Abstract

Background

Obesity is increasing in Sweden and is also of huge global concern. Obesity increases the risk of complications during pregnancy and the need for the induction of labor. Induction of labor increases the number of complications during delivery, leading to women with more negative birth experience. This study investigated how maternal body mass index (BMI) during antenatal care enrollment affects labor outcomes (proportion of cesarean section at induction of labor).

Method

This was a retrospective cohort study of 3772 women with mixed parity and induction of labor at Soderhospital, Stockholm, in 2009–2010 and 2012–2013. The inclusion criteria were simplex, ≥34 gestational weeks, cephalic presentation and no previous cesarean section. The women were grouped according to BMI, and statistical analyzes were performed to compare the proportion of cesarean sections after induction of labor. The primary outcome was the proportion of cesarean section after induction of labor divided by group of maternal BMI. The secondary outcomes were postpartum hemorrhage >1000 ml, time of labor, fetal outcome data, and indication for emergency cesarean section.

Result

The induction of labor in women with a high BMI resulted in a significantly increased risk of cesarean section, with 18.4–24.1% of deliveries, depending on the BMI group. This outcome persisted after adjustment in women with BMI 25–29.9 (aOR 1.4; 95% CI; 1.1–1.7) and BMI 30–34.9 (aOR 1.5; 95% CI; 1.1–2.1). There was also a significantly higher risk for CS among primiparous women (aOR 3.6; 95% CI; 2.9–45) and if the newborn weighted ≥ four kilos (aOR 1.6; 95% CI; 1.3–2.0).
Conclusion
Our findings show that a higher BMI increased the risk of cesarean section after induction of labor in the groups with BMI 25–34.9. Parity seems to be the strongest risk factor for CS regardless other variables.

Introduction
Overweight and obesity are increasing problems in Sweden, although they are also a huge global concern given the increased risk of complications they pose during pregnancy [1]. Studies have shown an increased risk of being overweight and obese at a lower socioeconomic status [2]. The proportion of Swedes with obesity has tripled since the 1980s [1]. In 2018, 26.4% of Swedish women were overweight (BMI>25), and 15.1% of them were obese (BMI>30) at enrollment in antenatal care. Large regional differences are present in the country; in some parts, half of all registered women are overweight or obese, while women in Stockholm have the lowest BMI in Sweden. Despite the lower incidence, as many as one in 4 women is overweight, and one in 10 women is obese in Stockholm [3].

Women with a high BMI have an increased risk of developing diabetes, preeclampsia (PE), and eclampsia during pregnancy [4, 5]. Maternal obesity is also associated with an increased risk for postdate pregnancy and fetal risks, such as large for gestational age (LGA), intrauterine growth restriction, intrauterine fetal death (IUFD), and Apgar score of <7 in 5 minutes [6–8].

Studies of gestational age in obese pregnancies have shown that a high maternal BMI increases the risk of a longer pregnancy (>41 weeks of gestation), which is associated with the risk of labor induction [8–11]. In the last five years, 21% of all pregnant women have been induced to labor in Sweden. Induction of labor (IOL) increases the risk of instrumental delivery, such as vacuum extractions and cesarean section (CS). The risk of CS after IOL was 22.6% vs. 9.4% in the spontaneous onset of labor in Sweden [12]. The corresponding figures for Soderhospital in Stockholm during the same period were 19.5% vs. 8% respectively [12]. Figures for obese women are even higher, where approximately 30% of obese women are delivered by emergency CS after a spontaneous onset of labor. Overweight and obesity are also associated with longer periods of active labor [14]. For cervical ripening and reaching active labor, studies have shown that obese women have a different course of labor compared with women with a normal weight (BMI<25) [7, 9, 10, 13, 14]. Cervical ripening is slower, which means that it takes longer to reach the active phase of labor and that they may need more doses of prostaglandins during IOL. Studies have also suggested that overweight and obese women may need higher doses of oxytocin during labor. Nevertheless, obese women have an increased risk of CS due to dystocia compared to normal-weighted women in normal deliveries, especially during IOL. In their assessment of the time of labor, Kobayash et al. showed [17] that the progress of labor differs between normal weights, overweight, and obese women. Obese women have slower progress between 4–7 cm of cervical dilation, and after that, the progress becomes normalized [15]. CS is more common in induced labor and is also associated with more serious complications. A previous CS increases the risk of a new CS, with an even higher risk for complications, especially in obese women. The aim of this study was to investigate how maternal body mass index (BMI) at antenatal care enrollment affects labor outcomes regarding the proportion of CS at IOL.
Materials and methods

A retrospective cohort study of all induced women during the years 2009–2010 and 2012–2013 was conducted at Soderhospital, Stockholm, Sweden. The year of 2011 was not included because there was a change in clinical practice of IOL at the clinic in that year. One changed from Miprostol and balloon as primary method of IOL to oral solution of misoprostol. Since the method was new at the time, there were too many confounders present to use data from that particular year.

This hospital is the second largest maternity clinic in Sweden and a secondary referral center in the center of Stockholm, with nearly 8,000 deliveries a year. Women were grouped by BMI. Women with normal weight, G1 (BMI < 25), overweight, G2 (BMI 25–29.9), and obesity were divided into two groups, G3 (BMI 30–34.9) and G4 (BMI > 35).

The primary outcome was the proportion of CS after IOL divided by group of maternal BMI. Secondary outcomes were postpartum hemorrhage (PPH) > 1000 ml, time of labor (from induction to delivery), indication for emergency CS, Apgar score < 7 at 5 min, and cord blood pH < 7.1. The inclusion criteria were induced women with simplex pregnancy ≥ 34 weeks, cephalic presentation and no previous CS. The exclusion criteria were multiple births, non-cephalic position, intrauterine fetal death (IUFD), and known fetal malformation or pregnancy < 34 weeks of gestation. As the incidence of women with a previous CS is very low (only 5%) in this study, they were removed from the study to give an even more homogeneous group with women with no history of previous CS.

All personal data were encoded so that individuals could not be identified in the analysis.

Statistics

Data were collected from the journal system Obstetrix (Cerner, North Kansas). Statistical analyses were performed using SPSS (23.0) (SPSS Inc., Chicago, Illinois). Categorical variables are presented as frequencies (%), and continuous variables are presented as mean values (with standard deviation (SD)). The method for comparing the means of continuous variables was an independent sample t-test used. To compare binary variables, calculations were performed either by Fisher’s exact test in groups < 5 or Chi-square test for the others.

Binary logistic regression was used to study the risk of CS after IOL. Associated factors examined were BMI group (G1–4), age (< 30 or > 30 years), previous vaginal delivery (yes/no), gestational age (> 41+0v or < 41+0v), Bishop score (BS) at the start of induction (> 5 or < 5), indication for IOL, oxytocin infusion (yes/no), systolic blood pressure > 140 mmHg (yes/no), and PPH > 1000 ml during childbirth. Fetal birthweight (> 4000 g or < 4000 g). The crude (unadjusted) association was first calculated for each possible explanatory variable. Variables that showed significant association were analyzed with multivariable models to study the adjusted associations with respect to the other possible explanatory variables (above). The associations are presented as odds ratios (OR) with a 95% confidence interval (CI). A p-value < 0.05 was considered statistically significant.

Ethical approval

The study was approved by the regional ethics committee (Karolinska Institute, file record: 2014/757-31/2). The study complies with the World Medical Association Helsinki Declaration regarding the ethical conduct of research involving human subjects.

Results

During the study time, 29441 women were delivered at the hospital. Of these, 4603 (16%) of the women were induced to labor (Fig 1) and 3772 of these induced women met the inclusion
criteria for this study and constituted the study sample. The proportion of overweight women (BMI 25–29.9) in the study was 22.6% (853/3772), 7.1% (266/3772) of them were obese (BMI ≥30–34.9) and 2.9% (108/3772) had severe obesity (BMI >35). This is consistent with the pregnant population in Stockholm. Maternal baseline data showed significant difference (33.1–33.9 years, p = 0.003) between the BMI groups (G1–G4) according to maternal age, gestational age. There were no significant difference in Bishop score (BS), gestational age, or method of induction between the four groups (Table 1).

There was a significant difference according to parity, where nulliparous women were more common in group G1. It was significantly more women that needed oxytocin infusion in group G2 (64.1%) compared to G3 that the lowest figures (59.8, p<0.001). Significant difference was also found in the indication for IOL (p <0.01). Postdated pregnancies were the most common indication in Groups G1 and G2, non-medical indication was the most common in G3, and maternal indication was the most common in G4. No significant difference in IOL method was found between the groups (p = 0.8). Differences in blood pressure at admission to the delivery ward were significant; however, they were normal in all four groups (p <0.01). We found that 19.3% (727/3772) of IOL ended in a CS. The highest frequency of CS was found in G4 compared to the group with the lowest BMI in G1 (24.1% vs. 18.4%, p <0.01, Table 2).

Vacuum extraction (VE) was significantly more common with vacuum among women with normal BMI compared to the overweight women (15.0% vs. 8.3–10.9%, Table 2). There was no significant difference in the frequency of PPH >1000ml, time from induction to delivery, or indication for emergency CS between the four groups (Table 2).

There was a significant difference in fetal weight (p <0.01). Fetal weight increased with maternal BMI (Table 3), and 21.4% (806/3772) of the newborns had a fetal weight ≥4000g. No
A significant difference was seen regarding Apgar <7 at 5 min or cord blood pH <7.10 (Table 3).

The associations between the different risk factors for CS and IOL are presented in Table 4. A significant difference was seen regarding the risk that the IOL ended in a CS in groups G2 (aOR 1.4; 95% CI 1.2–1.7) and G3 (aOR 1.1; 95% CI 1.1–1.9), but not significant in G4. After adjusting for other risk factors, the difference was still significant in G2 and G3 (aOR 1.4; 95% CI; 1.1–1.7 and aOR 1.5; 95% CI; 1.1–2.1, Table 4).

After adjustment for other risk factors, parity seemed to be strongest risk factor for CS. Further, the analysis showed an increased risk of CS after IOL if the woman was ≥30 years old, nulliparous, BS ≤5, or was induced ≥41+0 weeks. The results also showed that the risk of CS was increased with IOL due to maternal indication (aOR 1.4; CI 95% 1.0–2.0), fetal weight >4000 g (aOR 1.8; 95% CI 1.4–2.2), or a woman’s systolic blood pressure was >140 mm Hg (aOR 1.6; 95% CI 1.2–2.0) upon presenting for delivery. However, oxytocin infusion did not increase the risk of CS Table 4). Interactions were found between maternal age and parity p-
value < 0.001 and between parity and indication for IOL, p-value 0.02. There were no further interactions (p-values between 0.06–1.0).

Discussion

The main finding of the study was the increased risk of CS after IOL with a rise in maternal BMI. After adjustment, the outcomes persisted in the groups with BMI 25–29.9 and 30–34.9. This result is consistent with the results of previous studies [10, 11, 13, 14, 16]. There were less women in G4 compared to the other BMI groups, which could explain why the result isn’t significant for these women.

An increased incidence of VE was seen in normal-weight women with IOL compared to overweight and obese women. This has also been reported by Arrowsmith et al. in their 2011 study [11]. A significant increase in the risk for CS was seen in nulliparous women with increasing age and parity seems to be the strongest risk factor for CS. The risk of CS after IOL

increased significantly if the indication for IOL was maternal, as in the case of rising blood pressure, PE, pain, or other illness. One explanation could be that deterioration in the woman's condition may have interrupted the delivery.

Why do women with a higher BMI undergo CS to a greater extent after IOL than normal-weight women? As indicated in previous studies, with a higher BMI, the risk of prolonged labor progress of up to six centimeters was seen during labor. Although cervical ripening is often slower than in normal-weight women, studies have shown that the latter part of the delivery is as fast as in normal-weight women [10, 13, 17]. However, this is often interpreted as primary dystocia and is associated with an increased risk of unnecessary interventions, which

increases the risk of CS. This could explain the results of this study that the higher proportion of CS differed significantly between the BMI groups. Time from induction to delivery were longer in the groups with higher BMI even though it was not significant \( p = 0.06 \). Together with previous results and WHO guidelines, this study confirmed that the latency phase extends to a cervical dilatation of five centimeters [18]. It demonstrates the importance of knowledge about how cervical ripening and opening progress during active labor differ with varying BMI. Thus, it is essential to consider this in clinical practice to reduce the risk of CS, in order not to interrupt the labor when the woman has not yet entered the active phase. The results of the study also showed that there are higher proportions of women undergoing CS due to primary dystocia among overweight and obese women than among normal weight women. Although the proportion of primiparous women was higher among those with a BMI <25, the proportion of CS was lower, perhaps because the obese and overweight women have not reached active labor before it is interrupted.

There was no difference in PPH between the BMI groups. Results from other studies are variable, with some showing similar results [15, 19], while others showing increased risk of PPH among obese women [7]. The reason for this was not investigated in this study. However, some speculation can be made. In the labor of overweight and obese women, there is often a pronounced concern about heavy bleeding after delivery, and rapid measures are taken to prevent this potentially life-threatening scenario. The success of this could be due to a higher preparedness for major bleeding and one of the reasons why there was not an increased risk in the study.

Obese and overweight women are at increased risk of complications during pregnancy and labor, and fetal weight is higher at birth. This may lead to complications seen in children large for gestational age, such as prolonged labor, shoulder dystocia, and instrumental delivery (VE and CS). The children of women with a higher BMI were seen in the study to have a significantly increased risk of fetal weight over 4000 g; otherwise, no significant difference in fetal data was observed. These results are consistent with those of previous studies [5, 11].

**Strengths and limitations**

One of the strengths of this study is that it was carried out in one of Sweden’s largest delivery wards, with data from several years. Thus, the results can be generalized to a similar context in other parts of Sweden and Europe. It was a retrospective study; however, given that careful journal reviews were conducted of the included women, the results are more reliable compared to other retrospective studies based on, for example, diagnostic codes. The distribution of women with overweight and obesity in the study is consistent with the distribution in Stockholm, which is a strength of the study, as it reflects the population. A limitation with this group of women in Stockholm with the lowest BMI in the country, does not reflect the whole country. Another strength of the study is that baseline data did not differ significantly between the groups in terms of gestational age and BS, maternal age was significant different but the difference was 33.1–33.9 years and that difference in less than one year is of no clinical relevance, which is why it cannot be an explanation for the differences observed in the results of the study. A limitation may be that the study was conducted in only one hospital; a multicenter study would have been better, as a larger population from several contexts provides a greater generalization. We also observed a difference regarding parity, with more primiparous women in the normal weight group (G1). This difference can also be seen as a strength, as there is an increased risk in nulliparous women, with delivery tending to end by CS. Further, the proportion of nulliparous women in the study was lower among the overweight and obese groups. The increased risk of CS observed in women with BMI >25 was not explained by parity.
Conclusion

The findings of this study showed that a higher BMI increased the risk of CS after IOL in the groups G2 and G3 (BMI 25–34.9). Overweight and obese women were at increased risk of complications during pregnancy and labor. Parity seems to be the strongest risk factor for CS regardless other variables. The largest proportion of primiparous women was seen in the group with lowest BMI that also had the fewest CS. Thus, it is important to consider these findings to increase the chance of vaginal labor, avoid an unnecessarily CS, and reduce the risks of future pregnancy and labor.
