Japan is an aging society, and the incidence of diseases related to aging, such as pneumonia, heart failure, vertebral compression fracture (VCF), is increasing. Prolonged hospital stays are becoming a serious social problem, leading to elevated medical expenses. Thus, shortening the period of hospitalization is important. This study aimed to reveal determinants associated with prolonged hospital stays for patients with VCF. Our institution is the primary hospital in a rural area in the Kanto region of Japan. Altogether, 110 patients with a VCF, aged 65 years or older, including 79 women, were divided into two groups according to the average hospital stay period of 28 days: the long-stay group (mean stay 40.0 ± 11.6 days, n = 39) and the short-stay group (mean stay 20.6 ± 4.4 days, n = 71). Notably, the short-stay group included 55 women. Multivariate logistic regression analyses in male showed no variates significantly associated with prolonged hospitalization. By contrast, multivariate logistic regression analyses in female showed requiring emergency transportation to hospital was significantly associated with prolonged hospitalization [odds ratio 7.69, 95% confidence interval 1.13-52.29, P = 0.04]. In conclusion, this study implies that patients with better levels of activities of daily living are able to walk alone sooner and are easily discharged. Furthermore, the patient requiring emergency transportation might be in a poor social living environment, such as living alone. These results may give us a good opportunity to re-consider fundamental problems surrounding the elderly.

Keywords: activities of daily living; determinant; elderly patients; long hospital stay; vertebral compression fracture

Introduction

The rate of aging in Japan is currently the highest in the world, and the ≥ 65-year-old population is projected to account for nearly 40% of the total population by the year 2050 (Chen et al. 2016). Thus, the prevalence of several diseases, including vertebral compression fracture (VCF), pneumonia, heart failure, and age-related dementia, might increase further (Tsuda 2017; Miyashita and Yamauchi 2018; Shimada et al. 2018). Compared with other developed countries, prolonged hospital stays are considered one of the most serious social problems in Japan (Muramatsu and Liang 1999). A major goal is therefore to shorten the hospitalization period.

Our hospital has the aforementioned problem that our elderly patients with a wide variety of diseases were being hospitalized for long periods. Particularly, elderly patients with VCF were admitted to our hospital and then could not be easily discharged. Several Japanese studies reported that some determinants including the early ambulation program with rehabilitation and the difference of discharge destination were related to the hospital stay period on VCF (Kumagai et al. 2011; Ogawa et al. 2013). Furthermore, we hypothesized whether prolonged hospital stay periods are related to a social and medical environment around VCF patients living in a rural area and a clinical condition including the ability of walking in addition to these risk factors. The prolonged hospital stay could ensure that elderly patients with VCF could live healthy after discharge. This study aimed to identify the factors that could lead to long hospitalization periods for elderly patients with VCF. The study population thus included elderly patients hospitalized in our facility with VCF that did not require surgery. Our institution is the primary and designated emergency hospital in a rural area in the Kanto region of Japan. In 2015, 31.5% of the population in this region were ≥ 65 years of age.

Materials and Methods

This study was approved by the Ethics Committee on Research of Human Subjects at Hitachinomiya Saiseikai Hospital (approval number: 18-03) and was conducted in accordance with the Declaration of Helsinki. Written informed consent was waived because of the study’s retrospective design.

Subjects

We evaluated the medical records of all VCF patients admitted to our hospital from January 2016 to December 2017 and collected their data relative to our research. The diagnosis of VCF requires symptoms consistent with a compression fracture and magnetic resonance imaging and/or computed tomography evidence of the fracture.

The inclusion criteria were (1) age ≥ 65 years; (2) VCF of a thoracic and/or lumbar vertebra; and (3) symptoms of a compression fracture. The exclusion criteria were (1) VCF caused by a high-energy injury, (2) infection, or (3) it was a pathologic fracture; (4) its treatment required surgery; (5) the patient had been hospitalized two or more times; and (6) there was no imaging evidence of a compression fracture. The average hospital stay period in all patients with VCF in this study was 27.5 ± 12.1 days, approximately 28 days. We therefore divided the study subjects into those whose hospital stay was ≥ 28 days (long-stay group) and those whose hospital stay was < 28 days (short-stay group). The clinical characteristics were compared between the long- and short-stay groups.

Definitions

- Hypertension was defined as the patient having had medical treatment for hypertension and/or a history of hypertension before admission.
- Dyslipidemia was defined as a total cholesterol level of ≥ 220 mg/dl and/or low-density lipoprotein cholesterol level ≥ 140 mg/dl and/or medical treatment for dyslipidemia and/or a history of dyslipidemia.
- Diabetes mellitus was defined as a hemoglobin A1c level of ≥ 6.5%, the National Glycohemoglobin Standardization Program (NGSP) value, and/or medical treatment for diabetes mellitus and/or a history of diabetes mellitus. We also calculated the estimated glomerular filtration rate (eGFR) from the patient’s serum creatinine level, age, weight, and sex using the following formulas (Matsuo et al. 2009).
  
  $e\text{GFR} = 194 \times Cr^{-1.094} \times \text{age}^{0.287}$ (male)
  
  $e\text{GFR} = 194 \times Cr^{-1.094} \times \text{age}^{0.287} \times 0.739$ (female)
- Osteoporosis, dementia, and thyroid disease were defined according to the use of the particular medical treatment of each and/or a medical history of the disease. Being an insured person with long-term care insurance was qualified as having a need for long-term care because of the condition in question (Hamada et al. 2018).

Statistical analysis

Data are expressed as means ± SD or as the number and percentage. Categorical variables are presented as numbers (percentage) and were compared by using Pearson’s $\chi^2$ test or Fisher’s exact test. The Kolmogorov-Smirnov test was performed to determine if the continuous variables were normally distributed. Normally distributed continuous variables were compared between the groups by using an unpaired Student’s t test. Otherwise, continuous variables were compared by using a Mann-Whitney U test. The multivariate logistic regression model used the variables identified to incur a long hospital stay in the univariate analysis (defined as $P < 0.05$) without missing values. All variables were simultaneously adjusted in one step. Furthermore, multivariate logistic regression analysis predicting the long hospitalization period both in the male patient group and in the female patient group used variables that were the risk factors found in the univariate logistic regression analysis in all study population. The odds ratio (OR) and 95% confidence interval (CI) were calculated. A value of $P < 0.05$ was considered to indicate statistical significance (Wang et al. 2018). All analyses were performed using SPSS 23.0 statistical software/Windows (IBM, Armonk, NY, USA).

Fig. 1. Flow chart of the study.
Results
Among 139 VCF patients admitted to our hospital from January 2016 to December 2017, the final study population included 110 patients (39 in the long-stay group and 71 in the short-stay group) who met the inclusion criteria (Fig. 1).

Table 1 compares patients’ characteristics between the long- and short-stay groups. There were 15 men out of 39 VCF patients (38.5%) in the long-stay group and 16 men out of 71 VCF patients (22.5%) in the short-stay group. Mean height was significantly greater in the long-stay group (150.4 ± 10.0 cm) than in the short-stay group (145.5 ± 8.1 cm) (P = 0.01). The difference in the mean height may reflect the presence of 55 women in the short-stay group. Patients frequently lived alone in the long-stay group (43.6%) than in the short-stay group (23.9%) (P = 0.003). Levels of activities of daily living (ADL) before onset of the compression fracture were worse in the long-stay group. There were also significantly more long-term care insurance owners in the long-stay group (51.3%) than in the short-stay group (29.6%) (P = 0.02). The mean serum albumin level was lower in the long-stay group (3.8 ± 0.5 mg/dL) than in the short-stay group (4.0 ± 0.3 mg/dL) (P = 0.01). The mean white blood cell counts were higher in the long-stay group (7,808 ± 2,264/µL) than in the short-stay group (6,660 ± 1,947/µL) (P = 0.003).

Table 2 compares the characteristics of VCF and its treatment between the two patient groups. Patients in the long-stay group were significantly more likely to need emergency transportation to the hospital at VCF onset (20.5%) than those in the short-stay group (4.2%) (P =

ADL, activities of daily living.

Table 3 shows the clinical outcomes for the two
groups. The mean hospitalization period for all patients
was 27.5 ± 12.1 days. Patients in the long-stay group were
more likely to be discharged to somewhere other than their
homes than those in the short-stay group. Period for acquir-
ing an ability to walk by oneself was significantly longer in
the long-stay group (21.7 ± 6.8 days) than in the short-stay
group (11.8 ± 6.0 days) (P < 0.001). The prevalence of
deterioration of levels of ADL was similar in the two
groups, and there was no one whose levels of ADL were
improved during hospitalization compared with ADL before
admission.

Table 4 shows the univariate and multivariate logistic regression analyses to identify factors that predict pro-
longed hospitalization stays. The univariate logistic regres-
sion analysis showed that the following factors were signifi-
cantly associated with a long hospital stay: the patient’s
height, serum albumin level, and white blood cell count;
living alone; walking by oneself before the compression
fracture; owning long-term care insurance; requiring emer-
gency transportation to the hospital; ability of walking by
oneself at discharge; and discharged to home. The multi-

Univariate logistic regression analysis model indicated that the
living alone and the ability of walking by oneself at dis-
charge were significantly associated with prolonged hospi-
talization, including variables identified in the univariate
analysis that would incur a long hospital stay.

We then analyzed the variables found in the univariate
logistic regression analysis of the all study population in the
male patient group (N = 31) and in the female patient group
(N = 79), respectively. The male group was also divided
Determinants for Prolonged Hospitalization after VCF

into the long-stay group (N = 15, hospitalization period 42.2 ± 14.9 days) and the short-stay group (N = 16, hospitalization period 20.3 ± 4.6 days) according to this study definition. The female group was also divided into the long-stay group (N = 24, hospitalization period 38.7 ± 9.1 days) and the short-stay group (N = 55, hospitalization period 20.7 ± 4.4 days) according to this study definition. Table 5 showed univariate and multivariate logistic regression model both in the male patient group and the female patient group. Multivariate logistic regression model in the male patient group showed no significant variable associated with the prolonged hospital stay. By contrast, multivariate logistic regression model in the female patient group showed that the requiring emergency transportation to emergency department (ED) was significantly associated with prolonged hospitalization, and the living alone as well as the ability of walking by oneself at discharge trended to prolong hospitalization periods.

Discussion

VCF is one of the leading causes of hospitalization among elderly people. This is especially true in Japan, which is becoming a super-aging society (Arai et al. 2015). The mean hospital stay in Japan is considerably longer than in other developed countries and is becoming a serious social problem (Akiyama 2001). Prolonged hospitalization vastly increases medical expenses, and the problem must be considered and solved. Several studies that examined determinants for long hospital stays to identify ways to shorten the hospitalization period have been reported (Kuroda et al. 1992; Langhorne and Baylan 2017). However, effects of the living alone and ability to walk at discharge toward the prolonged hospital stay of VCF patients shown in this study were not mentioned in previous studies. Moreover, few focused on factors associated with long hospitalization periods in rural areas with limited medical resources compared with those in urban areas (Habibov 2010).

In the present study, we showed that patients who lived alone stayed in hospital longer than patients who lived with other family members. Indeed, several studies have shown that living alone was a risk factor for mortality, longer hospital stays following surgery, numerous readmissions, and more expensive medical costs for the elderly (Tabue Teguo et al. 2016; Turner et al. 2016). Unfortunately, the living alone is thought to be increasing in Japan. The problems of the increased number of older persons living alone, their longer hospitalization times, and the increased medical costs have not only been addressed by health care providers but are a concern of the general population benefiting from the present medical system in Japan. Also, older patients living alone might experience anxiety about the possibility of re-admission due to symptom recurrence after discharge (Andreasen et al. 2015). It is thus a challenging issue to try to reassure these patients, even before their admission, that they could be discharged without anxiety. Hence, we should work toward reducing their anxiety from beginning on the day of admission perhaps by coordinating their living environment with a care service system for the elderly, such as home nursing (Nordin et al. 2015).

This study showed that patients who could walk by themselves at discharge stayed in hospital a significantly shorter time than patients with lower ADL. Some studies reported that lower levels of ADL of elderly patients were a risk factor for longer hospital stays and depression (Zanocchi et al. 2002; Unsar et al. 2015). It has been

Multivariate logistic regression model used variables found in the univariate analysis to incur a long hospital stay (significance defined as P < 0.05) without missing values. All variables were simultaneously adjusted in one step. Significant variables in the model were living alone, long-term care insurance usage, requiring emergency transportation to hospital, walking by oneself at discharge, and discharge to home.

P < 0.05 is considered to indicate statistical significance.

OR, odds ratio; CI, confidence interval.
shown that aggressive support of elderly patients during hospitalization to maintain their ADL enabled them to maintain post-hospitalization mobility (Brown et al. 2016). We should make efforts to help patients with VCF to maintain their ADL; thus, their anxiety remains at a low level. Moreover, we should not forget that these patients who are living alone and/or with lower levels of ADL may need more support than those living with family and/or with higher levels of ADL. We therefore should hold a conference with several members including a caregiver to support a patient after discharge from early phase of hospital stay (Ulin et al. 2016). Furthermore, a study showed that long-stay nursing home residents with better levels of ADL before hospitalization had a better prognosis after hospitalization (Kruse et al. 2013). Univariate regression analysis in this study showed that the ability to walk alone before onset of VCF and at discharge were negatively associated with prolonged hospitalization. Moreover, this study showed that patients with VCF who could not walk alone before onset of VCF was not able to walk alone during hospitalization, and were hospitalized for longer time. It is therefore important that we should support the elderly patients to sustain their levels of ADL before hospitalization.

The present study showed that the patients with VCF in the female group requiring an emergency transportation

Multivariate logistic regression model used variables found in the univariate analysis of all study population to incur a long hospital stay (significance defined as P < 0.05) without missing values. All variables were simultaneously adjusted in one step. Significant variables in the model were living alone, long-term care insurance usage, requiring emergency transportation to hospital, walking by oneself at discharge, and discharge to home. Variable of discharge to home was not analyzed in multivariate logistic regression model of the male patient group, because all patients in the short group could discharge to their own home. P < 0.05 is considered to indicate statistical significance. OR, odds ratio; CI, confidence interval.
to ED was significantly associated with the prolonged hospital stay. This study also showed that the patients requiring an emergency transportation to ED (66.7%) were likely to live alone compared with those who did not need emergency transportation to ED (25.7%) (P = 0.02). It appears that the patients who needed emergency transportation were in relatively poor social living environment.

This study has some limitations: first, because the study was based on a single-center, retrospective, observational design, there is a risk of selection bias. Second, because our study population was relatively small, our statistical analysis has an inherent risk of a β error (Brogan et al. 1994). This study lacked some background data on the patients, including bone mineral density, young adult mean level of bone mineral density, and degree of pain related to the VCF. Finally, the study was conducted in one limited rural area, therefore, further studies in other setting including other rural areas must be necessary to conclude our findings.

In conclusion, the conditions of living alone and the inability of walking alone after discharge were determinants significantly associated with prolonged hospitalization. This study might imply that patients with better levels of ADL are earlier able to walk alone and are easily discharged. Furthermore, the patient requiring emergency transportation to ED might be in a poor social living environment. However, this study had several limitations, one of which was its relatively small study population. Future research is therefore necessary to elucidate the determinants of prolonged hospitalizations for elderly patients with VCF.
