ABSTRACT

Background. In a Dutch phase II trial conducted between 2006 and 2010, short-course radiotherapy followed by systemic therapy with capecitabine, oxaliplatin, and bevacizumab as neoadjuvant treatment and subsequent radical surgical treatment of primary tumor and metastatic sites was evaluated. In this study, we report the long-term results after a minimum follow-up of 6 years.

Methods. Patients with histologically confirmed rectal adenocarcinoma with potentially resectable or ablatable metastases in liver or lungs were eligible. Follow-up data were collected for all patients enrolled in the trial. Overall and recurrence-free survival were calculated using the Kaplan–Meier method.

Results. Follow-up data were available for all 50 patients. After a median follow-up time of 8.1 years (range 0.5–9.4), 16 patients (32.0%) were still alive and 14 (28%) were disease-free. The median overall survival was 3.8 years (range 0.5–9.4). From the 36 patients who received radical treatment, two (5.6%) had a local recurrence and 29 (80.6%) had a distant recurrence.

Conclusions. Long-term survival can be achieved in patients with primary metastatic rectal cancer after neoadjuvant radio- and chemotherapy. Despite a high number of recurrences, 32% of patients were alive after a median follow-up time of 8.1 years.
accomplished with neoadjuvant radiotherapy or chemora
diotherapy. Long-course radiotherapy with concomitant
5-fluorouracil-based chemotherapy is the standard neoad-
juvant regimen for locally advanced rectal cancer. In
patients with synchronously metastasized rectal cancer, this
neoadjuvant scheme creates a long interval between the
start of treatment and surgery during which distant
metastases may progress. Furthermore, 5-fluorouracil, or
its oral analog capecitabine, acts as a radiosensitizer and
has no or little effect on distant metastases.

In a Dutch trial, known in The Netherlands as the M1 study, a
new chemoradiotherapy regimen was proposed for patients
with rectal cancer and synchronous metastases. In this study,
patients were treated with a short-course of radiotherapy
(5 × 5 Gy), followed by chemotherapy that consisted of a
combination of capecitabine, oxaliplatin and bevacizumab, and
eventually followed by radical treatment of all tumor sites. In
this regimen, short-course radiotherapy is administered to
achieve control of the primary tumor, while systemic treatment
with capecitabine and oxaliplatin (CapeOx) in combination
with bevacizumab is administrated as treatment for metastatic
disease. In 72% of participants, radical treatment of both
metastases and the primary tumor could be performed. In the
initial analysis, patients had been followed for at least 2 years.
The aim of this update is to study the impact of the study
treatment on long-term survival and recurrence of disease.

MATERIALS AND METHODS

Study Design

Full details of the design, patients’ eligibility criteria,
and procedures have been reported previously. In brief,
this study is an open-label, phase II clinical study that is
registered with the Netherlands Trial Register (NTR2029).
Between April 2006 and December 2010, 50 patients were
included in seven centers in The Netherlands. The primary
endpoint of the initial study was the percentage of patients
receiving radical treatment of all tumor sites. As secondary
endpoints, 2-year survival, 2-year local and distant recur-
rence rate and treatment-related toxicity were assessed.

Eligibility

Patients were eligible for this study if they were diag-
nosed with primary metastasized rectal cancer and were at
least 18 years of age. Rectal adenocarcinoma should be
histologically confirmed, and liver or lung metastases
should be eligible for resection or radiofrequency ablation
(RFA). The Institutional Review Board at each participat-
ing center approved the study protocol, and all patients
provided written informed consent.

Treatment and Study-Related Procedures

Treatment and procedures have been described previ-
ously. In summary, preoperative treatment started with
external beam radiotherapy (5 × 5 Gy) on the mesorectum
and regional lymph nodes. The upper field border was set at
L5/S1. Within 2 weeks after completion of radiotherapy,
chemotherapy started with six cycles of 3 weeks, consist-
ing of capecitabine-oxaliplatin-bevacizumab. On the first
day of a chemotherapy cycle, patients received beva-
cizumab (7.5 mg/kg) and oxaliplatin (130 mg/m²), both as
an intravenous infusion. During the first 2 weeks of each
cycle, capecitabine (1000 mg/m²) was administered as an
oral drug. Surgery was planned 6–8 weeks after the last
dose of bevacizumab, and the surgical treatment strategy
was personalized for each patient by a multidisciplinary
team. Radical treatment (R0) of the liver metastases was
defined as microscopic tumor-free resection margins or an
ablation zone completely covering the metastasis, includ-
ing a ≥5 mm peritumoral margin on the 1-week post-RFA
computed tomography (CT) scan.

Baseline imaging of the primary tumor was performed
with a pelvic contrast-enhanced CT or magnetic resonance
imaging (MRI), and, for imaging of distant metastases, a
CT scan of the chest and abdomen was used. Radiologic
response evaluation was performed after two cycles of
chemotherapy using a CT scan. If no progression of disease
was seen on the CT scan, patients additionally received
four cycles of chemotherapy. After completion of preop-
erative treatment, resectability of both the primary tumor
and metastases were reassessed using the same imaging
procedures as were used at baseline.

Histopathologic evaluation of the resection specimens
was performed by a pathologist following local standards,
and pathologic response after neoadjuvant therapy was
assessed using Mandard’s classification.

Survival Follow-Up and Statistics

Follow-up visits as part of the study were carried out
every 3 months during the first 3 years. Thereafter, follow-
up was at the physician’s discretion. Overall and recur-
rence-free survival were calculated using the Kaplan–Meier
survival analysis method, with overall survival being
defined as the time from the start of radiotherapy until death
from any cause. Recurrence-free survival was calculated for
all patients in whom radical surgery was possible, with
recurrence-free survival being defined as the time from
radical surgery (after which the patient was rendered dis-
ease-free) to the diagnosis of first recurrence. The log-rank
test was used to compare the survival distribution of sub-
groups. All statistical analyses were performed using SPSS
(Released 2013. IBM SPSS Statistics for Windows, Version
RESULTS

Patient Characteristics

Follow-up data were available for all 50 patients. Patient and treatment characteristics are described in Table 1. Median follow-up duration was 8.1 years (range 6.0–9.8). Thirty-six patients in the study received radical treatment (R0), 10 patients had irresectable disease after neoadjuvant radio- and chemotherapy, and in 4 patients the resection of the primary rectal tumor was not radical (R1). Eleven of the 43 patients (25.6%) who received a resection of the primary rectal tumor, showed a pathological complete response, and seven patients (16.3%) showed a pathological near-complete response of the primary tumor.

Overall Survival

Median overall survival of the total cohort was 3.8 years (range 0.5–9.4) (Fig. 1a). The overall survival rate after 2 years of treatment was 74% (37 of 50 patients). The 5-year survival rate was 38.0% (19 of 50 patients), and, after a median follow-up time of 8.1 years, 32.0% (16 of 50 patients) of patients were alive. Fourteen of these 16 patients (28%) were disease-free after 8.1 years of follow-up. In 36 of 50 patients, in whom radical (R0) treatment of primary tumor and metastatic sites was achieved, median overall survival was 4.4 years (Fig. 1b). Survival of these patients was significantly better than in patients in whom treatment was not radical (median overall survival 2.8 years; log-rank test \( p = 0.004 \)).

Recurrence Rate

Of the 36 patients who received radical treatment, 29 (80.6%) had recurrence of the disease, with most of these recurrences being distant metastases. Only two patients developed a local recurrence, one in combination with a distant recurrence. Both patients with a local recurrence had a pathological partial response of the initial primary tumor. The number and location of recurrences are provided in Table 2. The 2- and 5-year recurrence rates were 72.2% and 80.6%, respectively. Patients with recurrence of metastatic disease had a median number of two metastases at presentation with recurrent disease. One of the patients with a local recurrence and 18 of 28 patients (64.3%) with a distant recurrence could be rendered disease-free after successful treatment of the recurrence. Treatment of the distant recurrences consisted of surgery (11), RFA of liver metastases (4), and stereotactic radiosurgery (3). Fourteen of these 18 patients (77.8%) developed a second recurrence. Median recurrence-free survival, calculated after the completion of treatment in this trial, was 7.4 months (Fig. 2a). Median time to recurrence was 7.1 months. Median recurrence-free survival for subgroups with or without pathological complete response was 16.2 vs. 6.6 months, and the difference between the groups was statistically significant (log-rank test \( p = 0.039 \)) (Fig. 2b).

Overall and recurrence-free survival of all individual patients are illustrated in a swimmers plot (Fig. 3).

*RT* radiotherapy, *CT* chemotherapy
Long-term follow-up of patients in this trial showed that long-term survival can be achieved in patients with primary metastatic rectal cancer with a treatment regimen consisting of neoadjuvant radio- and chemotherapy followed by surgical resection of both the primary tumor and metastatic sites. Thirty-two percent of patients were alive after a median follow-up of 8.1 years, and 28% of patients were disease-free at that time.

The number of long-term survivors in this trial can be considered high, regarding the poor prognostic features of the study population. For example, synchronous occurrence of distant metastases and an advanced stage of the primary tumor are known as poor prognostic features in colorectal cancer. In addition, patients with metastases in multiple organs, who were eligible for this study, have a worse progression-free survival. The median overall survival of 3.8 years is longer than could be expected in patients with primary stage IV rectal cancer, but is in accordance with other studies investigating neoadjuvant treatment before surgical resection of all tumor sites; however, these studies had a retrospective design and only included patients with liver metastases.

Despite the high number of long-term survivors, many radically treated patients experienced recurrence of disease (80.6%). Distant recurrences were mainly seen, which is known as the preferred pattern of recurrence in primary metastatic rectal cancer. Most of the recurrences occurred shortly after study treatment; 21 of 29 (72.4%) recurrences occurred within 1 year. The high early recurrence rate could be the result of missed (micro-) metastases by CT scan, which was the only mandatory method of radiological evaluation in this trial. Particularly in relation to the detection of extrahepatic tumor recurrences, which were seen in 20 of 36 (55.6%) patients who received radical treatment in this study, a combined positron emission tomography (PET)-CT scan outperformed a conventional CT scan. Because PET-CT could detect extrahepatic tumor sites at an earlier stage, a more radical treatment of all tumor locations could be performed to prevent recurrences. The high recurrence rate had no significant effect on survival, which may be explained by the fact that many patients could be treated with curative intent for their recurrence. Repeat treatments of recurrent colorectal cancer...

**FIG. 1** Overall survival (months) in a the total study population (N = 50) and b subgroups that did (N = 36) and did not (N = 14) receive radical treatment of primary tumor and/or distant metastases.

**TABLE 2** Anatomic location of recurrences of rectal cancer in patients receiving radical treatment (N = 36)

| Anatomic location                  | Frequency | Percentage |
|-----------------------------------|-----------|------------|
| Rectum (local)                    | 2         | 5.6        |
| Liver                             | 10        | 27.8       |
| Lung                              | 9         | 25.0       |
| Liver and lung                    | 3         | 8.3        |
| Liver, lung, and lymph nodes      | 2         | 5.6        |
| Other                             | 4         | 11.1       |
metastases is possible in approximately 50% of patients, and contributes to a prolonged survival. The high and early recurrence rate in our study is in accordance with other studies. The aim of the chemotherapy regimen in this study was to achieve both local control of the primary rectal tumor and adequate treatment of distant metastases. Therefore short-course radiotherapy (5 × 5 Gy) was followed by adequate systemic cycles of capecitabine, oxaliplatin and bevacizumab. Systemic chemotherapy is capable of downsizing metastatic lesions and can convert unresectable or borderline resectable metastases into resectable metastases. The high number of pathological complete (25.6%) or near-complete (16.3%) responses and low local recurrence rate (5.6%) in this study indicates local control can be achieved with the regimen used in this study. A study in patients with symptomatic primary rectal tumors and unresectable distant metastases showed that short-course radiotherapy and oxaliplatin-based chemotherapy can achieve local control, even in patients with near-obstructing primary tumors. This treatment regimen led to a favorable palliative effect in nearly two-thirds of patients, and palliative surgery was needed in only 20% of patients. An important predictor for pathological response of the primary tumor is the time between radiotherapy and surgery, a longer interval being associated with a higher rate of pathological response. In this study, an interval of approximately 25 weeks existed between short-course radiotherapy and surgery in patients receiving all six cycles of chemotherapy, which could explain the high pathological response rate.

Timing and sequence of surgical resection of a primary tumor with metastatic sites is still subject to debate; surgical treatment could be directed at the primary tumor first, at the metastases first (liver-first approach), or both primary tumor and metastases could be treated simultaneously. Because resection of the primary tumor has no impact on overall survival as opposed to resection of the metastasis, and the metastases can potentially give rise to further systemic spread of the disease, the latter should not be delayed and a metastasis-first or simultaneous approach are preferable. Furthermore, the complication rate of a simultaneous resection is not inferior to a staged resection, but total hospital stay is significantly shorter. Both resection of the primary rectal tumor and resection of hepatic or extrahepatic rectal cancer metastases can cause significant morbidity; therefore, radiological restaging after neoadjuvant therapy is important to make sure that all tumor locations are still resectable. A simultaneous resection of primary tumor and distant metastases was pursued in this study, although in 15 patients this was not feasible and a staged resection was performed.
CONCLUSIONS

We showed that long-term survival, as well as local control of the rectal tumor, can be achieved in patients presenting with rectal cancer and synchronous metastases in liver or lungs by preoperative treatment with short-course radiotherapy and chemotherapy with capecitabine, oxaliplatin and bevacizumab, followed by radical treatment. Patients should be carefully selected by a multidisciplinary team for this treatment strategy, and resectability of all tumor locations should be properly assessed at the start of treatment and reassessed after completion of neoadjuvant treatment.
