Received for publication, April 23, 1979

The presence and nature of interpeptide disulfide bonds in HANA (hemagglutinin and neuraminidase) glycoprotein and F (fusion) glycoprotein of HVJ (Sendai virus) are described. In the case of HANA, subunits of the same or very similar molecular weight were interconnected with a disulfide bond(s). Cleavage of the bond(s) can easily be achieved by the addition of 1 mM dithiothreitol with concomitant loss of the biological activities of the glycoprotein. After splitting of the interconnecting bonds, all the HANA protein subunits remained bound on the viral membrane.

To observe the cleavage of the interpeptide disulfide bond between the F1 and F2 subunits of F glycoprotein, higher concentrations of sulfhydryl compounds were required than were necessary for HANA protein. Splitting of the disulfide bond under either denaturing or non-denaturing conditions failed to release both segments of F protein from the virion. Therefore, F glycoprotein seems to have at least two membrane binding sites, one on F1 and the other on F2.

On the other hand, the disulfide bond which connects the HA1 and HA2 subunits of influenza virus is hardly cleaved under non-denaturing conditions. Addition of 8 M urea or 6 M guanidine HCl, which completely inactivates HA activity, was necessary for the splitting of this disulfide bond by thiol compounds. Interestingly, the HA1 subunit was released from the virion after the cleavage. Thus, unlike F1 and F2 of HVJ, the HA1 subunit seems to have no hydrophobic binding site to the membrane. A model for the arrangement of these subunits on the viral membrane is proposed.

Viral membranes have been used as a unique model system for the study of membrane structure and membrane assembly (1, 2). Because of its ability to induce cell fusion (3), HVJ (Sendai virus) is a particularly interesting object for such studies.

1 This work was supported in part by Cancer Research Grants and a Grant-in-aid for Special Project Research on Biomembranes from the Ministry of Education, Science and Culture of Japan and the Naito Memorial Foundation for the Promotion of Science.

Abbreviations: HVJ, hemagglutinating virus of Japan; TBS, Tris-buffered saline; SDS, sodium dodecyl sulfate; DTT, dithiothreitol; NDV, Newcastle disease virus; NA, neuraminidase; HA, hemagglutinating.
HVJ, a member of the paramyxovirus group, has two glycoproteins that constitute the spikes on the virus envelope (membrane). One of them, designated as HANA, seems to be responsible for the attachment of the virus to the cell membrane, resulting in the agglutination of cells (4). Neuraminidase activity is also associated with this glycoprotein. The other one, designated as F, is required for envelope fusion (virus membrane-cell membrane fusion) (5), and is therefore also required for the other biological activities of the virus, such as infectivity, hemolysis, and cell fusion.

During studies of the structure-function relationship of the viral glycoproteins, we found that HANA glycoprotein of HVJ is present as oligomers connected by an interpeptide disulfide bond(s), and cleavage of this bond by reduced glutathione is accompanied by concomitant loss of the biological activities. Although it is generally true that disulfide cross-linking is infrequent in membrane structures (6, 7), several proteins interconnected with disulfide bonds have recently been found, first in viral [myxo- (8) and RNA tumor (9) viruses] membranes and later in plasma membranes of platelets (10) and fibroblasts (11).

In this paper, we report that (a) splitting of the interpeptide disulfide bonds of HANA glycoprotein by several sulfhydryl compounds caused a concomitant loss of biological activities of HVJ, (b) several interpeptide bonds of viral proteins of myxo- and paramyxo-viruses show marked difference in sensitivity to thiol compounds, and furthermore (c) disulfide bond-splitting is a useful technique for studies on the mode of interaction of peptide segments with the membranes.

MATERIALS AND METHODS

Materials—HVJ, Z strain, was grown in the allantoic cavity of 10 day-old embryonated hen’s eggs and was purified by differential centrifugation as described by Maeda et al. (12). Influenza virus, A/Kumamoto (1976) strain, was grown and purified as described for HVJ. Miyadera strain of Newcastle disease virus was kindly provided by Dr. Y. Kawade and was purified in the same way as HVJ. Human red blood cells were obtained from Midori-zyuji Co. Ltd. and used within 4 weeks after drawing. Chemicals used were all obtained commercially.

Purification of Viral Glycoproteins—HANA and F glycoproteins were purified from HVJ by a modification of the method of Scheid and Choppin (13). A suspension of HVJ in 1 M sodium chloride containing 0.01 M Tris-HCl buffer, pH 7.6, at a concentration of 1 mg of protein per ml was treated with 2% (final concentration) Triton X-100 at room temperature for 30 min and then centrifuged at 130,000 x g for 60 min. The clear supernatant fluid containing most of the viral glycoproteins was dialyzed overnight against 0.05 M sodium acetate buffer, pH 5.0, containing 0.1% Triton X-100. The dialyzed solution, or in some cases undialyzed supernatant solution, was charged at 0°C onto a fetuin-Sepharose 4B column which had been equilibrated with 0.05 M sodium acetate buffer, pH 5.0, containing 0.1% Triton X-100. After washing the column with the same buffer to elute all of the proteins other than HANA protein, the column temperature was raised to 26°C and elution was continued. Purified HANA protein was thereby eluted. It was shown to be homogeneous upon SDS-polyacrylamide gel electrophoresis in the presence of 1% 2-mercaptoethanol. F glycoprotein was purified from the non-adsorbed fraction from fetuin-Sepharose column chromatography by concanavalin A-Sepharose column chromatography using stepwise elution with α-methylmannoside (M. Ozawa, unpublished). The fetuin-Sepharose column was prepared by coupling fetuin, which had been boiled for 5 min in 0.1 M sodium acetate buffer (pH 5.0) and dialyzed against 0.1 M sodium bicarbonate buffer (pH 8.7) containing 0.5 M sodium chloride, to BrCN-activated Sepharose 4B at a ratio of 10 mg of denatured fetuin to 1 ml of agarose beads.

SDS-Polyacrylamide Gel Electrophoresis—The procedure employed was essentially that described by Fairbanks et al. (14). Where indicated, the gel concentration was lowered to 5.0% from the original concentration of 5.6% without changing the ratios of N,N-methylene-bis-acrylamide and acrylamide monomer. The sample was dissolved in 1% SDS in the presence or absence of 1% 2-mercaptoethanol, boiled for 3 min, then immediately subjected to electrophoresis at 4 mA/tube for 2 h. Gels were stained with Coomassie brilliant blue for protein and with the periodic acid-Schiff reagent for carbohydrate (15). Elution of proteins from gels was performed essentially as J. Biochem.
DISULFIDE BONDS IN VIRAL GLYCOPROTEINS

1363

described by Bray and Brownlee (16). Prior to electrophoresis in the absence of 2-mercaptoethanol, virus sample were incubated with 10 mM iodoacetamide before addition of SDS.

Treatment of the Virus with Sulfhydryl and Other Compounds—The virus was incubated at 37°C for 20 min with a selected concentration of sulfhydryl compound (reduced glutathione, dithiothreitol, or 2-mercaptoethanol) or chelating agent in a balanced salt solution at a virus concentration of 1 mg of protein per ml. In the case of urea treatment and urea plus DTT treatment, the incubation time was extended to 60 min. The virus thus treated was precipitated from the mixture by centrifugation at 80,000 x g for 20 min, washed three times with Tricine-buffered saline (140 mM NaCl, 5.4 mM KCl, 40 mM Tricine-NaOH, pH 7.6; TBS), and finally suspended in the same buffer. In the case of urea plus DTT treatment, seven volumes of either TBS containing 1 M sodium chloride, or 5 mM sodium phosphate buffer supplemented with 1 mM EDTA, pH 7.6, were added to the reaction mixture, followed by centrifugation. The resulting precipitates were washed with the buffer which contained urea plus DTT to prevent reversal of the splitting, and then finally washed with TBS. The precipitate was solubilized with 1% SDS containing 1% 2-mercaptoethanol and subjected to electrophoresis as described above.

RESULTS

Splitting of Interpeptide Disulfide Bonds and Loss of HANA Activities—As described in a preliminary report (17), splitting of interpeptide disulfide bonds by reduced glutathione resulted in complete loss of both hemagglutinating and neuraminidase activities. Since the glutathione which cleaved the interpeptide disulfide bonds may still be attached to the protein by a disulfide bond, and may affect the biological activities, we used dithiothreitol instead. This readily cyclizes and is released from protein after splitting disulfide bonds (18), avoiding such modification.

Treatment of the virus with 10 mM DTT (about 4,000-fold molar excess with respect to HANA protein) as described in "MATERIALS AND METHODS" appeared to result in complete cleavage of these interpeptide disulfide bonds, since the electrophoretic pattern obtained with the treated virus in the absence of 2-mercaptoethanol was indistinguishable from that of untreated virus subjected to electrophoresis in the presence of 2-mercaptoethanol (data not shown). The treatment of the virus with DTT in a lower concentration range, from 0 to 1 mM, decreased the amounts of B-1 and B-3 (data not shown) in parallel with the loss of the biological activities (Fig. 1). Cleavage of the interpeptide disulfide bonds of F and B-2 proteins, however, was not observed under these conditions. The biological activities of F glycoprotein, i.e. hemolytic (Fig. 1) and cell fusing (data not shown) activities, were apparently lost, because a prerequisite for these activities, i.e. binding of the treated virus to cells, was completely inhibited by the treatment.

The possibility that the sulfhydryl compounds inactivate the virus by acting as chelating agents seems unlikely, because treatment of the virus with chelating agents such as 6 mM EDTA, 8 mM allylthiourea, and 8 mM o-phenanthroline had no effect on the biological activities (data not shown). To determine whether the susceptibility of hemagglutinating activity of HVJ to sulfhydryl compounds is a common feature of paramyxoviruses or not, the effect of these compounds on Newcastle disease virus (NDV) was examined. As shown in Fig. 2, treatment of NDV with 5 mM DTT resulted in complete loss of the hemagglutinating activity.

Mode of Binding of Interpeptide Disulfide Bond-Linked Fragments of Influenza Virus Glycoproteins to the Viral Membrane—As Laver (8) has already reported, HA1 and HA2 of influenza virus

Vol. 86, No. 5, 1979

Fig. 1. Effect of dithiothreitol treatment on the biological activities of HVJ. O, Hemagglutinating activity; ●, neuraminidase activity; △, hemolytic activity.
are interconnected by disulfide bonds and appear as an HA band in the absence of sulfhydryl compounds. An oligomeric form(s) of influenza neuraminidase which could be dissociated by sulfhydryl compounds has also been reported (19-21).

Since reductive cleavage of interpeptide disulfide bonds resulted in inactivation of the hemagglutinating and neuraminidase activities of paramyxoviruses, such as HVJ and NDV, we examined the effect of the cleavage on the activities of influenza virus. In contrast with paramyxoviruses, influenza virus showed no decrease in hemagglutinating or neuraminidase activity (up to 20 mM DTT; data not shown), nor cleavage of interpeptide disulfide bonds (Fig. 3) on treatment with thiol compounds under non-denaturing conditions. Therefore, we next treated the virus with DTT under denaturing conditions, i.e., in the presence of 8 M urea. The virus preparation, thus reduced and then washed, no longer contained HA₁ even though HA₂ and NA were still present (Fig. 4). This result may be explained as follows: HA₁ and HA₂ were interconnected by disulfide bond(s) but only HA₂ was embedded in the virus membrane. Thus, cleavage of the interpeptide disulfide bond under denaturing conditions can release the HA₁ subunit from the virion. Although the release of hemagglutinin-binding antigen (equivalent to HA₁) from the virion by guanidine HCl plus DTT extraction was reported previously (22), the lipid bilayer was destroyed by chloroform extraction before splitting the disulfide bonds, and furthermore the location of HA₂ was not studied in this case.

Treatment of HVJ with Dithiothreitol under Denaturing Conditions—As cleavage of the interpeptide disulfide bonds resulted in solubilization of a component of disulfide-linked complexes from influenza virus, we examined the effect of similar treatment on HVJ. Under non-denaturing conditions, splitting of disulfide bonds by DTT did not result in the release of any peptide (data not shown). Therefore, the treatment under denaturing conditions which solubilized the HA₁ glycoprotein from the influenza membrane was applied to HVJ. The virus treated with 40 mM DTT in the presence of either 8 M urea or 6 M guanidine HCl was washed under conditions known to remove the peripheral proteins from the membrane (23), e.g., with TBS (pH 7.6) containing 1 M sodium chloride or 5 mM sodium phosphate...
DISULFIDE BONDS IN VIRAL GLYCOPROTEINS

Fig. 3. SDS-polyacrylamide gel electrophoresis of dithiothreitol-treated influenza virus type A. (a) Untreated control; (b) the virus was treated with 20 mM dithiothreitol at pH 8.0 under non-denaturing conditions. Virus preparations were subjected to electrophoresis without addition of thiol compounds on 5.0% gel, and stained with Coomassie brilliant blue. The glycoprotein nature of GP-1, GP-2, GP-3, and HA was confirmed by parallel experiments in which gels were stained for carbohydrate.

Fig. 4. SDS-polyacrylamide gel electrophoresis of influenza virus type A treated with 8 M urea alone (a), or with 8 M urea plus 40 mM dithiothreitol (b). Samples were subjected to electrophoresis in the presence of 2-mercaptoethanol and stained for carbohydrate.

Fig. 5. SDS-polyacrylamide gel electrophoresis of HVJ treated with 8 M urea alone (a, c), or with 8 M urea plus 40 mM dithiothreitol (b, d). Samples (a, b) were washed with 1 M sodium chloride and (c, d) with 5 mM phosphate buffer containing 1 mM EDTA as described in “MATERIALS AND METHODS.” Gels were stained for carbohydrate. Vol. 86, No. 5, 1979

(pH 7.6) containing 1 mM EDTA. In no case was release of F₁ and F₂ subunits from the virion observed (Fig. 5). Since no decrease in HANA glycoprotein content was observed in these treated viruses [compare Fig. 5 with Fig. 1c of a previous report (17)], this suggests that all of the membrane glycoproteins present on HVJ membrane are embedded in the lipid bilayer.

To check the possibility that aggregated F₁ and F₂, although released from the virus, still cosedimented with the virus under the centrifugal conditions employed, F₁ and F₂ were prepared from
Fig. 6. Sucrose density gradient centrifugation of $F_1$ and $F_2$. (a), $F_1$ was dialyzed against 0.15 M sodium chloride containing 10 mM Tris-HCl (7.6) for two days with a change of dialysis buffer. (b), $F_1$ (0.1 nmol) was reconstituted with egg lecithin (1,000 nmol) by the cholate-dialysis method. (c), $F_1$ was dialyzed as described in (a). Centrifugation on a 5 to 30% (w/v) sucrose gradient was performed for 23 h at 150,000 $\times$ g.

The final $F_1$ and $F_2$ preparations gave single bands on SDS-polyacrylamide gel electrophoreograms. $^{14}\text{C}$-Di-palmitoyllecithin was included in egg lecithin as a tracer for phospholipid.

purified F protein by splitting the disulfide bond(s) with 10 mM DTT, treated with excess iodoacetamide and gel filtered on Sephadex G-100 in the presence of sodium cholate (M. Ozawa, unpublished). After prolonged dialysis to remove the detergent, purified preparations were centrifuged for 23 h at 105,000 $\times$ g on a 5% to 30% (w/v) sucrose gradient (Fig. 6). $F_2$ remained near the top of the gradient, so extensive aggregation of $F_2$ released from the virus was very unlikely. On the other hand, $F_1$ was aggregated and sedimented to the bottom in the absence of phospholipids (Fig. 6a), whereas in the presence of lecithin it was almost completely incorporated to liposomes (Fig. 6b). Therefore, $F_1$ seems to bind tightly to lipid bilayers.

DISCUSSION

Since identification of the protein components of a virus has usually been carried out by SDS-polyacrylamide gel electrophoresis in the presence of thiol compounds (mostly 2-mercaptoethanol) which cleave disulfide bonds, the presence and functional implications of interpeptide disulfide bonds in viral proteins have not yet been fully explored. In the previous study (17), we showed that in HVJ at least four proteins, i.e., B-1, B-2, B-3, and F, consist of two or more peptides interconnected by disulfide bonds, and we identified the peptide components of these four proteins. Recently Scheid and Choppin (24) conclusively demonstrated the presence of interpeptide disulfide bonds between $F_1$ and $F_2$ glycoproteins. This disulfide bond is derived from an intrapeptide bond of the inactive precursor protein $F_0$, which is cleaved to $F_1$ and $F_2$ upon proteolytic activation (5). A similar disulfide bond-linked glycoprotein is also present in influenza virus, a myxovirus with no fusion activity. As already demonstrated by Laver (8), HA glycoprotein of the myxovirus is composed of HA$_1$ and HA$_2$ interconnected by a disulfide bond. In this case also, proteolytic cleavage of the precursor protein is the reason for this type of interconnection (25).

Furthermore, the presence of interpeptide disulfide bonds in viral membrane glycoproteins has been reported recently in avian oncorna virus (8), murine leukemia virus (26, 27) and paramyxoviruses (24, 28). Therefore, the presence of such a bond may be a common feature in some types of viral proteins. Most of them interconnect non-identical subunits and seem to be derived from an intrapeptide disulfide bond by proteolytic processing of precursors; they may play some physiological role in virus assembly. However, no evidence for the presence of such a precursor protein was observed for HANA glycoprotein of HVJ (29) or neuraminidase of influenza virus (30). Furthermore, the disulfide bonds seem...
to interconnect subunits of identical or almost the same size in these cases. Therefore, it seems that we are dealing with at least two types of disulfide bonds in viral membranes. The sensitivity of disulfide bonds to sulfhydryl compounds, i.e., the ease of splitting by these compounds, seems to differ among these proteins (Fig. 7). In general, disulfide bonds of fusogenic paramyxovirus glycoproteins were found to be cleaved under non-denaturing conditions, whereas those of non-fusogenic influenza virus glycoproteins were much more stable, as shown in Fig. 7. Denaturation by the addition of urea, guanidine-HCl, or SDS was required for cleavage of the bonds by DTT. An increase in susceptibility to cleavage after denaturation seems to be a general feature, as in the case of a plant toxin, ricin (31). The rather unusual lability of HANA protein of fusogenic viruses with respect to sulfhydryl compounds could be biologically important, since the glycoprotein sticks out from the viral surface by about 120 Å (32), apparently preventing close contact of the lipid bilayers of the viral envelope and cell membrane; therefore, fusion of the viral membrane to the cell membrane may be prevented if this structure is not modified somehow after the contact.

A group of bacterial toxins (diphtheria, botulinus, and others) and plant toxins (ricin and abrin) are also composed of two kind of peptides, one required for binding and the other for inhibition of cellular metabolism. The peptides are interconnected with a labile disulfide bond which can be cleaved by thiol compounds under non-denaturing conditions. Cleavage of such disulfide bonds generally results in an increase of toxicity in cell-free assay, whereas toxicity toward intact cells is decreased either partially or drastically to less than 10% of that of the untreated toxin (31, 33-35). Thus, ease of cleavage of interpeptide disulfide bonds seems to be a common feature of a group of toxic proteins with binding subunit(s) interconnected with a catalytic subunit by a disulfide bond. Since several viruses which show a high fusion frequency of their envelope to the cell membrane also have rather a labile disulfide bond on their surface protein, as shown in this report, it is conceivable that this characteristic is important for the entry of these toxins and viruses through the plasma membrane. In contrast, influenza virus which has little or no chance of envelope fusion (12, 36), seems to possess rather rigid glycoprotein spikes. Further studies, however, are required to confirm this point.

Like the enveloped viruses, which are released from the cell membrane by budding, some kinds of plasma membranes have disulfide-linked peptides. Therefore, earlier generalizations regarding the paucity of disulfide bonds in membrane proteins (6, 7) can applied to erythrocyte membranes or intracellular membranes, but may not be applicable to surface membranes of some types of cells. Although the general biological importance of this difference is not clear at present, the release of LETS protein (fibronectin) (11) and glycoprotein of a corona virus (37) by reductive cleavage of disulfide bonds under non-denaturing conditions, and the inactivation of HANA protein by the same treatment as reported in this paper suggest some biological importance of such labile disulfide bonds on the membrane surface.

We have also presented here a unique and simple method to examine whether all of the components of interpeptide disulfide-linked subunits are embedded in the lipid bilayers, or whether some of them are merely anchored by a disulfide bond to other component(s) which are embedded in the lipid bilayer, and not bound directly to the membrane itself. HA₁ glycoprotein of influenza virus was found to be an example of the latter type; cleavage of the interpeptide disulfide bond between HA₁ and HA₂ under denaturing conditions resulted in solubilization of HA₁ from the virion, leaving HA₂ behind, as expected from a model reported earlier (1). In the case of F protein of HVJ, on the other hand, both F₁ and F₂ seem to
be embedded in the lipid bilayer since they remained there even after complete cleavage of interpeptide disulfide bonds (Fig. 8). All of the constituent peptides of B-1 and B-3, i.e., HANA protein of HVJ, also seem to be embedded in the lipid bilayer, since cleavage of disulfide bonds did not result in the solubilization of HANA protein (Fig. 5).

The majority of membrane proteins so far studied seem to be embedded in the membrane at only one specific hydrophobic segment of the polypeptide; e.g., glycoporphin A of human erythrocytes (38), cytochrome b₆ of liver microsomes (39), and histocompatibility antigens of mouse and man, i.e., H-2 (40) and HLA (41). This does not mean, however, that most of the membrane proteins are of this type, but may simply be a result of the fact that the proteins so far studied are those which are amphipathic in nature and have a large hydrophilic region. Proteins which may span the membrane several times are under intensive study, and the presence of multiple membrane binding sites in membrane proteins has become clear in the case of bacteriorhodopsin (42) and band 3 protein of human erythrocytes (43). Tight binding of the F₁ and F₂ segments of F glycoprotein of HVJ to the viral membrane shows that this is another case of the latter type of membrane protein.

We would like to thank Prof. R. Sato of the Institute for Protein Research for valuable discussions. We are also indebted to Prof. Y. Kawade of Kyoto University for providing Newcastle disease virus. The supply of outdated erythrocytes by Midori-zyuji Co., Ltd. is also gratefully acknowledged.
