I. INTRODUCTION

The general problem of externally generated time harmonic waves linearly interacting with a structure of limited spatial extent is basic in many fields of science \[1 \underline{2} \underline{3}\]. In recent years much work has been done elucidating the consequences for the scattering of waves in cases in which, in the geometric optics approximation, the ray orbits within the structure are chaotic. Examples include optical \[4\], acoustic \[5\], microwave \[6, 7, 8, 9\] and electronic cavities \[10, 11\]. In the case of complex or irregularly shaped enclosures that are large compared with a wavelength, small changes in the frequency and the configuration give rise to large changes in the scattering characteristics. This feature motivates treatments that are statistical in nature. In this regard random matrix theory \[12, 13\] has proven useful in predicting universal aspects of chaotic wave scattering problems in the cases of both time reversal symmetric systems (corresponding to matrix statistics of the Gaussian Orthogonal Ensemble, GOE) and time reversal symmetry broken systems (corresponding to matrix statistics of the Gaussian Unitary Ensemble, GUE).

Scattering problems can be characterized by the scattering matrix \( S \) which relates outgoing scattered wave amplitudes \( b \) to incoming waves \( a \), via \( b = Sa \). An alternative formulation is in terms of the impedance matrix \( Z \). To illustrate the impedance description, consider an electromagnetic wave scattering problem in which \( N \) transmission lines labeled \( i = 1, 2, \cdots, N \) of characteristic impedance \( Z_{0i} \) are connected to a cavity. Let \( V_i \) and \( I_i \) represent the voltage and current on transmission line \( i \) as measured at a suitable reference plane. Then the incident wave \( a_i \) and the reflected wave \( b_i \) may be expressed as

\[
a_i = (V_i + Z_{0i} I_i)/Z_{0i}^{1/2}, \quad b_i = (V_i - Z_{0i} I_i)/Z_{0i}^{1/2}.
\]

The impedance matrix \( Z \) relates the vector voltage to the vector current, via \( V = ZI \), and \( Z \) and \( S \) are related by \( Z = Z_0^{1/2}(1-S)^{-1}(1+S)Z_0^{1/2} \), where \( Z_0 \) is the \( N \)-dimensional identity matrix, and \( Z_0 = \text{diag}(Z_{01}, Z_{02}, \cdots, Z_{0N}) \). The impedance formulation is identical to the so called “\( R \)-matrix”, a formulation introduced by Wigner and Eisenbud in nuclear-reaction theory in 1947, and further developed in Refs. \[14, 15, 16, 17\].

Statistical variations of the elements of \( Z \) and \( S \) due to small random variations in the scattering are of great interest. These statistics have two fundamental influences, (i) universal aspects described by random matrix theory, and (ii) nonuniversal aspects dependent upon the details of the coupling of input channels (e.g., transmission lines) to the scatterer. Our main result concerns the quantity,

\[
VR_z = \frac{\text{Var}[Z_{ij}]}{\sqrt{\text{Var}[Z_{ii}] \text{Var}[Z_{jj}]}} \quad i \neq j,
\]

where \( \text{Var}[A] \), the variance of the complex scalar \( A \), is defined as the sum of \( \text{Var}[\text{Re}A] \) and \( \text{Var}[\text{Im}A] \). Our result is of the form

\[
VR_z = \begin{cases} F_1(\lambda) & \text{for GOE}, \\ F_2(\lambda) & \text{for GUE}, \end{cases}
\]

where \( \lambda \) is a parameter characterizing the losses within the scatterer. For example, in the case of an electromagnetic cavity, \( \lambda = \omega/(2Q\Delta \omega) \), where \( \omega \) is the frequency of the incoming signal, \( \Delta \omega \) is the average spacing between cavity resonant frequencies near \( \omega \), and \( Q \) is the quality factor of the cavity (\( Q = \infty \) if there are no internal losses). The remarkable aspect of \[2\] is that \( F_{1,2}(\lambda) \) depends only on the loss parameter and not on the nonuniversal properties of the coupling to the cavity. Thus \( VR_z \) is a universal function of the loss \( \lambda \). The results for \( F_1 \) and \( F_2 \) (to be derived subsequently) are shown in Fig. \[4\].
II. IMPEDANCE VARIANCE RATIO

In this section we will obtain the universal functions $F_{\varphi,\sigma}(\lambda)$ in Eq. (2). We adopt a formulation (e.g., see Refs. [22, 23]) that incorporates the nonuniversal effects of the specific coupling geometry of input-output channels to the scatterer, combined with the random matrix theory for the universal aspects of the chaotic wave behavior within the scatterer. (In what follows, we use terminology appropriate to microwave experiments.) Beginning with the case of zero loss ($\lambda = 0$), we have that, in the GOE case, the impedance matrix $Z$ is described by the following statistical model [22],

$$Z = -\frac{j}{\pi} \sum_n \Delta(k_n) \frac{R^{1/2}_s(k_n) w_n w_n^T R^{1/2}_s(k_n)}{k^2 - k_n^2}.$$  \hspace{1cm} (7)

Here $k$ is the wave number corresponding to the incoming frequency, $w_n$ is a vector whose elements are real, independent, zero mean, Gaussian random variables of unit variance. The eigenvalues $k_n^2$ are randomly chosen with statistics appropriate to GOE. This is done by generating ensembles of eigenvalues of random matrices and then scaling them such that the mean spacing between adjacent eigenvalues near $k_n^2$ is $\Delta(k_n)$. Here $\Delta(k)$ is given by the Weyl formula for the mean eigenvalue spacing. For example, for the case of a 2D cavity $\Delta(k)$ is independent of $k$, $\Delta = 4\pi/A$ where $A$ is the area of the cavity. The system-dependent part of the coupling is characterized by the corresponding radiation impedance matrix $Z_r = R_r + jX_r$. Note also that, since $Z_r$ depends only on local geometry near the entrances to the scattering region, its frequency dependence is much slower than that of $Z$ which depends on the geometry of the scattering region assumed to be characterized by much longer length scales. The radiation impedance is the impedance seen at the reference plane of the input channel when waves that leave the channel propagate outward and are not reflected back to their input by the distant walls of the cavity. Thus the radiation impedance is the impedance seen when the distant walls are removed to infinity, or (as can be done in an experimental measurement [1]) when the distant walls are lined with absorber. Hence the radiation impedance depends only on the local structure in the vicinity of the port coupling to the cavity and not on the shape or chaotic properties of the cavity. In the case of ports that are far apart, e.g., of the order of the cavity size, the off-diagonal elements of $Z_r$ are small and will be neglected. Thus we will take $Z_r$ to be a diagonal matrix with elements $Z_{rr} = R_{rr} + jX_{rr}$. In the GUE case, the elements of $w_n$ in (3) are complex with real and imaginary parts each individually having Gaussian statistics, $w_n^T$ in (3) is replaced by $w_n^*$ (where $^*$ denotes the conjugate transpose), and the statistics of $k_n^2$ are now those appropriate to GUE.

Equation (7) is derived in [22]. It results from a formal series expansion of the solution for $Z$ in terms of eigenfunctions of the closed cavity. The local structure
of the eigenfunctions is then assumed to satisfy the so-called "random plane wave hypothesis"; namely, that in the semi-classical limit \((k^{-1} \text{ is large compared to the typical dimensions of the structure})\), if ray trajectories in the closed cavity are chaotic, then eigenfunction \(n\) is statistically similar to a random isotropic superposition of plane waves of wave number \(k\) with magnitude \(|k| = k_n\). This gives Eq. 10. We then further supplement Eq. 10 with the known distribution function of \(k_n^2\) determined from random matrix theory and the local mean spacing \(\Delta_{k_n}^2\) between adjacent eigenvalues.

The universality of the result for \(VR_z\) (Fig. 1) can be shown from 11 as follows. The impedance matrix \(Z\) defined in 11 will have a mean and a fluctuating component. As shown in refs 22, 23, the value of the mean is determined by all terms in the sum and thus depends on the slow \(k\)-dependence of \(R_r(k)\) and \(\Delta(k)\), while the fluctuating component of \(Z\) is determined by terms in the sum in Eq. 11 for which \(k^2 \simeq k_n^2\). Thus if \(R_r(k_n)\) and \(\Delta(k_n)\) are approximately constant over a range of \(k^2\) values corresponding to many resonances, then the fluctuating part of \(Z\) will be universal after appropriate normalization. If we define \(\tilde{Z}\) to be the fluctuating part of \(Z\), we have

\[
\tilde{R}_r^{-1/2}(k) \tilde{Z} R_r^{-1/2}(k) = -\frac{j}{\pi} \sum_{n} \frac{w_n^* w_n}{s_n} \equiv \zeta^{(t)},
\]

where \(s_n\) are the eigenvalues of a GOE random matrix, normalized to have unit mean spacing between adjacent eigenvalues near \(s_n \approx 0\). Thus \(\zeta\) is a universal normalized impedance matrix. If \(Z_r\) is diagonal, we have \(\zeta_{ij} = R_{ri}^{-1/2} R_{rj}^{-1/2} Z_{ij}\). Hence the ratios \(VR_z\) defined by 10 is the same for \(Z\) and \(\zeta\), and is, therefore, universal. (We emphasize, however, that this conclusion relies on \(Z_r\) being diagonal.)

The effects of distributed loss, such as losses due to conducting walls or a lossy dielectric that fills the cavity, can be simply incorporated in Eq. 11. Since modal fluctuations in losses are small when the modes are chaotic and the wavelength is short, we can construct a complex cavity impedance accounting for distributed loss by simply replacing \(k^2\) in Eq. 11 by \(k^2(1 - jQ^{-1})\), where \(Q\) is the cavity quality factor. (In terms of the normalized impedance matrix \(\tilde{\zeta}\) defined in 11') we replace the denominator \(s_n\) by \(s_n - jk^2/(Q\Delta(k_n))\).

\[
Z_{ii} = -\frac{j}{\pi} \sum_{n=1}^{M} \frac{R_{ri} \Delta_{kn} w_{n}^2}{k^2(1 - jQ^{-1}) - k_n^2} \equiv R_{ii} + jX_{ii}
\]

\[
= \frac{1}{\pi} \sum_{n=1}^{M} R_{ri} \Delta_{kn} w_{n}^2 k^2/Q \left(\frac{k^2 - k_n^2}{(k^2 - k_n^2)^2 + (k^2/Q)^2}\right) + \frac{1}{\pi} \sum_{n=1}^{M} R_{ri} \Delta_{kn} w_{n}^2 (k_n^2 - k^2) \left(\frac{k^2 - k_n^2}{(k^2 - k_n^2)^2 + (k^2/Q)^2}\right).
\]

(Henceforth, we employ the notation \(\Delta_n \equiv \Delta(k_n)\).) Calculation of the moments of the impedance is facilitated by the fact that the eigenvalues and eigenfunctions in the chaotic cavities are statistically independent. For example, the expected value of \(X_{ii}\) is

\[
E[X_{ii}] = \frac{3}{2\pi} \frac{R_{ii} \Delta}{k^2/Q} + \frac{R_{ii}^2}{2\pi} \int dk^2 dp^2
\]

\[
\langle [w^2] g(|k^2 - k_n^2|/\Delta)(k^2 - k_n^2)/(k^2 - k^2)\rangle / (k^2 - k^2)^2 + (k^2/Q)^2 \rangle = X_{ii}(k).
\]

The second equality in 10 relating \(E[X_{ii}]\) to the radiation reactance requires \(Q \gg 1\) and is analogous to the Kramers-Kronig relation.

The second moment of \(X_{ii}\) can be determined in a similar way by integrating over all \(j\) except \(j = t, s\) and using the joint distribution function \(P_2(k^2, k_n^2) = [1 - g(|k^2 - k_n^2|/\Delta)]/(M\Delta)^2\), where \(g(|k^2 - k_n^2|/\Delta)\) is known from Random Matrix theory 13. Using the fact that \(g\) goes to zero at large argument and assuming that the radiation resistance \(R_{ri}(k_n)\) and the average spacing \(\Delta_n\) vary slowly over the damping width \(k^2/Q\), we obtain

\[
E[X_{ii}^2] = \frac{3}{2\pi} \frac{R_{ii} \Delta}{k^2/Q} + \frac{R_{ii}^2}{2\pi} \int dk^2 dp^2
\]

\[
\langle [w^2] g(|k^2 - k_n^2|/\Delta)(k^2 - k_n^2)/(k^2 - k^2)\rangle / (k^2 - k^2)^2 + (k^2/Q)^2 \rangle = X_{ii}(k).
\]

Combining Eq. 11 and Eq. 12, we obtain

\[
Var[X_{ii}] = \frac{R_{ii}^2}{\lambda} \left(\frac{3}{2\pi} - \frac{1}{\pi} \int_0^\infty dx g(x) \frac{4}{4 + (x\lambda)^2}\right),
\]

where \(\lambda = k^2/(Q\Delta)\). A similar moment evaluation can be carried out for \(R_{ij}\), as specified in Eq. 8, which yields the same expression as Eq. 12 for \(Var[R_{ij}]\). For GOE (the case we are now considering) we have that 13, 14, \(g(s) = f^2(s) - [\int_0^s d(s') f(s') - 1/2](df/ds)\), where \(f(s) = ([\sin \pi s]/\pi s)\).

In order to obtain the variance ratio, we also apply the previous process to the off diagonal term \(Z_{ij}, i \neq j\), which, based on Eq. 4, is given by

\[
Z_{ij} = \frac{1}{\pi} \sum_{n=1}^{M} \frac{R_{ri} R_{rj} \Delta_{in} w_{in} w_{jn} k^2/Q}{(k^2/Q)^2 + (k_n^2 - k^2)^2}
\]

\[
+ j \sum_{n=1}^{M} \frac{R_{ri} R_{rj} \Delta_{in} w_{in} w_{jn} k^2/Q}{(k^2/Q)^2 + (k_n^2 - k^2)^2}.
\]

Since \(w_{in}\) and \(w_{jn}\) are independent, the first moments of \(X_{ij}\) and \(R_{ij}\) are both zero, and the variance is equal to
the second moment,
\[
\text{Var}[X_{ij}] = \lim_{M \to \infty} \frac{M}{\pi^2} \int dk_n^2 \frac{R_{ri}R_{rj} \Delta_n^2 (u_{in}^2)(w_{jm}^2)}{[(k_n^2 - k^2)^2 + (k^2/Q)^2]} P_k(k_n^2)
\]
\[
= \frac{R_{ri}R_{rj}}{\lambda} \frac{1}{2\pi}
\]
(14)

The same result is obtained for \(\text{Var}[R_{ij}]\). Combining Eq. (14) with Eq. (12), we have Eq. (2) with

\[
VR_z = F_1(\lambda) = [3 - 2 \int_0^\infty dxg(x) \frac{4}{4 + (x/\lambda)^2}]^{-1}
\]
(15)

A similar calculation in the GUE case is facilitated by the simpler form of the function \(g(x)\) which is now given by \(g(x) = \sin^2(\pi x)/(\pi x)^2\). We obtain

\[
VR_z = F_2(\lambda) = [2 - 2 \int_0^\infty dx (\sin \pi x/\pi x)^2 \frac{4}{4 + (x/\lambda)^2}]^{-1}
\]
\[
= [1 + e^{-4\pi \lambda}/4\pi \lambda]^{-1}
\]  
(16)

We note that subsequent to a previous announcement of our work \[24\], the two-frequency correlation functions for the elements of the impedance and the scattering matrix have recently been calculated by Savin, Fyodorov, and Sommers \[25\], and are consistent with the preceding in the limit of zero frequency separation.

III. SCATTERING VARIANCE RATIO

We now consider the scattering matrix in the high loss limit, \(\lambda \gg 1\). For simplicity, we consider the case of two channels connecting to the scatterer, \(N = 2\), and \(Z\) and \(S\) are \(2 \times 2\) matrices. We note that a chaotic scattering process can be divided into a direct process and a delayed process, which leads to a separation of the mean part (equal to \(Z_r\)) and the fluctuating part \(\delta Z\) of the cavity impedance, \(Z = Z_r + \delta Z\). The fluctuating part \(\delta Z\) decreases as loss increases. Thus in the high loss limit, \(\delta Z \ll Z_r\), which implies \(Z_{12}, Z_{21} \ll Z_{11}, Z_{22}\). (Recall, the mean parts of the off diagonal components are zero.) We may now form \(S\) using \(S = Z_0^{-1/2}(Z - Z_0)/(Z + Z_0)^{-1/2}\). Since the off diagonal terms of \(Z\) are small, the diagonal components of \(S\) are dominated by the diagonal components of \(Z\). We then find for \(S_{11}\),

\[
S_{11} \cong \frac{Z_{11} - Z_{01}}{Z_{11} + Z_{01}} = \frac{(Z_r - Z_{01}) + \delta Z_{11}}{(Z_r + Z_{01}) + \delta Z_{11}}
\]
\[
\cong S_{r1} + \frac{2Z_{01}}{(Z_{r1} + Z_{01})^2}\delta Z_{11},
\]
(17)

where \(S_{r1} = (Z_{r1} - Z_{01})/(Z_{r1} + Z_{01})\), and \(Z_{01}\) is the characteristics impedance of channel 1. Thus, we obtain

\[
\text{Var}[S_{11}] = \frac{2Z_{01}}{(Z_{r1} + Z_{01})^2}\text{Var}[Z_{11}].
\]  
(18)

In addition, we can express \(S_{12}\) in the high damping limit as

\[
S_{12} = \frac{2Z_{12}\sqrt{Z_{01}Z_{02}}}{(Z_{11} + Z_{01})(Z_{22} + Z_{02})} \cong \frac{2Z_{12}\sqrt{Z_{01}Z_{02}}}{(Z_{r1} + Z_{01})(Z_{r2} + Z_{02})}
\]
(19)

which leads to

\[
\text{Var}[S_{12}] = \frac{2\sqrt{Z_{01}Z_{02}}}{(Z_{r1} + Z_{01})(Z_{r2} + Z_{02})^2}\text{Var}[Z_{12}],
\]
(20)

and similarly for \(\text{Var}[S_{21}]\). Combining Eq. (18) and Eq. (20), we recover Eq. (6) and we note that this result is independent of the coupling (i.e., independent of \(Z_r\)).

To illustrate the influence of coupling on \(VR_z\) at finite loss parameter \(\lambda\), we consider the impedance matrix in the GOE case using the model normalized impedance \(\zeta\) used in Ref. \[22\].

\[
Z = Z_r^{1/2}\zeta R^{1/2} \zeta r X_r,
\]

where \(\zeta\) is given by \(\zeta_j = -(j/\pi)\sum_{n=1}^M w_{in} w_{jn}/(k_n^2 - k_r^2 - j\lambda)\), which leads to \(\delta Z\) and \(\bar{k}_n^2\) set to be \(M/2\), such that mean of \(\zeta\) is zero. Realizations of \(\zeta\) are produced numerically by generating Gaussian random variables \(w_{in}\) and spectra \(\bar{k}_n^2\) from the eigenvalues of random matrices. We express a model scattering matrix \(S\) as

\[
S = (\gamma_r^{1/2}(\gamma_r^{1/2})^*) + (\gamma_{r,x} + 1)^{-1}(\gamma_r^{1/2}(\gamma_r^{1/2})^* + j\gamma_x - 1),
\]
(21)

where \(\gamma_r = Z_0^{-1}R_r\) and \(\gamma_x = Z_0^{-1}X_r\). When \(\gamma_r\) is the identity matrix and \(\gamma_x\) is zero, we reach the so-called perfect coupling condition, which means that the scattering is determined by the delayed process and the direct process is absent. We now consider an example in which the two-port couplings are the same so that \(\gamma_{r,x} = \text{diag}(\gamma_{r,x}, \gamma_{r,x})\), where \(\gamma_{r,x}\) is a scalar. Figures \[2\](a) and (b) show results for the variation of \(VR_z\) with the coupling parameters \(\gamma_r\) and \(\gamma_x\) for a high loss case \((\lambda = 5)\) and for the lossless case \((\lambda = 0)\). In Fig. \[2\](a), we fix \(\gamma_x\) to be zero, and vary \(\gamma_r\), while in Fig. \[2\](b), \(\gamma_r\) is fixed to be 1 and \(\gamma_x\) is varied. Compared to the high damping case, \(VR_z\) in the lossless case has a much larger deviation from the constant 1/2. Note that \(VR_z\) is 1/2 in the perfect-coupling case (i.e., \(\gamma_r = 1\), \(\gamma_x = 0\)), no matter whether the cavity is highly lossy or lossless. This is related to the concept of “weak localization” reviewed in \[20\].

In the case of an \(N\)-port we can think of the above two-port consideration of \(VR_z\) as applying to the \(N\)-port converted to a two port by opening channels 3, 4, \(\cdot\cdot\cdot, N\); i.e., the incoming waves \(a_3, a_4, \cdot\cdot\cdot, a_N\) are identically zero (for a microwave cavity with transmission line inputs, this corresponds to terminating transmission lines 3, 4, \(\cdot\cdot\cdot, N\) with their characteristic impedances, \(Z_{03}, Z_{04}, \cdot\cdot\cdot, Z_{0N}\)). Thus ports 3, 4, \(\cdot\cdot\cdot, N\) effectively add to the loss due to the energy flux leaving through them. If the ports 3, 4, \(\cdot\cdot\cdot, N\) are assumed to act like distributed loss, they can be taken into account by increasing the loss parameter \(\lambda\). [This increased loss enhances the validity of Eq. (6).]
IV. EXPERIMENTAL TESTS

We provide experimental results testing the theoretical predictions for the statistical fluctuations in the variance of the $S$ and $Z$ elements, in the limit of large damping. The experiments are done in an air-filled, quarter bow-tie shaped cavity which acts as a two-dimensional resonator below 19.05 GHz (Fig. 3(a)) [22]. This cavity has previously been used for the successful study of the eigenvalue spacing statistics [28], eigenfunction statistics [29, 30], and for studying the universal fluctuations in the impedance [9] and scattering matrix [31] for a wave chaotic system. The cavity is driven by two ports; each of which consists of the center conductor (diameter $2a=1.27\text{mm}$) of a coaxial cable that extends from the top lid of the cavity and makes contact with the bottom plate of the cavity (Fig. 3(b)). From direct $S_{21}$ measurements, we estimate that the cavity has a typical loaded $Q$ of about 150 between 4-5GHz and about 300 between 11-12GHz. This translates to a damping parameter of $\lambda > 0.5$ for the entire frequency range of this experiment. Hence we examine experimentally the time-reversal symmetric (GOE) cases for the $Z$ and $S$-variance ratios in the high damping limit.

To perform an approximation to ensemble averaging, two perturbers (shown gray in Fig. 3(a)), made up of rectangular ferromagnetic solids wrapped in Al foil (of dimensions $26.7 \times 40.6 \times 7.87 \text{mm}^3$), are systematically scanned and rotated throughout the volume of the cavity by means of a magnet that is placed outside the cavity. The ensemble set consists of one-hundred different positions and orientations of the perturbers within the cavity. The perturbers are on the scale of half the wavelength or bigger over the entire frequency range of the experiment. The full two by two $S$ matrix is measured between 4 and 12 GHz for each position of the perturbers. Below 4 GHz the mode density is too low to obtain meaningful ensemble averaging, while above 12 GHz the coupling becomes too weak to couple to the modes of the cavity, at least for this port geometry. Once the $S$ matrix has been measured, it is then converted to $Z$ through $Z = Z_0(I + S)(I - S)^{-1}$.

To eliminate the effect on the average of short ray orbits returning to the antenna (these lead to rapidly varying-with-frequency systematic deviations of the average from the ensemble average, as discussed in [22]) we perform frequency averaging over a sliding window of width 300 MHz. We denote such sliding averages of impedance and scattering variance ratios by $\overline{VR_z}$ and $\overline{VR_s}$. The inset in Fig. 4 shows $\overline{VR_z}$ (solid line) over a frequency range 4 GHz to 12 GHz. Denoting the average of $\overline{VR_z}$ over the entire range, 4GHz-12GHz, by $\overline{VR_z}$, we obtain $\overline{VR_z} = 0.49$, and we find that $|\overline{VR_z} - \overline{VR_z}| \leq 0.02$ over the entire frequency range. This value of experimentally obtained $\overline{VR_z}$ is close to the ideal theoretical value of $1/2$ for large damping. Also shown in the inset is the variance ratio obtained with no frequency averaging (small circles) These are deviations from the frequency averaged ratio values with a standard deviation of 0.04. Nevertheless the mean value of the variance ratio over the entire frequency range is 0.49.

The circles, stars and dashes in Fig. 4 show the variation in $\ln[Var[Z_{21}]]$, $\ln[\sqrt{Var[Z_{11}]}Var[Z_{22}]]$ and $\ln[\overline{VR_z}\sqrt{Var[Z_{11}]}Var[Z_{22}]]$ respectively, as a function of frequency. The agreement is quite good (i.e., the dashes overlie the open circles) at all frequencies.

Similarly in Fig. 5, we present data for the scatter-
FIG. 4: \(\text{Var}[Z_{21}](\text{circles}), \sqrt{\text{Var}[Z_{11}]\text{Var}[Z_{22}]}(\text{stars})\) and \(\overline{VR_s}\sqrt{\text{Var}[S_{11}]\text{Var}[S_{22}])(\text{dashes})\) are plotted on a natural-logarithmic scale as a function of frequency from 4 to 12 GHz. Inset shows the ratio \(\overline{VR_s}\) versus frequency (solid line). The small circles show \(VR_s\) without any frequency averaging.

Experimentally we obtain \(\overline{VR_s} = 0.50\) and \(|VR_s - \overline{VR_s}| \leq 0.08\) over the range 4 GHz to 12 GHz. The circles, stars and dashes in Fig. 5 show the variation in \(\text{Var}[S_{21}], \sqrt{\text{Var}[S_{11}]\text{Var}[S_{22}]\) and \(\overline{VR_s}\sqrt{\text{Var}[S_{11}]\text{Var}[S_{22}]\) respectively, as a function of frequency. Similar to the impedance data (Fig. 4), we observe that the data for \(\overline{VR_s}\sqrt{\text{Var}[S_{11}]\text{Var}[S_{22}]\) overlie the data for \(\text{Var}[S_{21}](\text{open circles}),\) again indicating that the experimentally obtained value for \(\overline{VR_s}\) shows good agreement with the asymptotic theoretical values for highly damped time-reversal symmetric systems over a large frequency range.

To sum up, we have used random matrix theory in conjunction with the radiation impedance characterizing the system-dependent coupling details to evaluate the variance ratios (1) and (5). The main result is that the impedance variance ratio (1) is a universal function of the loss in the scatterer.

This work was originally stimulated by discussion with J. P. Parmantier who pointed out to us the result of Ref. [18]. We also acknowledge discussions with P. A. Mello and D. V. Savin. This work was supported in part by the DOD MURI for the study of microwave effects under AFOSR Grant F496200110374, and DURIP grants FA95500410295 and FA95500510240.
