Abstract
Perovskite solar cells (PSCs) have great potentials in photovoltaics due to their high power conversion efficiency and low processing cost. PSCs are usually fabricated from PbI2/dimethylformamide solution with some toxic additives, such as N-methyl pyrrolidone and hexamethylphosphoramide. Here, we use an environmental friendly aprotic polar solvent, 1,3-dimethyl-2-imidazolidinone (DMI), to fabricate perovskite films. By adding 10 vol% DMI in the precursor solution, high-quality perovskite films with smooth surface are obtained. By increasing annealing temperature from 100 to 130 °C, the average grain size of the perovskite increases from ~ 216 to 375 nm. As a result, the efficiency of the PSCs increases from 10.72 to 14.54%.

Keywords: Perovskite solar cell, Aprotic polar solvent, Lewis acid–base adduct, 1,3-Dimethyl-2-imidazolidinone

Background
Recently, organometallic halide perovskite solar cells (PSCs) have attracted great attentions due to rapid growth of power conversion efficiency (PCE) and low processing cost [1–8]. Currently, the perovskite solar cells are mainly fabricated through solution-based processing, including one-step [9–12], two-step [13, 14], and additive-assisted deposition methods [15, 16]. The two-step method has been widely used for achieving high-efficient perovskite solar cells. In the traditional two-step method, the CH3NH3PbI3 (MAPbI3) perovskite is formed through intercalation of CH3NH3I (MAI) into the PbI2 lattice, which usually leads to rough surface due to volume expansion and existence of some small grains on the perovskite films [17, 18].

Generally, dimethylformamide (DMF) is used as solvent for preparing PbI2 and MAPbI3 films. The volatile DMF solvent has a high saturated vapor pressure, which makes the PbI2 crystallize rapidly during spin-coating of the PbI2/DMF solution, so it is hard to control the crystallinity of the PbI2 films. The morphology of the perovskite film depends on the PbI2 strongly. In order to obtain smooth and dense perovskite films with large grains, researchers usually added some additives to the PbI2/DMF precursor solution. For example, Zhang et al. reported preparation of a smooth MAPbI3 film by incorporating 4-tert-butylpyridine (TBP) into the PbI2/DMF precursor solution [19]. Li et al. mediated the nucleation and grain growth pathway to obtain large perovskite grains in micrometer scale by introducing an acetonitrile to the PbI2/DMF solution [20]. Recently, Lewis acid–base adduct approach was also used to fabricate high-quality perovskite films. Some aprotic polar solvents, such as DMF, N,N-dimethyl sulfoxide (DMSO), N-methyl pyrrolidone (NMP), and hexamethylphosphoramide (HMPA), have been used as Lewis base solvents to improve the quality and performance of the perovskite solar cells [21–23]. Lee et al. [24] pointed out that aprotic polar solvents, containing oxygen, sulfur, or nitrogen ligands, were Lewis bases, which can form Lewis acid–base adducts of PbI2·xSol with PbI2 through dative bonds. The Lewis adducts of PbI2·xSol lead to high-quality perovskite films and high-efficient PSCs. However, the above aprotic polar solvents are toxic, which harm health and environments.

1,3-Dimethyl-2-imidazolidinone (DMI) is also an aprotic polar solvent with low volatility. The DMI has a five-membered ring and a carbonyl (see Additional file 1: Figure S1). Due to the isolated electron pair on the O...
atom of the carbonyl, DMI can also form a Lewis adduct with PbI₂. More importantly, the potential toxicological risk of DMI is less than carcinogen HMPA and reproductive toxicity NMP. Thus, it is a good alternative solvent to the HMPA and NMP, in forming perovskite through the Lewis adduct approach because it provides a safer working environment [25]. Here, we introduce the DMI solvent into the PbI₂/DMF precursor solution to improve quality of the perovskite films.

**Methods**

**Device Fabrication**

The perovskite films and solar cells were fabricated by a modified two-step method, which has been reported in details in our previous paper [22]. In brief, a compact TiO₂ blocking layer was spin-coated a mildly acidic solution of titanium isopropoxy solution in ethanol at 2000 rpm for 30 s on FTO substrate, followed by sintering at 500 °C for 30 min. A meso-porous TiO₂ layer was then deposited on the blocking layer by spin-coating diluted TiO₂ paste (Dyesol-30NRT, Dyesol) in ethanol (1:6, weight ratio) at 3500 rpm for 30 s. The FTO substrate was sintered at 500 °C for 30 min. The FTO substrate was then dropped with 1 M PbI₂/DMF solution adding with different volume fractions of DMI and then spin-coated at 3000 rpm for 30 s. The PbI₂ precursor film was directly dipped into a solution of CH₃NH₃I (MAI) in 2-propanol with a concentration of 30 mg/mL for 120 s to prepare MAPbI₃ films and then annealed at 100 °C for 30 min. A HTM layer was then deposited by spin-coating a solution prepared by dissolving 100 mg spiro-OMeTAD, 40 μL 4-tert-butylpyridine (TBP), 36 μL butylpyridine (TBP), 36 μL of a stock solution of 520 mg/mL TFSI in acetonitrile, and 60 μL of a stock solution of 300 mg/mL FK102 dopant in acetonitrile in 1 mL chlorobenzene. Finally, a 60-nm-thick Au electrode was fixed at 0.06 cm². ZnO nanostructures were measured by an Edinburgh FLS 920 instrument (Livingston, WL, UK). The current-voltage curves were measured in air illustrated by a solar simulator (AM 1.5G, 100 mW/cm², 91195, Newport) at a scan rate of 5 mV/s.

**Results and Discussion**

Figure 1a, b shows FTIR transmittance spectra of the pure DMF and DMI solvents and their corresponding Lewis adducts. The stretching vibration of C=O bonds is located at 1670 and 1697 cm⁻¹ for the DMF and DMI solvents, respectively. When forming Lewis adducts, the C=O peaks separately downshift to 1658 and 1668 cm⁻¹. It indicates that both of the DMI and DMF can interact with PbI₂ through dative Pb–O bonds, which separately form Lewis adducts of PbI₂/DMF and PbI₂/DMI [26, 27]. Figure 1c shows TGA curves of PbI₂ powder and its Lewis adducts of PbI₂/DMI and PbI₂/DMF. The PbI₂/DMF decomposes completely to PbI₂ at 120 °C, while PbI₂/DMI decomposes completely at 200 °C. It indicates that the PbI₂/DMI adduct is more stable than the PbI₂/DMF due to the stronger molecular interaction between DMI and PbI₂. Therefore, it inclines to form PbI₂/DMI when DMI exist in the PbI₂/DMF precursor solution. Figure 1d shows XRD curves of the Lewis adducts of PbI₂/DMI and PbI₂/DMF, which are prepared from PbI₂/DMF solution adding with and without 10 vol% DMI. The PbI₂/DMI has two characteristic diffraction peaks at 7.97° and 9.21°, which are smaller than those of the PbI₂/DMF (9.12° and 9.72°).

When immersed in MAI/2-propanol solution, the Lewis adducts of PbI₂/DMI convert to perovskite through molecular exchange between DMI and MAI basing on following formula:

\[
PbI₂ \cdot DMI + MAI \rightarrow MAPbI₃ + DMI
\]  

(1)

Additional file 1: Figure S2 shows XRD curves of the annealed perovskite films prepared by immersing Lewis adducts of PbI₂/DMI in the MAI/2-propanol solution for different times. The XRD peaks at 12.7° and 14.2° are assigned to (001) of the PbI₂ and (110) of the perovskite, respectively [11, 28]. It shows that the PbI₂/DMI converts to perovskite completely within 2 min. There are some residual PbI₂ in the perovskite films when the reaction time is less than 120 s.

Figure 2 shows SEM images of the PbI₂ films and corresponding perovskite films prepared from the PbI₂/DMF solution adding with different amounts of DMI. All the samples are annealed at 100 °C for 30 min before SEM characterization. Compared to DMF, DMI has a higher boiling point and stronger interaction with PbI₂. Therefore, the morphology of the PbI₂ films change evidently with the concentration of DMI. The PbI₂ grains change from ramiform to plate-
like when 10 vol% DMI is added to the PbI₂/DMF precursor solution (see Fig. 2a, b). However, the PbI₂ films change to porous and even discontinuous, when the DMI concentration increases to 20 vol% (Fig. 2c). The resulting MAPbI₃ films are affected by the PbI₂ films significantly. Thus, the perovskite film has a uniform grain and smooth surface for the sample prepared from the solution adding with 10 vol% DMI (see Fig. 2e), which is better than that without DMI. However, excessive DMI might lead to discontinuous...
films (see Fig. 2f), which are disadvantageous for the photovoltaic performance of PSCs.

In spite of uniform grain and smooth surface, the grain size of MAPbI₃ fabricated from PbI₂/DMF solution with 10% DMI and annealed at 100 °C is not large enough. According to the TGA curves in Fig. 1c, the DMI escapes from the Lewis adducts at higher temperature than the DMF. Herein, we increase the annealing temperature. Figure 3a, b shows top-viewed SEM images of the perovskite films prepared by annealing at 100 and 130 °C from the solution adding with 10 vol% DMI for 10 min. It is clear that the grain size increases as the annealing temperature rises. The average grain sizes are 216 and 375 nm for the samples prepared from annealing temperature of 100 and 130 °C, respectively (see Additional file 1: Figure S3). Figure 3c, d shows cross-sectional SEM images of the perovskite solar cells. It shows that the perovskite solar cells have about 250-nm-thick perovskite layers. It contains only one grain in most area for the samples annealed at high temperature (130 °C), which ascribes to the larger grain size than the film thickness. When increasing the annealing temperature to 160 °C, there are some residual PbI₂ in the perovskite films (see Additional file 1: Figure S4), which results in a poor photovoltaic performance (see Additional file 1: Figure S5 the best PCE = 8.53%).

Figure 4a shows J–V curves of the best cells fabricated from the solution adding with different DMI additives. The corresponding photovoltaic parameters are listed in Table 1. The PSCs exhibit the best photovoltaic performance with a PCE of 14.54%, a short current density (J_{sc}) of 21.05 mA/cm², an open voltage (V_{oc}) of 1.02 V, and a fill factor (FF) of 67.72% for the samples fabricated from DMF solution adding with 10 vol% DMI and annealing at 130 °C. For the PSCs fabricated from the same precursor solution and annealing at 100 °C, the best PCE is only 12.84%. The PSCs fabricated from the solution with DMI additive have better photovoltaic performances than those from the solution without DMI (the best PCE = 10.72%, J_{sc} = 20.14 mA/cm², V_{oc} = 0.97 V, FF = 55.14%). A series of photovoltaic parameters for the PSCs fabricated from different conditions exhibit the similar tendency to the best PSCs as shown in Fig. 4c–f. The devices fabricated from the solution with 10 vol% DMI and annealing at 130 °C exhibit higher PCE than that from the pure DMF. Figure 4b shows an incident photon-to-current efficiency (IPCE) result of a PSC fabricated from DMF solution adding with 10 vol% DMI, which exhibits a good quantum yield. It is noted that the integrated J_{sc} is about 10% lower than that obtained from the reverse scan. This discrepancy might derive from the spectral mismatch between the IPCE light source and solar simulator and from the decay of the devices during the measurement in air [29]. To check the stabilization or saturation point of photocurrent for the PSCs fabricated from the solution with 10 vol% DMI and annealing at 130 °C, we measured the steady-state current of a typical PSC at a bias voltage close to the maximum power point (0.78 V), as shown in Additional file 1: Figure S6a. The PSC

![Fig. 3 SEM images of the MAPbI₃ films (top) and corresponding perovskite solar cells (bottom).](image-url)
shows a stable output. The device shows an evident hysteresis phenomenon in Additional file 1: Figure S6b.

Figure 5a shows impedance spectra of the PSCs measured in the dark at a forward bias of 0.9 V. The inset of Fig. 5a is an equivalent circuit composed of series resistance ($R_s$), recombination resistance ($R_{rec}$) and the transport resistance ($R_{HTM}$) [30]. The $R_s$ of the PSCs reduces from 26.16 to 14.30 $\Omega$ by adding 10% DMI in DMF and annealing at 130 °C compared to without DMI. The small $R_s$ facilitates carrier transport, leading to a high $J_{sc}$ [31]. On the contrary, the $R_{rec}$ increases from 46.49 to 2778 $\Omega$ by adding 10 vol% DMI in DMF and annealing at 130 °C compared to pure DMF. The high $R_{rec}$ effectively suppresses the charge recombination for improved device performance.

Figure 5b shows steady-state PL spectra of the MAPbI$_3$ films deposited on mesoporous TiO$_2$ substrate. The PL spectra are quenched for the perovskite films fabricated from the solution with 10% DMI and

| Sample                | $J_{sc}$ (mA/cm$^2$) | $V_{oc}$ (V) | FF (%) | PCE (%) | $R_s$ (\$\Omega$) | $R_{rec}$ (\$\Omega$) |
|-----------------------|----------------------|--------------|--------|---------|-------------------|----------------------|
| W/O DMI, 100 °C       | 20.14                | 0.97         | 55.14  | 10.72   | 26.16             | 46.49                |
| 10% DMI, 100 °C       | 20.94                | 1.01         | 60.73  | 12.84   | 14.65             | 1206                 |
| 10% DMI, 130 °C       | 21.05                | 1.02         | 67.72  | 14.54   | 14.30             | 2778                 |
annealing at 130 °C, which indicates that the charges transfer effectively from MAPbI$_3$ into a TiO$_2$ film before they are recombined at the interface for the sample. Compared with those fabricated from the pure DMF, adding some DMI additive can improve the charge transfer. To gain more insight into charge transfer, time-resolved PL of the MAPbI$_3$ films deposited on the mesoporous TiO$_2$ substrate are also carried out (see Fig. 5c). The spectra are well fitted with a bi-exponential decay function:

\[ I(t) = A_1 \frac{t}{\tau_1} + A_2 \frac{t}{\tau_2} \]  

where \( \tau_1 \) and \( \tau_2 \) are the decay time of the two decay processes, respectively. It indicates that there is a fast (\( \tau_1 \)) and a slow (\( \tau_2 \)) decay in the PSCs. The fast decay process is regarded as a quench effect of free carriers in the perovskite film to the electron transport layer (ETL) or HTM, whereas the slow decay process is regarded as the radiative decay [32, 33].

The \( \tau_1 \) reduces from 3.71 to 2.80 ns when adding 10% DMI and annealing at 100 °C. Furthermore, the \( \tau_1 \) reduces to 1.90 ns when adding 10% DMI and annealing at 130 °C, demonstrating that the electrons transfer faster from the perovskite film to the TiO$_2$ ETL layer, as witnessed by stronger steady-state PL quenching. We believe that the enhanced charge transfer rate is ascribed to the increase of large grains and reduce of grain boundary in the perovskite films by adding DMI.

**Conclusions**

We fabricated high-quality perovskite films with large grains by adding some environmental friendly DMI additives to the PbI$_2$/DMF solution. It forms a compact Lewis adduct film of PbI$_2$-DMI, which converts to perovskite films through molecular exchange between DMI and MAI. High-quality perovskite films with large grains are easily obtained by annealing at high temperature. The performances of the perovskite solar cells are thus improved significantly by adding 10 vol% DMI in the precursor solution and annealing at 130 °C.
