Non Standard Finite Difference scheme for Mutualistic Interaction

Description

Gianluca Gabbriellini

December 21, 2013

Abstract

One of the more interesting themes of the mathematical ecology is the description of the mutualistic interaction between two interacting species. Based on continuous-time model developed by Holland and DeAngelis 2009 for consumer-resource mutualism description, this work deals with the application of the Mickens Non Standard Finite Difference method to transform the continuous-time scheme into a discrete-time one. It has been proved that the Mickens scheme is dynamically consistent with the original one regardless of the step-sizes used in numerical simulations, in opposition of the forward Euler method that shows numerical instabilities when the step size overcomes a critical value.

1 Introduction

The mutualism is acknowledged as a fundamental process in ecological systems: it is an interaction between individuals of different species, from which the interacting populations have beneficial effects. Like predation and competition, is now recognized as a consumer-resource (C-R) interaction [1]. The C-R interaction relates the process of nutrient transfer between a consumer and a resource: is a mechanism that describes the way by which individuals interact with each other [2]. All the types of mutualism belong to one of the three general forms of C-R interaction: uni-directional, bi-directional and indirect C-R mutualisms [3].

From a mathematical point of view only few authors have been attempts to modelize the mutualism, probably because it is difficult to retrieve the experimental data. One of the first attempts is based on Lotka-Volterra competition equations [8], but it conducts to the boundless growth of the interacting population. Subsequently, other models are proposed where a stable equilibrium for populations are reached [5], [6]. Holland and DeAngelis [2] developed a general continuous-time model to describe the population dynamic for two mutualistic species; whose model is based on a modified version of the Rosenzweig-MacArthur [10] model of predation.

Although a continuous-time models based on differential equations constitute the first step to modelize a population evolution problem, for the more complexes issues investigated in mathematical biology, the numerical method is the only practicable way. Also, discrete-time models become essential when one wants to describe experimental data that have been collected with a certain interval of time. One of the critical aspects of the discretization methods is just the dependence from this interval, the time step. Since the time step should be selected only in relation to the characteristics of the problem under examination, it is necessary to choose a reliable discretization method that allows to make this transformation without any restriction on time step, as well as not to introduce artifacts, change the linear stability properties etc.. Since, in general, these requirements are not satisfied from all the discretization methods (see i.e. [15]), in this paper is discussed the application of the Non Standard Finite Difference scheme [12] to the system of differential equations discussed by Holland and DeAngelis in the articles [3] and [1]. Of this work is only considered the equations describing the population dynamic for bi-directional C-R mutualism, since the uni-directional problem is easily solved once it has solved the bi-directional one.
2 Time continuous approach

A mathematical model for population growth can be generally described by a system of first order of autonomous ordinary differential equations:

\[
\begin{align*}
\frac{d\xi}{dt} &= f(\xi, k) \\
\xi(t_0) &= \xi_0
\end{align*}
\]  

with \( f : \mathbb{R}^n \rightarrow \mathbb{R}^n \) is supposed to be sufficiently smoothed; \( \xi = \xi(t) : [0, +\infty) \rightarrow \mathbb{R}^n \) are the coordinates, with initial condition \( \xi_0 \in \mathbb{R}^n \); finally \( k = (k_1, k_2, \ldots) \) represents the system parameters. If \( f \) is globally Lipschitz then there exists a unique solution \( \xi \) for all \( t \geq t_0 \), hence the eq. (1) defines a dynamical system on \( \mathbb{R}^n \). For a system defined with eq. (1) we define a steady state solution (or also fixed point of \( f \)) a point \( \tilde{\xi} \in \mathbb{R}^n \) that satisfies the relation:

\[ f(\tilde{\xi}) = 0 \]  

In the continuation of the text will be used the set \( \Gamma_c = \{ \tilde{\xi} | f(\tilde{\xi}) = 0, \tilde{\xi} \in \mathbb{R}^n \} \) to refer to the set of steady states solutions.

If \( f \in C^1 \) it is possible to calculate the \( n \times n \) Jacobian matrix as here indicated with \( J_f \). In term of the Jacobian matrix, as given \( \sigma(J_f) \) the set of its eigenvalues, a theorem ensures that a steady-state \( \tilde{\xi} \in \mathbb{R}^n \) for which \( J \) has no eigenvalues with zero real parts (hyperbolic steady-state) is [7]:

- asimptotically stable if and only if \( \Re \lambda < 0 \) for all \( \lambda \in \sigma(J_f) \),
- unstable if and only if \( \Re \lambda > 0 \) for all \( \lambda \in \sigma(J_f) \).

The same is not true for a non-hyperbolic steady-state.

3 Finite difference approaches

To transform a continuos-time model into a discrete one, the continuos variable \( t \in [0, \infty) \) must be replaced by the discrete variable \( n \in \mathbb{N} \) and the variable \( \xi \) must take discrete values \( \xi_n \). The result is a difference equation. Let \( f : \mathbb{R}^n \rightarrow \mathbb{R}^n \) consider a sequence \( \{\xi_n\}_{n=0}^\infty \): it can be defined by a mapping \( \Lambda : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}^n \) of the form \( H(\xi_{n+1}, \xi_n) \). In some case, such as the one discussed on this paper, is possible that \( \xi_{n+1} \) is given explicitly in terms of \( \xi_n \):

\[ \xi_{n+1} = F(\xi_n) \]  

where \( F : A \subseteq \mathbb{R}^n \rightarrow \mathbb{R}^n \).

For a dynamical discrete system defined by eq. (3) a steady-state \( \tilde{\xi}_n \in \mathbb{R}^n \) respects the following conditions:

\[ F(\tilde{\xi}_n) = \tilde{\xi}_n \]  

Likewise to the continuous case, also in discrete case it is useful to define with \( \Gamma_d = \{ \tilde{\xi}_n | F(\tilde{\xi}_n) = 0, \tilde{\xi}_n \in \mathbb{R}^n \} \) the set of steady-states.

To check the stability of the system described by eq. (4) the procedure is similar to the continuous case. If \( F \in C^1 \) is possible to calculate the \( n \times n \) Jacobian matrix, indicated with \( J_F \). Given \( \sigma(J_F) \) the set of the Jacobian eigenvalues, a theorem (see i.e. [9]) ensures that a steady-state \( \tilde{\xi} \in \mathbb{R}^n \) is:

- locally asymptotically stable if and only if \( \Re \lambda < 1 \ \forall \lambda \in \sigma(J_F) \): this point is an attractor.
- unstable if and only if \( \Re \lambda > 1 \ \forall \lambda \in \sigma(J_F) \): this point is a repeller.
- no conclusions on stability if \( \Re \lambda > 1 \) for some \( \lambda \in \sigma(J_F) \).
The finite difference method is called *elementary stable* if, for any value of the time step $\Delta t$, the linear stability of each $\tilde{\xi}_n \in \Gamma_d$ is the same as the stability of each $\tilde{\xi} \in \Gamma_c$.

From a theoretical point of view this criterion is good in every case to control the stability of the steady-states. Nevertheless, in the case of multi-dimensional systems, especially in two and three dimensions, it is more convenient to use an alternative method, the so-called Jury criterion [19]. Let $\tilde{J}_F := J_F(\tilde{\xi}_n)$, for two dimensional systems the characteristic polynomial of the Jacobian can be written as:

$$\lambda^2 - \lambda tr \tilde{J}_F + det \tilde{J}_F$$

in order to have $\Re \lambda < 1$ for all $\lambda \in \sigma(J_F)$, the Jury condition states that:

$$|tr \tilde{J}_F| < 1 + det \tilde{J}_F < 2.$$  

Therefore, this criterion establishes that exists a necessary and sufficient condition to guarantee the asymptotical stability of the steady-state solutions.

**The forward-Euler method.** This is one of the oldest way to derive a finite difference equation from a differential equation. This numerical procedure requires that the system (1) is transformed by introducing these substitutions:

$$\xi(t) \rightarrow \xi_n$$

$$\frac{d\xi(t)}{dt} \rightarrow \frac{\xi_{n+1} - \xi_n}{\Delta t},$$

where $\Delta t$ is the step size and $\xi_{n+1} \approx \xi(t + n\Delta t)$. As showed by Mickens (see i.e. the reference [16]), in many cases the transformation of eq. (8) leads to numerical instabilities which occur as solutions of the finite difference equations, steady-states, bifurcations etc. that do not appear in the original differential equation.

### 3.1 Non Standard Finite Difference method

To avoid these potential problems, Mickens [12] suggests what is known as the Non Standard Finite Difference (NSFD) method. An important concept on which the NSFD schemes is based is the Dynamic Consistency [17]. This criterion states that, let the first-order autonomous ODE

$$\frac{d\xi}{dt} = f(\xi,k)$$

and given $U$ its set of properties, the difference equation

$$\xi_{n+1} = F(\xi_n,k,\Delta t)$$

is *dynamically consistent* with (9) if it respects the same set of properties. As indicated in [11], the dynamic consistency is verified when a difference equation possess the same stability, bifurcations and chaos of the original differential equation.

A finite difference method is called a NSFD scheme is almost one of the following conditions is satisfied:

I. The order of the discrete derivative should be equal to the order of the corresponding derivatives of the differential equation.

II. Denominator functions for the discrete representation must be non-trivial. The following replacement is then required:

$$\Delta t \rightarrow \phi(\Delta t) + O(\Delta t^2)$$

where $\phi(\Delta t)$ is such that $0 < \phi(\Delta t) < 1 \forall \Delta t > 0$.

III. Nonlinear terms must be replaced by non-local discrete representations, i.e.

$$\xi^2 \rightarrow \xi_n \xi_{n+1}$$
IV. Special conditions that hold for the solutions of the differential equations should also hold for the solutions of the finite difference scheme.

V. The scheme should not introduce spurious solutions.

The NSFD scheme incorporates the principle of Dynamical Consistency.

A very important characteristic of dynamical systems, especially in those of biological interest, is that all solutions must remain non-negative in order to maintain the problem well-posed, from biological and mathematical points of view. A method that respects the Mickens rules (I to V) and preserves the solution positivity is called Positive and Elementary Stable Non standard (PESN) method. The appropriate non-local approximation that provides such a scheme is constructed by using the indications suggested by Patankar [20]. Applying these measures, the discrete scheme will comply with the physical properties of the differential equations, without any restriction on the step size $\Delta t$.

4 An elementary application: the logistic population model

The logistic equation, originally due to Pierre Francois Verhulst [4], is the law that regulates with good approximation the growth rate of a certain population number as function of time. The model is based on the assumption that the population evolves in an environment with limited resources with no immigration or emigration phenomena. Let $x(t)$ the population at instant $t$, the law that regulates it can be expressed from the following first-order autonomous ODE:

$$\frac{dx}{dt} = rx(t) - \frac{rx^2(t)}{E}$$

where $E$ is the carrying capacity of the system and $r$ is the intrinsic growth rate ($r = b - d$, where $b$ is the instantaneous birth rate and $d$ the instantaneous death rate); also we assume $r, k > 0$. The eq. (11) is the same as (1) assuming $\xi = x(t)$ and $f$ coinciding with the right hand term. In this equation the term $rx(t)$ is the intrinsic population growth rate, while $-rx^2(t)/E$ is the self-limiting term. These two factors of $f$ have opposite signs then $f$ can be greater, lesser or equal to zero: this determines respectively the increase, the decrease or the constancy of the population.

Applying the condition dictated by eq. (2), is simple to calculate the two steady-states: a trivial solution $\tilde{x}_1 = 0$ and a non-trivial $\tilde{x}_2 = E$. Substituting these solutions in the Jacobian $J(x) = 1 - 2x/E$ the following inequalities $J(\tilde{x}_1) > 0$ and $J(\tilde{x}_2) < 0$ hold. We can deduce that only the solution $\tilde{x}_2 = E$ is asymptotically stable.

This can be deduced also by an alternative way. The differential equation (11), solved by variables separation technique, admits the following solution:

$$x(t) = \frac{E}{1 + \left(\frac{E}{x_0} - 1\right)e^{-rt}}$$

Calculating the limit of eq. (12) for $t \rightarrow +\infty$ the population has just $E$ as its asymptotic value.

4.1 Discrete model of logistic equation.

Following the NSFD rules, the logistic model of eq. (11) can be transformed in the discrete scheme:

$$\frac{\Delta x(t)}{\phi(\Delta t)} = rx(t) - \frac{rx^2(t)}{E}$$

where $\Delta x(t) = x_{n+1} - x_n$ and $\phi(\Delta t)$ is a function of the time step in respect of the rule II; in accord with rule III, $x^2 \rightarrow x_n x_{n+1}$. Therefore $x_{n+1}$ can be so explicited:

$$x_{n+1} = \frac{1 + r\phi(\Delta t)}{1 + \frac{r\phi(\Delta t)}{E}x_n} x_n$$
where \( x_0 = x(t = 0) \) is the initial population. It is simple to show that the condition of positiveness \( x_{n+1} \geq 0 \) is automatically satisfied if \( \phi \) satisfy the rule II of the NSFD scheme. The steady-states of eq. (14) are \( \hat{x}_1 = 0 \) and \( \hat{x}_1 = E \): for the trivial steady-state, \( J(\hat{x}_1) = 1 + r\phi > 1 \) for \( r > 0 \) and \( 0 < \phi < 1 \), then is unstable; for the non trivial one, \( J(\hat{x}_2) = 1/(1 + r\phi) < 1 \), then is asymptotically stable. We conclude that the NSFD scheme well reproduces the behavior of the differential equation (13).

In opposition, the Euler and Runge-Kutta discretization methods are dynamically inconsistent with the original differential equation [13], showing numerical instabilities. Also in [18] is remarked that the application of these two standard schemes produces a not correct monotonicity and oscillations for particular values of the mesh \( \Delta t \).

5 Mutualistic interaction between two species

It is now considered a more complex case respect to the logistic equation: this is the formulation introduced by Holland and DeAngelis 2009 [3] for the mutualism description, based on Rosenzweig-MacArthur model of predator-prey interactions. After a brief review of the problem in continuous-time domain, two discrete schemes will be proposed.

5.1 Continuous-time domain

Subsequently it will be denoted with \( x(t) \) and \( y(t) \) the numbers (or densities) of the mutualistic species. In a mutualistic model, the growth rate of each species must involve the same terms of the logistic equation (11) that represent effect separate from mutualism: a linear term that represent the intrinsic population growth rate and a quadratic one to modify the growth rate with density dependent self-limitation. Also, for each species, in case of bi-directional mutualism, other two terms are need:

- a positive term that quantify the advantages that the presence of a species induces on the growth of the other (\( \alpha_{ij} \) in eq. (15)),
- a negative term that describes the disadvantages that the presence of a species induces on the growth of the other (\( \beta_i \) in eq. (15)).

With these two conditions, a community of two mutualistic species can be described by the following system [3]:

\[
\begin{align*}
\frac{dx}{dt} &= r_1 x + \alpha_{12} \frac{xy}{h_2 + y} - \beta_1 \frac{xy}{e_1 + x} - d_1 x^2 \\
\frac{dy}{dt} &= r_2 y + \alpha_{21} \frac{xy}{h_1 + x} - \beta_2 \frac{xy}{e_2 + y} - d_2 y^2
\end{align*}
\]

\( x(0) \geq 0, \; y(0) \geq 0 \) \hspace{1cm} (15)

where all parameters are constants, reals and non-negative. To create correspondence with the notation of eq. (1), we assume \( k_1 = (r_1, \alpha_{12}, h_2, \beta_1, e_1, d_1) \) and \( k_2 = (r_2, \alpha_{21}, h_1, \beta_2, e_2, d_2) \).

5.2 Discrete-time domain

**Forward Euler method.** It is required to apply the rules (7) and (8) to the differential equation system (15). The result is:

\[
\begin{align*}
\frac{x_{n+1} - x_n}{\Delta t} &= r_1 x_n + \alpha_{12} \frac{y_n x_n}{h_2 + y_n} - \beta_1 \frac{y_n x_n}{e_1 + x_n} - d_1 x_n^2 \\
\frac{y_{n+1} - y_n}{\Delta t} &= r_2 y_n + \alpha_{21} \frac{y_n x_n}{h_1 + x_n} - \beta_2 \frac{y_n x_n}{e_2 + y_n} - d_2 y_n^2
\end{align*}
\]

\( x_0 > 0, \; y_0 > 0 \) \hspace{1cm} (16)
Then they are calculated:

\[
\begin{align*}
x_{n+1} &= x_n \left(1 + \Delta t \left(r_1 - d_1 x_n + y_n \left(\frac{\alpha_{12}}{h_2 + y_n} - \frac{\beta_1}{e_1 + x_n}\right)\right)\right) \\
y_{n+1} &= y_n \left(1 + \Delta t \left(r_2 - d_2 y_n + x_n \left(\frac{\alpha_{21}}{h_1 + x_n} - \frac{\beta_2}{e_2 + y_n}\right)\right)\right)
\end{align*}
\]

(17)
\[x_0 > 0, y_0 > 0.\]

It is worth noting that the above system is not unconditionally positive due to the presence of negative terms that can allow the generation of negative solutions. This feature is considered to be precursor for numerical instabilities.

For the calculation of the fixed points, the following system must have resolved:

\[
\begin{align*}
x_n &= x_n \left(1 + \Delta t \left(r_1 - d_1 x_n + y_n \left(\frac{\alpha_{12}}{h_2 + y_n} - \frac{\beta_1}{e_1 + x_n}\right)\right)\right) \\
y_n &= y_n \left(1 + \Delta t \left(r_2 - d_2 y_n + x_n \left(\frac{\alpha_{21}}{h_1 + x_n} - \frac{\beta_2}{e_2 + y_n}\right)\right)\right)
\end{align*}
\]

(18)
\[x_0 > 0, y_0 > 0.\]

The scheme (17) and the solutions coming from system (18) will be compared in the Section 6 with results obtained by using NSFD scheme that will be shown in the following paragraph.

**NSFD scheme.** Now, we transform the differential equations in system (15) respecting the following NSFD rules:

- II rule: denominators of left-hand side are replaced with \(\phi = \phi(\Delta t)\);
- III rule and PESN criterion: the terms on the right of the equations are replaced with a non-local approximation.

Then, the resulting finite difference system is:

\[
\begin{align*}
\frac{x_{n+1} - x_n}{\phi(\Delta t)} &= r_1 x_n + \alpha_{12} \frac{y_n x_n}{h_2 + y_n} - \beta_1 \frac{y_n x_{n+1}}{e_1 + x_n} - d_1 x_n x_{n+1} \\
\frac{y_{n+1} - y_n}{\phi(\Delta t)} &= r_2 y_n + \alpha_{21} \frac{y_n x_n}{h_1 + x_n} - \beta_2 \frac{y_n x_{n+1}}{e_2 + y_n} - d_2 y_n y_{n+1}
\end{align*}
\]

(19)
\[x_0 > 0, y_0 > 0.\]

Then they are calculated \(x_{n+1}\) and \(y_{n+1}\):

\[
\begin{align*}
x_{n+1} &= F_1(x_n, y_n, \phi, k_1) \\
y_{n+1} &= F_2(x_n, y_n, \phi, k_2)
\end{align*}
\]

(20)
\[x_0 > 0, y_0 > 0.\]

where:

\[
F_1(x_n, y_n, \phi, k_1) = \frac{(e_1 + x_n)(h_2 + y_n) + \phi(e_1 + x_n)(r_1(h_2 + y_n) + y_n\alpha_{12})}{(c_1 + x_n)(h_2 + y_n) + \phi(h_2 + y_n)(d_1 x_n(e_1 + x_n) + y_n\beta_1)}
\]

(21)
\[
F_2(x_n, y_n, \phi, k_2) = \frac{(e_2 + y_n)(h_1 + x_n) + \phi(e_2 + y_n)(r_2(h_1 + x_n) + x_n\alpha_{21})}{(e_2 + y_n)(h_1 + x_n) + \phi(h_1 + x_n)(d_2 y_n(e_2 + y_n) + x_n\beta_2)}
\]

(22)
The elements of matrix are the following:

The dynamical system has 6 steady-states, indicated with \( \Gamma \) \( t \) \( b \) \( a \) zero-growth isoclines are depicted. \( \alpha \) zero-growth isoclines of each system’s equation and are represented by the points where the isoclines intersect system of differential equation (15). From graphical point of view, the steady-states are found plotting the \( r \) \( inv \) \( r \) \( involved \) \( parameters \) \( mutualism \). In this paper a unique simulation for steady-state analysis is reported, hypothesizing for the many simulations assuming different values for the model’s parameters, i.e. \( \) \( In \) continuous-time domain the problem is largely discussed in \[ 1 \] and \[ 3 \]: these authors have performed the forward Euler schemes found in Subsection 5.2 with the continuos-time one described by the system (15). To discuss the stability of all \( \tilde{\xi} \) \( n \) \( \in \) \( \Gamma_2 \), it is convenient to check if the Jury condition mentioned in eq. (6) it is respected for each of these. To do this, it is need to calculate the Jacobian matrix \( J \) \( in \) which:

\[ \begin{align*}
\lambda^2 & \geq \frac{\max \{ \left[ \frac{\lambda}{2 |\mathcal{R}(\lambda)|} \right] \} \} \text{ if } \mathcal{R}(\lambda) \neq 0 \text{ for } \lambda \in \Omega.
\end{align*} \]

Following the definition given in (4), the steady-states are calculated by solving the below system:

\[ \begin{align*}
F_1(x_n, y_n, \phi, k_1) &= x_n \\
F_2(x_n, y_n, \phi, k_2) &= y_n
\end{align*} \]

To do this, it is need to calculate the Jacobian matrix \( J_F(x_n, y_n) = (j_{ij})_{2 \times 2} \). The elements of matrix are the following:

\[ \begin{align*}
j_{11}(x_n, y_n) &= \frac{(1 + \phi r_1)(h_2 + y_n) + \phi y_n \alpha_{12}((e_1 + x_n)^2 + \phi y_n \beta_1(e_1 + 2x_n))}{(h_2 + y_n)((e_1 + x_n)(1 + \phi d_1 x_n) + \phi y_n \beta_1)^2} \\
j_{12}(x_n, y_n) &= \frac{\phi x_n(e_1 + x_n)(h_2(e_1 + x_n)(1 + \phi d_1 x_n) \alpha_{12} - ((1 + \phi r_1)(h_2 + y_n)^2 + \phi y_n \alpha_{12}) \beta_1)}{(h_2 + y_n)^2((e_1 + x_n)(1 + \phi d_1 x_n) + \phi y_n \beta_1)^2} \\
j_{21}(x_n, y_n) &= \frac{\phi y_n(e_2 + y_n)(h_1(e_2 + y_n)(1 + \phi d_2 y_n) \alpha_{21} - ((1 + \phi r_2)(h_1 + x_n)^2 + \phi x_n \alpha_{21}) \beta_2)}{(h_1 + x_n)^2((e_2 + y_n)(1 + \phi d_2 y_n) + \phi x_n \beta_2)^2} \\
j_{22}(x_n, y_n) &= \frac{(1 + \phi r_2)(h_1 + x_n) + \phi x_n \alpha_{21}((e_2 + y_n)^2 + \phi x_n \beta_2(e_2 + 2y_n))}{(h_1 + x_n)((e_2 + y_n)(1 + \phi d_2 y_n) + \phi x_n \beta_2)^2}
\end{align*} \]

6 Numerical simulations

In this Section are presented some numerical simulations to test the dynamic consistence of the NSFD and the forward Euler schemes found in Subsection 5.2 with the continuos-time one described by the system (15).

6.1 Steady-states analysis

In continuous-time domain the problem is largely discussed in [1] and [3]: these authors have performed many simulations assuming different values for the model’s parameters, i.e. assuming different types of mutualism. In this paper a unique simulation for steady-state analysis is reported, hypothesizing for the involved parameters \( r_1, r_2, \alpha_{12}, \alpha_{21}, \beta_1, \beta_2, e_1, e_2, d_1 \) and \( d_2 \) the same values used by Holland and DeAngelis [3] for bi-directional mutualism. The steady-states have been calculated applying the condition (2) to the system of differential equation (15). From graphical point of view, the steady-states are found plotting the zero-growth isolines of each system’s equation and are represented by the points where the isoclines intersect between them. The phase-plane diagrams for the x-y dynamics is showed in Figure 1a where the zero-growth isolines are depicted.

In the discrete case, NSFD derived scheme has been compared with the Euler one calculating the solutions of the systems (25) and (18) respectively. The Figure 1b represents the isoclines described by the Euler and NSFD schemes for \( \Delta t = 10^{-3} \). From those graphs can be seen that, for the assumed parameters, the dynamical system has 6 steady-states, indicated with \( \Gamma_0, \Gamma^1, ..., \Gamma^5 \) in counterclockwise sense. Also, none
Figure 1: Comparison between phase-plane diagrams for continuous-time and discrete-time cases. (a) Zero-growth isoclines for the system of eq. (15) are represented as black ($dx/dt = 0$) and red ($dy/dt = 0$) lines. (b) Zero-growth isoclines come from the system (25): black dotted line for the first equation and red dotted line for the second equation; zero-growth isoclines come from system (18): in blue the first equation and in green the second one (completely masked by NSFD lines). For the discretization parameters, the following values have been used: $\Delta t = 10^{-3}$, $q = 10$. The steady-states are marked with letters $\Gamma_0$ to $\Gamma_5$: the square $(\Gamma_0, \Gamma_2, \Gamma_4)$ indicates the repellers of the system as well as the circle $(\Gamma_1, \Gamma_3, \Gamma_5)$ indicates the attractors. The values assigned at each parameter is $[3]$: $r_1 = r_2 = 0.3$, $\alpha_{12} = \alpha_{21} = 0.6$, $q_1 = q_2 = 1$, $\beta_1 = \beta_2 = 0.2$, $d_1 = d_2 = 0.01$, $h_1 = h_2 = 0.3$ and $e_1 = e_2 = 0.3$.

**Table 1:** Steady-states of Figure 1. A=attractor, R=repeller.

| Steady-state | x-coordinate | y-coordinate | $\lambda_1$ | $\lambda_2$ | Stability |
|--------------|--------------|--------------|-------------|-------------|-----------|
| $\Gamma_0$  | 0            | 0            | 0.30        | 0.30        | R         |
| $\Gamma_1$  | 30           | 0            | -19.11      | -0.30       | A         |
| $\Gamma_2$  | 25.62        | 83.17        | -0.80       | 0.41        | R         |
| $\Gamma_3$  | 69.83        | 69.83        | -0.70       | -0.30       | A         |
| $\Gamma_4$  | 83.17        | 25.62        | -0.80       | 0.41        | R         |
| $\Gamma_5$  | 0            | 30           | -19.11      | -0.30       | A         |

Figure 2: (a) Plot of eq. (27) versus the time step $\Delta t$. Each curve is related to at least one of the steady-states $\Gamma_0$, $\Gamma_1$, ..., $\Gamma_5$. (b): plot of eq. (28) versus $\Delta t$. In both figures, the solid curves are related to the NSFD and the dashed curves to the Euler method.
of the two discretization methods introduces spurious solutions: the coordinates of the steady-states are the same and the isoclined are perfectly superimposed. The Table 1 summarizes the results of these simulations and the conclusions on steady-states stability for continuous and discrete-time schemes. From the examination of the signs of the eigenvalues, it emerges that $\Gamma_0$, $\Gamma_2$ and $\Gamma_4$ are repellers (indicated in figure with a black square) and $\Gamma_1$, $\Gamma_3$ and $\Gamma_5$ are attractors (black circle).

However, when $\Delta t$ is increased up to $8.445 \cdot 10^{-2}$ we observe that the Euler scheme converges toward wrong steady-states or the two populations have a boundless growth. On the contrary the phase-plan of the NSFD remains unchanged.

Since one of the requisite for the dynamic consistence is the invariance of the stability conditions regardless to the discretization step-size, has been checked for NSFD scheme if the Jury condition is guaranteed or not independently from the value of $\Delta t$. This check is not performed for Euler scheme because, as explained above, it fails the convergence to the correct fixed points for certain values of the step-size.

In order to do this verify, the condition (6) is splitted in two inequalities what will be proved for all $\xi \in \Gamma_d$, rendering explicit the dependence from $\Delta t$ of the Jacobian elements:

$$ det(J_0(\Delta t)) - 1 < 0 \tag{27} $$

$$ det(J_0(\Delta t)) + 1 - |tr(J_0(\Delta t))| > 0 \tag{28} $$

The Figures 2a and 2b represent respectively the left term of eq. (27) and (28), both evaluated as function of $\Delta t$: in both graphics every curve is related to at least one steady-state $\Gamma_0$, $\Gamma_1$, ..., $\Gamma_5$. Only for reasons of correct graphic visualization the two figures have different scales on abscissa. It is easy to see that both the inequalities (27) and (28) are satisfied for NSFD schemes only from $\Gamma_1$, $\Gamma_2$ and $\Gamma_3$ steady-states for each value of $\Delta t$ represented. Nevertheless, has been checked that all the curves are monotone for $0 < \Delta t \leq 10$, then the conclusions about the steady-states stability are unchanged up to $\Delta t = 10$.

### 6.2 Transient dynamics

In this Section a transient analysis has been performed with the purpose to emphasize the possible criticalities of the two considered discretization schemes.

The phase-plan portraits of NSFD and forward Euler difference equations has been showed in Figure 3a and b respectively: it is possible to observe some differences highlighted by red rectangles in the Figure 3b named with $D_1$ and $D_2$. The Figures 3c and d represent the magnification of what happens in $D_1$ and $D_2$ respectively: it is possible to note that in subdomain $D_1$ the population $x$ assumes negative values for about $y \geq 45$ and the population $y$ assumes negative values for about $x \geq 45$. All these negative values appear in the transient.

The Figures 4a and c show a plot of the population vs the iteration number using respectively (17) and (20) schemes. In order to highlight the numerical instabilities, larger values of $\Delta t$ are used in this computation: respectively $8 \cdot 10^{-2}$ for 4a and $8.44 \cdot 10^{-2}$ for 4c; the initial population size is $(x_0, y_0) = (30, 10)$. It can be seen from the Figures 4a that for NSFD equations, after a transient in which the populations $x$ and $y$ reach their maximum value about 72 and 11 individuals, they converge smoothly toward 30 and 0 individuals. For Euler equations there are at least two undesiderable features: the jump after 40 iterations about some negative values after about 60 iterations, as showed in zoomed window (green line). Nevertheless, with both methods, all the populations converge to the correct steady-state $\Gamma_1$. The relative phase-plan is depicted in the Figure 4b, where the different trajectories are evident, especially in the first iterations.

For computation of Figure 4c the conditions are the same, exception for the time step that now is $\Delta t = 8.44 \cdot 10^{-2}$. The remarkable fact is that, while for NSFD the transient preserves the same aspect of Figure 4a, the Euler scheme now converges toward $\Gamma_5$ instead of $\Gamma_1$. In Figure 4d is plotted the relative phase-plan where the anomaly is clear.

Is important to note that none of these anomalies occur with $\Delta t < 10^{-2}$: in particular can be easily checked that with $\Delta t = 10^{-3}$ the curves of evolution of the populations coming from NSFD and Euler schemes are perfectly superimposable. The first numerical instabilities in forward Euler scheme begin to occur when $\Delta t$ overcomes the critical value of $\Delta t_c \simeq 5 \cdot 10^{-2}$. The reason is that in forward Euler, the step sizes larger
Figure 3: (a) Phase-plane portrait of system (20). (b) Phase-plane portrait of system (17). (c) Particular of subdomain D₁ belongs to (b). (d) Particular of subdomain D₂ belongs to (b). Has been used the same parameters used for Figure 1 computation, \( \Delta t = 6 \cdot 10^{-2} \).

Figure 4: Comparison between transients of Euler, eqs. (17), and NSFD difference equations, eqs. (20). (a) \( x \) populations vs iteration number: red points for NSFD and blue points for Euler scheme; \( y \) populations vs iteration number: violet points for NSFD and green points for Euler scheme. \( \Delta t = 6 \cdot 10^{-2} \). (b) Phase-plan of (a). (c) The same of plot (a), but with \( \Delta t = 8.44 \cdot 10^{-2} \). (d) Phase-plan for (c) simulation.
than $\Delta t$, are greater than some characteristic time relevant of this physical problem. The same is not true employing the NSFD technique, in which the numerical instabilities are eliminated since the selected step size of eq. (23) is never larger than the smallest time scale of the system.

7 Conclusions

On the base of the work published by Holland and DeAngelis in 2009, in which is constructed and analyzed a population dynamic continuous-time model that link consumer functional responses of one mutualistic species with resources supplied by another, in this paper a strong non-standard finite difference scheme to solve the continuous-time model is constructed. As showed by numerical simulations, the NSFD framework reproduces the dynamical features of the continuous-time analogous. In particular, it is proved that the method guarantees the correct asymptotic behavior regardless from the size of the time step. It was shown that using the same initial conditions the forward Euler induces scheme-dependent numerical instabilities for $\Delta t$ greater than a critical values, that manifest as jumps in the population evolution in time domain and convergence toward wrong steady-state solutions. On the other hand, in tests that were performed, the NSFD scheme shows none of these problems confirming the versatility of the method.
