FINITELY PRESENTED GROUPS ACTING ON TREES

M.J. DUNWOODY

Abstract. It is shown that for any action of a finitely presented group $G$ on an $\mathbb{R}$-tree, there is a decomposition of $G$ as the fundamental group of a graph of groups related to this action. If the action of $G$ on $T$ is non-trivial, i.e. there is no global fixed point, then $G$ has a non-trivial action on a simplicial $\mathbb{R}$-tree.

1. Introduction

A group $G$ is said to split over a subgroup $C$ if either $G = A \ast_C B$, where $A \neq C$ and $B \neq C$ or $G$ is an HNN-group $G = \langle A, t | t^{-1}at = \theta(a) \rangle$ where $\theta : C \to A$ is an injective homomorphism. It is one of the basic results of Bass-Serre theory (see [6] or [20]), that a finitely generated group $G$ splits over some subgroup $C$ if and only if there is an action of $G$ on a tree $T$, without inversions, such that for no vertex $v \in V_T$ is $v$ fixed by all of $G$. Here the tree is a combinatorial tree, i.e. a connected graph with no cycles, and an action without inversions is one in which no element $g \in G$ transposes the vertices of an edge. Tits [23] introduced the idea of an $\mathbb{R}$-tree, which is a non-empty metric space in which any two points are joined by a unique arc, and in which every arc is isometric to a closed interval in the real line $\mathbb{R}$. Alternatively an $\mathbb{R}$-tree is a 0-hyperbolic space. A tree in the combinatorial sense can be regarded as a 1-dimensional simplicial complex. The polyhedron of this complex will be an $\mathbb{R}$-tree - called a simplicial $\mathbb{R}$-tree. However not every $\mathbb{R}$-tree is like this. A point $p$ of an $\mathbb{R}$-tree $T$ is called regular if $T - p$ has two components. An $\mathbb{R}$-tree is simplicial if the points of $T$ which are not regular form a discrete subspace of $T$. It is fairly easy to construct examples of $\mathbb{R}$-trees where the set of non-regular points is not discrete. There are good introductory accounts of groups acting on $\mathbb{R}$-trees in [2] and [21]. We assume that all our actions are by isometries. It is a classical result that a group is free if and only if it has a free action on a simplicial tree. As the real line $\mathbb{R}$ is an $\mathbb{R}$-tree and $\mathbb{R}$ acts on itself freely by translations, any free abelian group has a free action on a $\mathbb{R}$. Morgan and Shalen [17] showed that the fundamental group of any compact surface other than the projective plane and the Klein bottle has a free action on an $\mathbb{R}$-tree. Rips showed that the only finitely generated groups that act freely on an $\mathbb{R}$-tree are free products of free abelian groups and surface groups. Rips never published his proof, but there are proofs of more general results by Bestvina -Feighn [4] and by Gaboriau-Levitt-Paulin (see [19] or [5]). Bestvina and Feighn classify the stable actions of finitely generated groups on $\mathbb{R}$-trees. Recall, that an action of a group $G$ on an $\mathbb{R}$-tree is said to be stable if there is no sequence of arcs $l_i$ such that $l_{i+1}$ is properly contained in $l_i$ for every $i$, and for which the stabilizer $G_i$ of $l_i$ is properly contained in $G_{i+1}$ for every $i$. In particular [4] Bestvina and Feighn proved that if

a finitely presented group has a non-trivial minimal stable action on an $\mathbb{R}$-tree then it has a non-trivial action on some simplicial tree.

A group is said to be $(FA)$ if it has no non-trivial action on a simplicial $\mathbb{R}$-tree and it is said to be $(FR)$ if it has no non-trivial action on any $\mathbb{R}$-tree. A trivial action is one in which there is a point of the tree that is a global fixed point. In contrast A.Minasyan [16] and I [11] in separate papers have given examples of finitely generated groups that are $(FA)$ but not $(FR)$. These provided a negative answer to Shalen’s Question A of [21]. In an earlier paper [11] I gave an example of a finitely generated group that had a non-trivial action on an $\mathbb{R}$-tree with finite cyclic arc stabilizers but for which any simplicial decomposition has an edge group that contains a non-cyclic free group. This gave a negative answer to Conjecture D of [21]. In this paper it is shown that there are positive answers to these questions for finitely presented groups. The situation is therefore similar to that of accessibility in finitely generated groups, in that finitely presented groups are accessible [7], but there are examples of finitely generated groups that are not accessible [8], [9]. The questions are closely related.

A morphism from a segment $I$ to an $\mathbb{R}$-tree $T$ is a continuous map $\phi : I \to T$ such that $I$ may be subdivided into finitely many subsegments that $\phi$ maps isometrically into $T$. Let $T, T'$ be $\mathbb{R}$-trees with actions of groups $G, G'$ respectively. Let $\rho : G \to G'$ be a homomorphism. A morphism from $T$ to $T'$ is a map $\phi$ equivariant with respect to $\rho$ which induces a morphism on every segment $I \subset T$.

In this paper the following theorem is proved.

**Theorem 1.1.** Let $G$ be a finitely presented group and let $T$ be a $G$-tree, i.e. an $\mathbb{R}$-tree on which $G$ acts by isometries.

Then $G$ is the fundamental group of a finite graph $(\mathcal{Y}, Y)$ of groups, in which every edge group is finitely generated and fixes a point of $T$. If $v \in VY$, then either $\mathcal{Y}(v)$ fixes a vertex of $T$ or there is a homomorphism from $\mathcal{Y}(v)$ to a target group $Z(v)$ (a parallelepiped group), which is the fundamental group of a cube complex of groups based on a single $n$-cube $c(v)$.

Every hyperplane of $c(v)$ is associated with a non-trivial splitting of $G$.

There is a marking of the cube $c(v)$ so that the corresponding $\mathbb{R}$-tree with its $Z(v)$-action is the image of a morphism from a $\mathcal{Y}(v)$-tree $T_v$ and this tree is the minimal $\mathcal{Y}(v)$-subtree of $T$.

The action of a target group on an $\mathbb{R}$-tree is usually unstable, but a parallelepiped group of rank $n$ contains a free abelian group of rank $n$ and this acts freely on $\mathbb{R}$ by translation.

The main theorem in a previous version of this paper is incorrect. I thought that the Higman group $H = \langle a, b, c, d | aba^{-1} = b^2, bcb^{-1} = c^2, cdc^{-1} = d^2, dad^{-1} = a^2 \rangle$ had an action on a nonsimplicial $R$-tree, since it had non-compatible decompositions as a free product with amalgamation. In fact this is not the case. I thought that adding linear combinations of tracks corresponding to these decompositions would result in infinitely many non-trivial such decompositions. In fact all the tracks obtained correspond to trivial decompositions (see [1]).

We do not encounter Levitt (or thin) type actions in our analysis (see [2]). This is because any such action is resolved by a simplicial action.

2. Target Groups

In [12] rectangle groups were constructed.
The rectangle group $R = R(m.n.p.q), m, n, p, q \in \{2, 3, \ldots\} \cup \{\infty\}$ is the group with presentation

$$R = \langle a, b, c, d | a^m = b^n = c^p = d^q = 1, ab^{-1} = cd^{-1}, ac^{-1} = bd^{-1} \rangle.$$  

Think of the relations as saying that opposite edge vectors are equal and that the corners are assigned orders, a corner can have infinite order.

In the group $R$ above, let $x = ab^{-1} = cd^{-1}, y = ac^{-1} = bd^{-1}$, then $xy = ab^{-1}bd^{-1} = ad^{-1} = ac^{-1}cd^{-1} = yx$, and $x, y$ generate a free abelian rank 2 group.

Also $R$ has incompatible decompositions as a free product with amalgamation

$$R = \langle a, b \rangle \ast_{ab^{-1} = cd^{-1}, a = d^{-1}} \langle c, d \rangle,$$

and

$$R = \langle a, c \rangle \ast_{ac^{-1} = bd^{-1}, a = d^{-1}} \langle b, d \rangle,$$

the amalgamated subgroup in each case is free of rank two.

The decompositions are incompatible because the lines dividing the rectangle intersect.

A cube complex is similar to a simplicial complex except that the building blocks are $n$-cubes rather than $n$-simplexes. A rectangle group $R$ acts on a simply connected 2-dimensional cube complex $\tilde{C}$ with orbit space $C$. This is illustrated in Fig 3. Apart from some exceptional cases, when two or more of $m, n, p, q$ are 2, there are three orbits of 2-cells, each with trivial stabilizer. In all cases there are four orbits of edges also with trivial stabilizers, and four orbits of vertices labelled $A, B, C, D$ with stabilizers which are cyclic of orders $m, n, p, q$ respectively. In the group $R(2, 2, 2, 2)$ the subgroup $\langle x, y \rangle$ has index 2 and there is one orbit of 2-cells. In $R(2, 2, 2, q)$ or $R(2, 2, p, q)$ for $p, q \geq 3$ there are two orbits of 2-cells and both $C$ and $\tilde{C}$ are 2-orbifolds.

In [12] it is shown that for any action of $J = \langle x, y \rangle$ on an $\mathbb{R}$-tree there is an action of the rectangle group on an $\mathbb{R}$ tree $T$ which restricts to the given action on the minimal $J$-subtree of $T$. This action is unstable in all cases when there are 3 orbits of 2-cells.
There is a Euclidean 2-dimensional subspace $E$ of $\tilde{C}$ acted on by $\langle x, y \rangle$. For the action of $\langle x, y \rangle$ on $E$ there is one orbit of 2-cells, each of which is made up of 4 smaller rectangles of $\tilde{C}$. In the diagram the points $A, B, C, D$ are stabilised by $a, b, c, d$ respectively.

Note that the blue rectangle $aB, aC, aD$ is in the same $R$-orbit as the red rectangle $A, B, C, D$, and $bD = bd^{-1}D = yD, cD = cd^{-1}D = xD$.

A parallelepiped group of dimension $n$ has $2^n$ generators corresponding to the vertices of an $n$-cube. The generators corresponding to a 2-dimensional face satisfy the relations of a rectangle group. Such a group has an action on an $n$-dimensional cube complex $C_n$ for which the orbit space is an $n$-cube. There is a subgroup $J_n$ that is free abelian of rank $n$, which acts on a subcomplex $E_n$ of $C_n$ so that the orbit space $J_n \backslash E_n$ consists of $2^n$ smaller cubes.

In [12] there is a detailed description of the action for $n = 3$.

3. Finitely presented groups

Let $X$ be a finite CW 2-complex. We introduce the idea of a complex of groups $G(X)$ based on $X$. This is a slightly different notion to a special case of the complex of groups described by Haefliger [14]. Haefliger restricts $X$ to be a simplicial cell complex. One can get from our situation to that of Haefliger by triangulating each 2-cell. We are only concerned with the situation when each group assigned to a 2-cell is trivial.

Thus the 1-skeleton $X^1$ of $X$ is a graph. We take the edges to be oriented, and use Serre’s notation, so that each edge $e$ has an initial vertex $\iota e$ and a terminal vertex $\tau e$ and $\bar{e}$ is $e$ with the opposite orientation. Let $G(X^1)$ be a graph of groups based on $X^1$. The attaching map of each 2-cell $\sigma$ is given by a closed path in $X^1$. Let $S$ be a spanning tree in $X^1$. The fundamental group $\pi(G(X), S)$ of the complex of groups $G(X)$ is the fundamental group of the graph of groups $G(X^1)$ together with extra relations corresponding to the attaching maps of the 2-cells. Thus $\pi(G(X), S)$ is generated by the groups $G(v), v \in V(X^1)$ and the elements $e \in E(X^1)$. For each $e \in E(X^1), G(e)$ is a distinguished subgroup of $G(\iota e)$ and there are injective homomorphisms $t_e : G(e) \to G(\tau e), g \mapsto g^{\tau e}$. The relations of $\pi(G(X), S)$ are as follows:-
the relations for $G(v)$, for each $v \in V(X^1)$

\[ e^{-1}ge = g^e \text{ for all } e \in E(X^1), \quad g \in G(e) \leq G(v), \]

where $e = 1$ if $e \in E(S)$.

For each attaching closed path $e_1, e_2, \ldots, e_n$ in $X$ of a 2-cell, there is a relation

\[ g_0 e_1 g_1 e_2 x_2 \ldots g_{n-1} e_n = 1, \]

where $g_i \in G_{\tau e_i} = G_{\tau e_{i+1}}$, called the attaching word. The elements $g_i$ are called joining elements. Such a word represents both a path $p$, called the attaching path in the Bass-Serre tree $T$ corresponding to the graph of groups $G(X^1)$, for which initial point $\tau p$ and end point $\tau p$ are in the same $\pi(G(X^1), S)$-orbit and an element $g \in \pi(G(X^1), S)$ for which $g \tau p = \tau p$. Adding the relation identifies the points $\tau p$ and puts $g = 1$. If we carry out all these identifications, we obtain a $G$-graph $\Gamma$ in which the attaching paths are all closed paths. We describe specifically how this path arises (as in [6], p15). We lift $S$ to an isomorphic subtree of $S_1$ of $\Gamma$. Thus the vertex set of $S_1$ is a transversal for the action of $G$ on $\Gamma$. For each edge $e$ in $X - S$ we can choose an edge $\tilde{e} \in T$ such that $\tilde{e}$ maps to $e$ in the natural projection, and $i\tilde{e}$ is a vertex of $S_1$. Let $\tilde{S}$ be the union of $S_1$ with these extra edges. Note that it will not normally be the case that $\tau \tilde{e} \in \tilde{S}$ and so $\tilde{S}$ is not usually a subtree of $T$, but there will be an element $c(e) \in G$ such that $c(e)^{-1}(\tau \tilde{e}) \in \tilde{S}$. These elements (called the connecting elements) together with the stabilizers of elements of $V S_1$ generate $G$. Clearly $\tilde{S}$ consists of a transversal for the action of $G$ on both the edges and vertices of $\Gamma$. Let $\nu = v_0$ be the vertex of $\tilde{S}$ lying above $w_1$, and put $x_0 = g_0$. Suppose we have constructed $v_i$ and $x_i \in G$ so that $v_i$ is the terminal vertex of the path corresponding to $g_0 e_1 g_1 e_2 g_2 \ldots g_{i-2} e_{i-1}$, and so that if $\tilde{v}_i$ is the element of $\tilde{S}$ in the orbit of $v_i$, then $v_i = x_i \tilde{v}_i$. This is certainly true when $i = 0$. To construct $v_{i+1}$ and $x_{i+1}$, put $x_{i+1} = x_i c(e_{i+1}) g_{i+1}$ where we put $c(e) = 1$ if $e \in S$. Then $x_{i+1} \tilde{v}_{i+1} = x_i c(e_{i+1}) \tilde{v}_{i+1}$ is the terminal vertex of the edge $x_i \tilde{e}_{i+1}$ with initial vertex $v_i$. Note that $x_i$ is obtained from $g_0 e_1 g_1 e_2 g_2 \ldots g_{i-2} e_{i-1}$ by replacing each $e_i$ by $c(e_i)$.

We now foliate each 2-cell of $X$ in a particular way. Thus let $D = \{(x, y) | x, y \in \mathbb{R}, x^2 + y^2 \leq 1\}$ be the unit disc.

![Figure 4. Foliated 2-cell](image-url)
Give this the foliation in which leaves are the intersection of \( D \) with the vertical lines \( z = c \) where \( c \) is a constant in the interval \([-1,1]\). Let \( \sigma \) be a 2-cell of \( X \) which is attached via the closed path \( e_1, e_2, \ldots, e_n \). We map \( D \) to \( \sigma \) so that for some \( j = 2, \ldots, n-1 \) the upper semi-circle joining \((-1,0)\) and \((1,0)\) is mapped to the path \( e_1, \ldots, e_j \). Thus there are points \( z_0 = (-1,0), z_1, \ldots, z_j = (1,0) \) on the upper semi-circle so that \( z_i \mapsto ie_i, i = 1, 2, \ldots, e_j + 1 \) and the map is continuous and injective on each segment \([z_i, z_{i+1}]\), except if \( ie_i = ie_{i+1} \) in which case the map is injective on the interior points of this segment. In a similar way the lower semi-circle is mapped to the path \( \bar{e}_n, \ldots, \bar{e}_{j+1} \).

Let, then, \( X \) be a 2-complex of groups in which each 2-cell is foliated as described above and let \( T \) be a \( G \)-tree, i.e. \( T \) is an \( R \)-tree on which \( G \) acts by isometries. We say that the \( X \) resolves \( T \) if there is an isomorphism \( \theta : \pi(X,S) \to G \) which is injective on vertex groups (and hence on all groups \( G_\sigma \) for all cells \( \sigma \) of \( X \)). In this situation (see [14]), the complex of groups is developable, i.e. there is a cell complex \( \check{X} \) on which \( G \) acts and \( G(X) \) is the complex of groups associated with this action. We also require that there be a \( G \)-map \( \alpha : \check{X} \to T \) such that for each 1-cell \( \gamma \) the restriction of \( \alpha \) to \( \gamma \) is injective and for each 2-cell \( \sigma \) and each \( i \in T \), the intersection of \( \sigma \) with \( \alpha^{-1}(i) \) is either empty or a leaf of the foliation described above.

We show that if \( G \) is finitely presented then any \( G \)-tree has a resolution, i.e. there is a cell complex \( X \) as above that resolves \( T \). Our approach is similar to that of [18].

Since \( G \) is finitely presented, there is simplicial 2-complex \( X \) such that \( \pi(X,S) \cong G \). Here \( S \) is a spanning tree in the 1-skeleton of \( X \). Let \( \check{X} \) be the universal cover of \( X \). Clearly there is a \( G \)-map \( \theta_0 : \check{V}\check{X} \to T \), which can be obtained by first mapping a representative of each \( G \)-orbit of vertices into \( T \) and then extending so as to make the map commute with the \( G \)-action. Now extend this map to the 1-skeleton so that each 1-simplex \( \gamma \) with vertices \( u, v \) of \( \check{X} \) is mapped injectively to the geodesic joining \( \theta_0(u) \) and \( \theta_0(v) \). It may be necessary to subdivide \( \check{X} \) and choose the map \( \theta_0 \) to ensure that \( \theta_0(u) \neq \theta_0(v) \) for every 1-simplex \( \gamma \). We can extend the map to every 1-simplex so that it commutes with the \( G \)-action giving a \( G \)-map \( \theta_1 : \check{X}^1 \to T \). Now we extend the map to the 2-simplices. Let \( \sigma \) be a 2-simplex with vertices \( u, v, w \). If \( \theta_0(u) \) lies on the geodesic joining \( \theta_0(v) \) and \( \theta_0(w) \) then we can map \( \sigma \) as indicated in Fig 3(ii). Each vertical line is mapped to a point. If \( \theta_0(u), \theta_0(v) \) and \( \theta_0(w) \) are situated as in Fig 3(i) so that no point is on the geodesic joining the other two, then we subdivide \( \sigma \) as in Fig 3(iii). The new vertex is mapped to the point \( p \) of (i) and the three new simplexes now have the middle vertex mapped into the geodesic joining the images of the other two sides and are mapped as shown in (iii).

Again this map can be extended to every subdivided 2-simplex so that it commutes with the \( G \)-action. We change \( X \) to be this subdivided complex. Regard \( X \) as a 2-complex in which each cell is attached via a loop of length three. We can make a complex of groups in which each \( G_\sigma \) is the trivial group. Since \( G \) is the fundamental group of \( X \) it is the fundamental group of this complex of groups. We have described a way of foliating the 2-cells which shows that this complex of groups resolves \( T \).

We now describe some moves on a resolving 2-complex which can be made on a resolving complex which change a resolving 2-complex to another resolving 2-complex.
Move 1. Subdividing a 1-cell.
Let $\gamma$ be a 1-cell, with vertices $u, v$, which may be the same. This can be replaced by two 1-cells $\gamma_1, \gamma_2$ and a new vertex $w$, so that $\gamma_1$ has vertices $u, w$ and $\gamma_2$ has vertices $v, w$. The groups associated with $w, \gamma_1, \gamma_2$ in the new complex of groups are all $G(\gamma)$. The attaching maps of 2-cells are adjusted in the obvious way.

Move 2. Folding the corner of a 2-cell.
Suppose that one end of a foliated 2-cell is as in Fig 4. Thus $v$ is the end vertex of the 2-cell and adjacent vertices are $x, y$ and $x, y$ are mapped to the same point of $T$, so that they lie on the same vertical line. Let the adjacent 1-cells to $v$ be $e_1$ and $e_2$, which conflicts with our earlier notation but is in line with that of [11] and [3]. Let the groups associated with the cells (in the complex of groups) be denoted by the corresponding capital letters.

Folding the corner results in a fold of the graph of groups associated with the 1-skeleton of $X$. Such a fold is one of three types which are listed in [3] (as Type A folds) or in [11]. They are shown in Fig 6 for the reader’s convenience. As the group acting is always $G$ it is not necessary to carry out vertex morphisms (see [11]) which are necessary when carrying out morphisms of trees rather than graphs.

The attaching word of the 2-cell, whose corner has been folded is changed in a way which we will describe in an example. One can arrange that the joining element at the pivot vertex is trivial, by changing the lift of the spanning tree. In this case, any other attaching word of a 2-cell that involves $e_1$ or $e_2$, $\bar{e}_2$ is replaced by the folded edge element $< e_1, e_2 >$ and $e_1$ is replaced by $< e_1, e_2 >$. Let the new complex of groups be $X'$

Clearly there is a surjective homomorphism $\phi : \pi(X, S) \to \pi(X', S')$ in which $g_{e_1}g_{e_1}^{-1}$ and $e_2$ are both mapped to $< e_1, e_2 >$. In fact this homomorphism is an isomorphism since the resolving isomorphism $\alpha : \pi(X, S) \to G$ factors through $\phi$. We conclude that $X'$ also resolves the $G$-tree $T$. 

**Figure 5.** Foliating a simplex
If both the upper semi-circle and the lower semi-circle consist of a single 1-cell, then folding results in the elimination of a 2-cell, and a reduction in the number of 1-cells.

**Move 3** Contracting a leaf.

Consider a foliated 2-cell. Let $\ell$ be a particular vertical line of the foliation. This will contain points $u, v$ of the upper semi-circle and lower semi-circle respectively. After subdividing the relevant 1-cells, it can be assumed that these points are vertices. Contracting the leaf $\ell$ results in the 2-cell $\sigma$ being replaced by two 2-cells $\sigma_1$ and $\sigma_2$. The vertices $u, v$ become a single vertex $w$ and its group $G_w$ is the subgroup of $G$ generated by $G_u$ and $G_v$ in $G$, except if $u, v$ belong to the same $G$-orbit, in which case $G_w$ is generated by $G_u$ and an element $g \in G$ such that $gv = u$. Let $g_u, g_v$ be the respective elements of $G_u$ and $G_v$ in the attaching word for $\sigma$. Let the edge after reaching $u$ in the attaching word end up in $\sigma_2$. This means that the edge after reaching $v$ ends up in $\sigma_1$. Suppose first that $u, v$ are in different orbits, then after the move the element for $w$ in $\sigma_2$ is $g_u$ and the element for $w$ in $\sigma_1$ is $g_v$. Note that an edge has to be removed from the spanning tree $S$. If $u, v$ are
in the same orbit then the element for \( w \) in \( \sigma_2 \) is \( g_u g \) and the element for \( w \) in \( \sigma_1 \) is \( g_v g^{-1} \).

A similar argument to that for Move 2 shows that the complex we have created also resolves the \( G \)-tree \( T \).

Let \( \sigma \) be a 2-cell of \( X \). We now examine what can happen as we repeatedly fold corners of \( \sigma \), at each stage replacing \( \sigma \) by the new 2-cell created. Since each 1-cell of \( \tilde{X} \) injects into \( T \) we can assign each 1-cell \( \gamma \) of \( X \) a length, namely the distance in \( T \) between \( \theta(u) \) and \( \theta(v) \) where \( u, v \) are the vertices of a lift of \( \gamma \) in \( \tilde{X} \).

As above let \( x \) be the corner vertex and let \( e_1, e_2 \) be the incident edges. If \( e_1, e_2 \) have the same length, then we can fold the corner of \( \sigma \). If \( e_1 \) is shorter than \( e_2 \) then subdivide \( e_2 \) so that the initial part has the same length as \( e_1 \) and then fold the corner. If \( e_2 \) is shorter than \( e_1 \) then we subdivide \( e_1 \) and then fold the corner. Now repeat the process. This process may terminate when all the 2-cell is folded away.

However it may happen that the folding sequence is infinite i.e. it never terminates.

First we give an example making it easier to understand the following general explanation. This example is a corrected version of Example 6 of [10].

![Diagram](image)

**Figure 7.** Folding sequence

**Example 3.1.** Let the complex \( X_1 \) have four vertices \( A, B, C, D \) and three oriented edges \( e, f, g \). Let \( \iota e = A, \tau e = B, \iota f = B, \tau f = D, \iota g = D, \tau g = C \). Let the groups of \( A, B, C, D \) be finite cyclic of order 3 and generated by \( u, v, y, z \) respectively. Let the 6-sided 2-cell be attached via the word

\[
 w \cup w' = e^{-1}ebfgc^{-1}gd
\]

Here \( w = e^{-1}ebf \) and \( w' = fd^{-1}gcg \). In this case \( X_1 \) is a 2-sphere with 4 cone points. Let \( G_1 \) be the group of this complex of groups.
The attaching word is describing a loop in $\tilde{X}_1$ the universal cover of the complex of groups. This loop maps to the loop, starting at $B$ $eefg\tilde{a}f$ in $X_1$. This loop is obtained by omitting the joining elements, which are elements of the vertex group that has been reached at that point. How a path in $\tilde{X}_1$ corresponds to such a word was described earlier. We now discuss how the joining elements occur in $w \cup w'$. In this case the 1-skeleton of $X_1$ is a tree. We choose a particular lift of this tree in $X_1$ to the universal orbifold cover $\tilde{X}_1$, which is the (hyperbolic) plane tessellated by 6-gons. Here $\tilde{X}_1$ is the universal cover of the complex of groups described above. The attaching word traces out a loop in $\tilde{X}_1$, which is the boundary of a fundamental region. Note that although the image of the path backtracks in $X_1$, it is not allowed to backtrack in $\tilde{X}_1$. This means that there must be non-trivial joining elements where the image backtracks. In $X$ each fundamental region has 6 vertices, including one point (incident with 3 edges in $\tilde{X}_1$) from the orbits corresponding to $A$ and $C$ and two vertices (incident with 6 edges in $\tilde{X}_1$) from each of $B$ and $D$. At one of the visits of the attaching word to vertices corresponding to $B$ or $D$ we have to use a non-trivial joining element. We can choose where this is. We get a presentation for $G_1$ in which the generators are $a, b, c, d$ and a relation obtained by deleting the edges in the attaching word. This is because the 1-skeleton of $X_1$ is a tree. Thus there is a relation $a^{-1}bd^{-1}c = 1$. There are also relations $a^3 = b^3 = c^3 = d^3 = 1$.

Clearly there is a surjective homomorphism $\phi$ from $G_1$ to the rectangle group

$$G = \langle a, b, c, d | a^3 = b^3 = c^3 = d^3, x = a^{-1}b = c^{-1}d, y = a^{-1}c = b^{-1}d \rangle.$$

Consider the folding sequence corresponding to the “marking” in which lengths are assigned to the edges with $|e| = |g| = 1, |f| = \sqrt{2}$. Initially we have the 2-cell attached along $w \cup w' = \tilde{e}a^{-1}ebfg\tilde{c}^{-1}\tilde{g}\tilde{d}\tilde{f}$. The attaching word is quadratic - its image in $X_1$ is $eefg\tilde{a}f$ and we will see that there is an infinite folding sequence in which $w = \tilde{e}a^{-1}ebf$ is folded against $\tilde{w}' = fd^{-1}gc\tilde{g}$. The total length along top or bottom is $1 + \sqrt{2}$. After the first subdivision and fold we have a new complex $X_2$ with the same vertices $A, B, C, D$ and with edges $b, c$ and a new edge $h$ with length $\sqrt{2} - 1$ with $th = A, \tau h = D$ and the attaching word has become $eb\tilde{e}b^{-1}a^{-1}bhgc^{-1}\tilde{d}h$. Note that the joining element $a^{-1}$ has changed to a conjugate $b^{-1}a^{-1}b$ as its position has changed.

The 2-cell has $w = eeb\tilde{e}b^{-1}a^{-1}bh, \tilde{w}' = hd^{-1}\tilde{g}c\tilde{g}$. After the next subdivision and fold we have a new complex $X_3$ with the same vertex set but with edges $h, g, j$ where $ij = D, \tau j = B$ and $j$ has length $1 - (\sqrt{2} - 1) = 2 - \sqrt{2}$ and the attaching word has become $jb\tilde{j}(b^{-1}db)h(b^{-1}a^{-1}bhgc\tilde{g})$. Note that in this graph there is a vertex $D$ of valency 3 whereas previously no vertex had valency more than 2. The attaching word visits the vertex $D$ three times. As before we move the non-trivial joining element so that it is not at the start or end point of $w = jb\tilde{j}(b^{-1}db)h(b^{-1}a^{-1}b)h$.

As noted above this change of position of the joining element corresponds to a change of the lift of a spanning tree - in this case the whole of the 1-skeleton $S_1$ of $X_1$. Having chosen a lift $D$ of $D$ there are 27 different lifts of $S_1$ to $X_1$. These are acted on by the stabilizer of $D$ and there are nine different orbits under this action. The attaching map must have at least one non-trivial joining element on a visit to $D$, since otherwise one could have used the trivial group as the group at $D$. We can choose the lift of $S_1$ so that the joining element is non-trivial at exactly one visit. In this case we do it so that the non-trivial joining element is at a visit which is not the start or end point of $w$. We now have $w = jb\tilde{j}(b^{-1}db)h(b^{-1}a^{-1}b)h$. 

and \( \tilde{w}' = gc^{-1}g \). We can translate the whole lift by \( b \) giving an attaching word \( jbd\bar{h}a^{-1}h \bar{g}(bc^{-1}b)\bar{g} \). All we have done here is conjugate all the elements by \( b \) to make the elements shorter. The next subdivision and fold starts at \( D \) and folds \( j \) the shorter edge against \( g \), so that we then have a new edge \( k \) with length \( 1 - (2 - \sqrt{2}) = \sqrt{2} - 1 \) replacing \( g \). Here \( \bar{g}k = B, \tau k = C \) and the attaching word is \( \bar{h}d\bar{a}^{-1}hj(c^{-1}bc)k(bc^{-1})\bar{k} \). Now note that the situation we have reached is similar to the initial situation scaled by \( \sqrt{2} - 1 \). In fact the positions of \( A \) and \( C \) have been transposed from the original position. To get an exact scaling carry out the next 3 folds to get the initial position scaled by \( (\sqrt{2} - 1)^2 \).

The foliation of \( X_1 \) corresponding to our marking, lifts to a foliation of \( \bar{X} \) and there is an \( \mathbb{R} \)-tree \( T_1 \) in which the points are leaves of this foliation. Clearly \( T_1 \) is a \( G_1 \)-tree. Let \( C \) be the cube complex for the rectangle group \( G \). As described in

![Figure 8](image)

there is a cube complex \( \bar{C} \) on which \( G \) acts. Thus

\[
G = \langle a, b, c, d | a^3 = b^3 = c^3 = d^3, x = a^{-1}b = c^{-1}d, y = a^{-1}c = b^{-1}d \rangle.
\]

There is a Euclidean subspace \( E \) of \( \bar{C} \) acted on by \( \langle x, y \rangle \) Assume that \( x \) acts on \( E \) by translation 2 in the \( x \)-direction, and \( y \) by translation of \( 2\sqrt{2} \). There is a foliation on \( C \) which induces a foliation on \( \bar{C} \) and \( E \) given by the lines \( x + y = c \). The leaves of the foliation on \( \bar{C} \) give an \( \mathbb{R} \)-tree \( T \). There is a map \( \theta : X_1 \to C \), which induces a homomorphism, denoted \( \theta' : G_1 \to G \). The map \( \theta \) induces a map \( \bar{\theta} : \bar{X}_1 \to \bar{C} \) in which a 2-cell of \( \bar{X}_1 \) maps into \( E \) as indicated in Fig 8. It can be seen that the foliation of \( E \) lifts to the foliation on \( \bar{X}_1 \) which is the one induced on the 2-cell of \( X_1 \) corresponding to the marking with \( |e| = |f| = 1, |g| = \sqrt{2} \). Thus there is a map \( \bar{\theta} : T_1 \to T \) which commutes with the actions of \( G_1 \) and \( G \) via \( \theta' \).

In \( G_1 \) the three elements \( y = b^{-1}d, y' = a^{-1}c \) and \( x = a^{-1}b = c^{-1}d \) freely generate a subgroup \( F \) and the minimal \( F \)-subtree of \( T_1 \) is non-simplicial. The elements \( y, y' \) are hyperbolic elements with the same hyperbolic length \( 2\sqrt{2} \). Their axes intersect is a segment of length \( 2\sqrt{2} \). In \( G \) these elements become equal and so have the same axis. There may be a \( G_1 \)-tree \( T' \) for which there are morphisms \( T_1 \to T' \to T \), in which the two axes have a larger intersection than in \( T_1 \).

**Proof of Theorem 1.1.** Let \( T \) be a \( G \)-tree, where \( G \) is a finitely presented group. We have seen that \( G \) is the fundamental group of a complex of groups \( G(X) \) that resolves the action.

Let \( \sigma \) be a 2-cell of \( X \). We now examine what can happen as we repeatedly fold corners of \( \sigma \), at each stage replacing \( \sigma \) by the new 2-cell created. Since each 1-cell
of $\tilde{X}$ injects into $T$ we can assign each 1-cell $\gamma$ of $X$ a length, namely the distance in $T$ between $\theta(u)$ and $\theta(v)$ where $u, v$ are the vertices of a lift of $\gamma$ in $\tilde{X}$.

As above let $x$ be the corner vertex and let $e_1, e_2$ be the incident edges.

If $e_1, e_2$ have the same length, then we can fold the corner of $\sigma$. If $e_1$ is shorter than $e_2$ then subdivide $e_2$ so that the initial part has the same length as $e_1$ and then fold the corner. If $e_2$ is shorter than $e_1$ then we subdivide $e_1$ and then fold the corner. Now repeat the process. This process may terminate when all the 2-cell is folded away.

However it may happen that the folding sequence is infinite i.e. it never terminates. We examine when this happens. Suppose this is the case and that the 2-complexes in the sequence are $X_n, n = 1, 2, \ldots$.

We can assign lengths to the edges (1-cells) of $X_n$. Traversing the top semicircular boundary of the 2-cell $\sigma$ determines to a path (or rather walk) $w$ in the 1-skeleton of $X_1$. Let $w'$ be the path corresponding to the lower semicircular boundary. These paths are usually not segments - they can even backtrack. Let $\ell_n$ be the total length of edges of $X_n$. It is clear that $\ell_n \geq \ell_{n+1} \geq 0$. We have $\ell_{n+1} = \ell_n$ if and only if the fold is a subdivision or a type II fold. In going from $X_n$ to $X_{n+1}$ an arc $[y_n, y_{n+1}]$ of the upper semicircular boundary of $\sigma$ is identified with an arc $[y_n', y_{n+1}]$ of the lower semicircular boundary. Each such arc is identified with a 1-cell of $X_n$ and so has a length. In $X_n$ the folding has identified $[x, y_n]$ with $[x, y_n']$. We assume that $y = \lim_n y_n$, and that $y' = \lim y_n'$. It is possible that $y = y'$ is the end point of $\sigma$ and we will see that this is often the case. Let $\lambda_n$ be the length of the arc $[y_n, y]$. Thus $\lambda_n$ is the length of the arc which remains to be folded.

We show that there can only be finitely many type II folds in our sequence. This is because there can only be a finite number of type II folds to start with as each such fold will use up the full length of an edge of $X_1$. In our sequence, a type I fold can only be followed by a type II fold if the type II fold is between edges in the same orbits as as the ones that were folded together in the type I fold. Thus there is a vertex in $[x, y]$ such that the adjacent edges are in the same orbit. Such a vertex must have been a vertex in the original path $[x, y]$ in $X_1$ and so this happens only finitely many times. Each type III fold decreases the first Betti number of the quotient graph and so there can only be a finite number of type III folds. In our sequence there are therefore only finitely many type II or type III folds. Assume then that all folds in the sequence are of type I. Consider the subspace of $X_1$ which is the union of the images of the paths corresponding to $[x, y]$ and $[x, y']$. If this is not a subgraph of $X_1$, then one of the paths corresponding to $[x, y], [x, y']$ in $X_1$ must end in part of an edge not visited by the other path. It is not hard to see that this will not produce an infinite folding sequence. Thus we assume that this subgraph is all of the 1-skeleton of $X_1$.

In our sequence of subdivision and type I folds the number of edges in the quotient graph does not increase, since any subdivision which increases the number of edges by one is immediately followed by a type I fold which reduces it by one. Clearly there can only be a finite number of type I folds which are not preceded by a subdivision, since the number of such folds is bounded by the number of edges of $X_1$. It may happen that a fold at the $n$-th stage involves an edge which is not in the subgraph $X'_{n+1}$ determined by the remaining folding sequence. This can happen for only a finite number of folds, since if this happens $X'_{n+1}$ has fewer edges than
Thus we assume that each folded edge is in the subgraph determined by the remaining folding sequence.

For a type I fold $\ell_n$ and $\lambda_n$ are reduced by the same amount.

Since we are assuming that each folded edge is in the subgraph determined by the remaining folding sequence, it is clear that $\ell_n$ tends to zero as $\lambda_n$ tends to zero. Since $\ell_n - \lambda_n$ is constant, it follows that $\ell_n = \lambda_n$.

Let $w, w'$ be the directed paths in $X$ which are the images of $[x, y], [x, y']$ respectively. Clearly they are initial parts of the paths $w, w'$, so they begin at the same point. In fact we can assume that they end at the same point by using a Move 3 to contract the leaf that contains the points $y$ and $y'$. In fact we will show that $y$ and $y'$ are always vertices in the original graph.

From length considerations every edge of $X$ occurs exactly twice in $w \cup w'$ or at least one edge occurs only once. If the latter occurs we will arrive at a contradiction by showing that the folding sequence must have been finite. Let $e$ the edge which occurs only once in $w \cup w'$. Without loss of generality suppose it is in $w$. In fact we can assume that it is the first edge of $w$, since we can fold away any edges which precede it. This folding will not affect the edge $e$. There is also a folding sequence starting at the other end of $\sigma$. It is not hard to see that this must also be an infinite sequence and in the limit all of $w \cup w'$ is folded away. Folding away those edges which occur before $e$ in this sequence and after $e$ in the original sequence, we arrive at a new 2-cell in which the entire path $w$ consists of a single edge $e$. But such a folding sequence must be finite - it will just fold $e$ onto the path $w'$. We have the desired contradiction.

An infinite folding sequence therefore occurs when there is a 2-cell in which the attaching map contains every edge exactly twice. As we shall see, however, a quadratic attaching map does not necessarily correspond to an infinite folding sequence.

We want to show that we can carry out folding on the different 2-cells and end up with a complex in which each cell is attached via a quadratic word.

After carrying out a finite number of Type 3 moves we can assume that each leaf of the foliation intersects the top and bottom of each 2-cell in at most one vertex. The argument above shows that the limit points $y, y'$ of an infinite folding sequence must be vertex points on the same leaf of a foliation and so $y = y'$ will be an end point of the 2-cell. If one considers the folding sequence starting from the other end of the 2-cell, we see that the first point reached where the attaching word becomes quadratic must also correspond to a leaf of the foliation which, if it was different from an end point of the 2-cell, would contain two vertices. Thus every 2-cell corresponds to a finite folding sequence or it corresponds to an infinite folding sequence given by a quadratic attaching word.

Suppose a complex is given by a single quadratic word $w \cup w'$. A marking is an assignment of positive lengths to the letters in such a way that the total length of $w$ is the same as that of $w'$. Let $a_1, a_2, \ldots, a_r$ be the letters which lie both in $w$, and $w'$. Let $b_1, b_2, \ldots, b_s$ be the letters which occur twice in $w$ (and so not in $w'$) and let $c_1, c_2, \ldots, c_t$ be the letter which occur twice in $w'$, then the $a_i, b_j, c_k$ can be assigned arbitrary positive lengths $\alpha_i, \beta_j, \gamma_k$ subject only to the single constraint $\beta_1 + \beta_2 + \cdots + \beta_s = \gamma_1 + \gamma_2 + \cdots + \gamma_t$. The subspace of the real numbers generated by the coefficients therefore, has maximal dimension $r$ if there are no letters that
occur twice in either $V$ or $W$ and it has dimension $r + s + t - 1$ if there are letters that do occur twice in either $w$ or $w'$.

Choose a resolving complex $X$ that has fewest 1-cells. Each attachment of a 2-cell must induce an infinite folding sequence, since Type I and Type III folds result in a reduction in the number of edges, so any Type I fold must be preceded by a subdivision, and there are no Type III folds. We define an equivalence relation on the set $U$ of 1-cells that occur as a face of a 2-cell of $X$. We require that $e \sim f$ if there is a 2-cell that includes both $e, f$ in its attaching map. We take $\sim$ to be the smallest equivalence relation for which this is the case. For any 2-cell $\sigma$ of $X$ all the 1-cells to which it is attached lie in a single equivalence class. Thus for each equivalence class there is a subcomplex consisting of those 1-cells and its vertices together with the 2-cells attached to that class. Any two such complexes intersect in a set of vertices, but no edges. If two 2-cells $\sigma, \sigma'$ share an edge $e$ and vertex $v$ in their boundaries, then we will see that we can choose the same joining elements in $G_u$ for the two 2-cells. This is because, as in the example above, if a vertex requires a joining element, then at some stage in the folding sequence the attaching words for both $\sigma$ and $\sigma'$ will contain a subword of the form $f_j u f$. In the tree $T$, $f$ will map to an arc, $\tau f = u$ will map to a point $v$ and $j_u f$ will map to an arc intersecting $f$ in the single point $v$. Thus $f$ and $j_u f$ determine different directions $d_1, d_2$ at $v$, such that $d_2 = j_u d_1$. This will be true for both the attached two cells, so that we can choose the same $j_u$ for both attaching words.

For the moment let us assume that there is a single equivalence class, and so there is a single subcomplex $X$ itself.

In the resolution of the action of $G$ on $T$ each 1-cell $e$ is effectively assigned a length $|e| \in \mathbb{R}$, which is the length of the arc in $T$ joining the images in $T$ of the end points of a lift of $e$ to the universal cover $\hat{X}$. Let $A$ be the the subgroup of $\mathbb{R}$, regarded as an additive group, generated by the set $\{|e| | e \in X^1\}$. The group $A$ is isomorphic to $\mathbb{Z}^n$ for some $n$. Let $P_n$ be a parallelepiped group corresponding to an $n$-cube, in which we will assign orders to the vertex elements in a certain way.

As described in [12] the group $P_n$ acts on a 1-connected, $n$-dimensional cubing $C_n$ that contains an $n$-dimensional Euclidean space $E_n$ and $P_n$ contains a free abelian rank $n$ subgroup $J_n$ that acts on $E_n$ by translations of 2 units in each of the coordinate directions. The space $P_n \setminus C_n$ is obtained from $J_n \setminus E_n$ by identifying a single antipodal pair of $n$-cells in $J_n \setminus E_n$. We show that there is a subgroup $G'$ of $G$ generated by cyclic subgroups of distinct vertex groups of $X$ and a map $\theta : \hat{X} \to C_n$ which is equivariant with respect to a homomorphism $G' \to P_n$. For each 2-cell $\sigma$ in $X$ there is a lift $\hat{\sigma}$ such that $\theta(\hat{\sigma}) \subset E_n$, and the map $\theta$ is defined by specifying how $\theta$ acts on these 2-cells.

Suppose $A$ is generated by the real numbers $\alpha_1, \alpha_2, \ldots, \alpha_n$. We assume now that $J_n$ acts on $E_n$ by translations of $2\alpha_i$ in each of the coordinate directions. We give $E_n$ the structure of a cell complex in the obvious way so that, as for the rectangle group, $J_n$ acts cellularly and there is one orbit of $n$-cells subdivided into $2^n$ orbits of smaller $n$-cells. For the left hand vertex $v$ in a particular 2-cell $\hat{\sigma}$ of $\hat{X}$ let $\theta(v)$ be the origin in $E_n$. Each 1-cell in $\hat{X}$ has a particular length in $A$, and this length will determine a vertex of $E_n$. Proceeding around the boundary of $\hat{\sigma}$ will determine a loop in the positive quadrant of $E_n$. The distance from the origin will increase as one passes along the top or bottom of $\hat{\sigma}$ away from $v$ and one will reach the same point which is the image of the right hand vertex of the 2-cell. If a vertex is
visited more than once in passing along the top or bottom, then on one of the visits one has to use a joining element to pass to the antipodal subcube in $E_n$. This will mean that the path traced out in $E_n$ never backtracks, though its image in $X$ will backtrack.

We illustrate the above argument with another example.

**Example 3.2.** Consider the pair $(a\tilde{ab}c\tilde{e}, \tilde{d}de\tilde{c})$. Suppose a 2-cell corresponding to this pair arises in the action of a group $G$ on an $\mathbb{R}$-tree with marking $|a| = 1, |b| = \sqrt{2}, |c| = \sqrt{3}, |d| = \sqrt{5}, |e| = 1 + \sqrt(2) + \sqrt(3) - \sqrt(5)$.

In this case $n = 4$. The path traced out by the word $ww'$ visits the vertices 

$$(0, 0, 0, 0), (1, 0, 0, 0), (2, 0, 0, 0), (2, 1, 0, 0), (2, 2, 0, 0), (2, 2, 1, 0), (2, 2, 2, 0), (1, 1, 1, 1), (0, 0, 0, 1), (0, 0, 0, 0),$$

If the 1-skeleton of $X$ is a tree $X^1$, in the loop in $X^1$ corresponding to the boundary of $\sigma$ the path corresponding to successive visits to a particular vertex will pass over each edge an even number of times. It the edge is oriented then it must pass over the edge the same number of times in each direction. This means that in $E_n$ if two vertices of $\tilde{\sigma}$ are in the same $G$-orbit, then their images in $E_n$ are in the same $J_n$-orbit. Consider the subgroup $G_\sigma$ of $G$ generated by the joining elements of $\sigma$. The group $G_\sigma$ is the fundamental group of the complex $X_\sigma$ of groups corresponding to $\sigma$. All the vertex groups and edge groups are cyclic. Each one is generated by a power of a joining element. An element that fixes an edge of $X_\sigma$ must fix every edge for the reason explained above. Thus $G_\sigma$ has a cyclic normal subgroup $N_\sigma$ such that $G_\sigma/N_\sigma$ acts on $\tilde{X_\sigma}$ with trivial edge stabilizers. We now show that there is a a map $\theta_\sigma : \tilde{X_\sigma} \to \tilde{C_n}$ which is equivariant with respect to a homomorphism from $G_\sigma$ to $P_n$ with kernel $N_\sigma$.

We map $G_\sigma$ into $P_n$ by mapping $N_\sigma$ to the identity element and giving each joining element to a vertex element in which its order is the order of that element modulo $N_\sigma$. The defining relations between the joining elements of $G_\sigma$ are given by the attaching maps of $\sigma$ as described above. If we map $\tilde{\sigma}$ into $E_n$ then the relation is a consequence of the relations of $J_n$. Thus we have a homomorphism from $G_\sigma$ to $P_n$.

If a different 2-cell $\sigma'$ of $X$ shares an edge $e$ with $\sigma$, then there will be a lift $\tilde{\sigma'}$ that shares an edge with $\tilde{\sigma}$ and the boundary map of $\sigma'$ will determine a closed path in $E_n$. Thus the maps $\theta_\sigma$ and $\theta_{\sigma'}$ match up nicely and carrying out the extension to every 2-cell we see that there will be a map $\theta : \tilde{X} \to \tilde{C_n}$ which restricts to $\theta_\sigma$ on each 2-cell $\tilde{\sigma}$. This map will be equivariant with respect to $G'$, the subgroup of $G$ generated by all the $G_\sigma$ for every 2-cell $\sigma$. An infinite folding sequence will produce an in infinite non-decreasing sequence of edge groups whose union will be a normal subgroup of the group of the cube complex that is the kernel of the map to the target group.

Note that any folding sequence results in a sequence of complexes that resolve the action on $T$ and it can never be the case that the joining element becomes trivial in the folding. This is because at some stage in a folding sequence the joining element will lie between an edge $e$ and $\tilde{e}$ and if the joining element is trivial, then the action on $T$ will not be resolved. Two vertices in different $G$ orbits in $\tilde{X}$ may end up in the same $J_n$-orbit (I don’t know if this can happen - it may be that if two vertices are mapped to the same $J_n$-orbit, then some folding sequence will result in a Type III fold and the images of the vertices lying in the same $G$-orbit ). If it can happen, then a way of dealing with this is to give the vertex element in $P_n$ as its order.
the lowest common multiple of the finite orders of any joining elements mapped to it (modulo the smallest power of that element that fixes an edge) and map each joining element to an appropriate power of the vertex element in $P_n$.

If the one skeleton $X^1$ of $X$ is not a tree, then let $W$ be a spanning tree for $X^1$. In this case we take $G'$ to be the subgroup of $G$ generated by the joining elements corresponding to a lift of $W$ to $\tilde{X}$ together with a connecting element generator for each edge $e$ of $X$ that is not in $W$. If $u, u'$ are the vertices of $e$ then the lift of $W$ to $\tilde{X}$ will contain unique lifts $\tilde{u}, \tilde{u}'$ of $u, u'$. There will not usually be an edge of $\tilde{X}$ joining $\tilde{u}, \tilde{u}'$ but there is a lift $\tilde{e}$ of $e$ with $\tilde{e} = \tilde{u}$. The generator corresponding to $e$ is an element $c(e)$ of $G$ such that $c(e)^{-1} \tau \tilde{e} = \tilde{u}'$. The edge $e$ is given a length $\frac{1}{2}|e|$ in our action on $T$. We want the corresponding generator to be mapped to a translation by $|e|$ in $J_n$. In this case let $A$ be the subgroup of $\mathbb{R}$ generated by \{\{e|e \in EW\} \cup \{\frac{1}{2}e|e \in EX^1 \setminus EW\}\}. Taking a generator $\frac{1}{2}|e|$ for $e \in EX^1 \setminus EW$ means that there is a translation of $|e|$ in $J_n$ since it is through an even number of units. Let $G'$ be the subgroup of $G$ generated by all the joining elements and connecting elements. We can now define a homomorphism from $G'$ to $P_n$. We map each joining element as before, as it will correspond to a vertex of the spanning tree. For each edge $e$ that is not in the spanning tree, we introduce a vertex that is the midpoint of the subdivided edge. In $P_n$ we give the corresponding vertex element $v(e)$ the order two. If the vertex element in $P_n$ corresponding to the initial vertex of $e$ in $Y$ is $u$, then we map the connecting element $c(e)$ to the element $v(e)u^{-1}$, which will then correspond to a translation of length $|e|$.

Now consider the case when $U$ may have more than one equivalence class for the relation $\sim$. Let $Y$ be the graph in which $XY$ is the union $VX$ with the set of equivalence classes $U/\sim$ that have more than one element.

Let $(Y, Y)$ be the graph of groups in which for each $v \in VX$, $\mathcal{Y}(v) = G_{v'}$, where $G_{v'}$ is the $G$-stabiliser of the image $v'$ under $\theta$ of the lift of $v$ in the lift of $W$ to $\tilde{X}$. For each $v$ that is an equivalence class in $U/\sim$ we take $\mathcal{Y}(v)$ to be the group $G'$ defined above. The set $EY$ is the union of $EX \setminus U$ with an edge for any $v \in VX$ that is the vertex of an edge $e$ that lies in the equivalence class $[e]$ of $U$, joining $v$ to $[e]$. The group in $(\mathcal{Y}, Y)$ attached to this edge will be the cyclic subgroup of $G$ generated by the joining element of $v$. If $v$ has not had a joinig element attached to it, then let the group attached to this edge be the identity subgroup.

The graph of groups we have constructed has the properties listed in the statement of the theorem, and so the proof is complete.  

□

Not every quadratic word will correspond to an infinite folding sequence. We say that the pair $(V, W)$ of words is admissible if the word $V \cup W$ is quadratic and for some marking the corresponding folding sequence starts at one end and finishes at the other. Here we may have to include joining elements to represent the attaching word in $\tilde{X}$, for example if either $V$ or $W$ contains a subword $e\bar{e}$. If $(V, W)$ is admissible then any marking which produces such a folding sequence is called an admissible marking. We now explore which pairs of words $(V, W)$ are admissible. Which pairs are admissible seems quite tricky to determine. We have seen in Example 3.1 that the pair $(eeff, gg)$ is admissible with the admissible marking $|e| = |g| = 1, |f| = \sqrt{2}$ On the other hand the pair $(aabbcc, ddee)$ of Example 3.2 with marking $|a| = 1, |b| = \sqrt{2}, |c| = \sqrt{3}, |d| = \sqrt{5}, |e| = 1 + \sqrt{2} + \sqrt{3} - \sqrt{5}$ reaches a Type III fold after eleven folds and the pair $(aabbcc, ddee ff)$, $|a| = 1, |b| = \sqrt{2}$
CONJECTURE 3.3. If \((V, W)\) is admissible, then any marking of maximal dimension is an admissible marking.

We have seen above that the pair \((aab, bcc)\) is admissible. Another example is \((abcd, dcba)\). If the conjecture is true then \((aabb, ccdd)\) and \((ab\bar{a}b, cd\bar{c}d)\) are not admissible, as there are markings of maximal dimension that result in folding sequences that give Type III folds.

Proposition 3.4. If Conjecture 3.3 is true then so are the following statements.

(i) A quadratic pair is admissible if and only if one marking of maximal dimension is admissible.

(ii) If a pair \((V, W)\) is admissible then any pair of edges which occurs in both \(V\) and \(W\) must have the same orientation.

(iii) Let \((V, W)\) be an admissible pair. If an edge pair with the same orientation occurs in \(V\), then no edge pair with opposite orientations can occur in \(W\).

Proof. ([i]). This is immediate.

([ii]) Suppose the pair \((UaV, W\bar{a}X)\) is admissible. By folding from both ends we can assume that \(U\) and \(X\) are empty. Let \(b\) be the first edge of \(W\), so that \(W = bW'\). If \(a\) is longer than \(b\) then folding will give \((aV, W'\bar{a}b)\) which means that \((aV, W'\bar{ab})\) is admissible. There will certainly be a marking of maximal dimension in which \(a\) is longer than \(b\). Note that \(W'\) has fewer edges than \(W\). By repeating this process we get an admissible pair \((a\bar{V}, \bar{a}U)\). But since the first internal vertices match up, this cannot be admissible.

([iii]) First note that if \(V = aUaX\) and \(W = bY\bar{b}Z\), then by folding and assuming \(b\) is longer than \(a\) produces an admissible pair \((UaX, bY\bar{b}aZ)\), which contradicts (ii). Thus the original pair was not admissible. In general if \(W\) contains a pair of edges \(b, \bar{b}\) that do not have the same orientation, then by folding from one end we can assume that \(V = aUaX, W = W'bY\bar{b}Z\). Then by assuming the length of \(b\) is greater than the total length of \(W'\), by folding we get an admissible pair \((a'UW'a'X, bY\bar{b}Z)\). But we have just seen that this cannot be admissible.
