on ocean circulation and variability, and/or model validation. This is visible in the different spatial resolution of the sampling plans, on a regular grid of casts, or along repeated transects, sometimes with both being used during the same cruise.

During the years, and despite some improvements in sensor quality, sensors and instruments were prepared through the same procedures before and after their use and had the same quality assurance protocols, apart from the two SeriousGame cruises in 2014. CTD data followed all quality check, assessment, standard, and best practices, as defined at an international level (see Bushnell et al., 2019) and through standardized procedures for all sensors (Hood et al., 2010). Pre- and post-calibration, redundant sensors, and water samples analyzed onboard have achieved the best accuracy standard for the instruments used. The presence of the same operators on board for most of the cruise years has assured a reduced uncertainty of the measurements, further increasing the quality of the dataset.

The final results are coherent datasets of CTD data that can be used for all studies, as described in the paper for the WMT or for salt fingering.

Author contributions. AR led some projects and cruises, acquired funding and data, finalized the data quality procedures described in the paper, realized the datasets, and wrote the paper. MB led some cruises, finalized data quality procedures described in the paper, realized the datasets, and collaborated on the writing of the paper. RS and AC led some projects, acquired funding and data, and collaborated on the data analyses and the writing of the paper with FP and GQ.

Competing interests. The contact author has declared that none of the authors has any competing interests.
