Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
Diagnostic accuracy of CT and radiographic findings for novel coronavirus 2019 pneumonia: Systematic review and meta-analysis

Systematic review

ABSTRACT

Purpose: To evaluate pooled prevalence, sensitivity, and specificity of chest computed tomography (CT) and radiographic findings for novel coronavirus-2019 (COVID-19) pneumonia.

Methods: We performed systematic literature search in PubMed and Embase to identify articles reporting baseline imaging findings of COVID-19 pneumonia. The quality of the articles was assessed using NIH quality assessment tool for case series studies. The pooled prevalence, sensitivity, specificity, and diagnostic odds ratio of imaging findings were calculated.

Results: Fifty-six studies (6007 patients, age, 2.1–70 years, 2887 females, 5762 CT, 396 radiographs,) were included. The mean interval between onset of symptoms and CT acquisition was 1–8 days. On CT, the pooled prevalence of ground glass opacities (GGO), GGO plus consolidation, and consolidation only was 66.9% (95% CI 60.8–72.4%), 44.9% (38.7–51.3%), and 32.1 (23.6–41.9%) respectively. Pooled sensitivity and specificity of GGO on CT was 73% (71%–80%) and 61% (41%–78%), respectively. For GGO plus consolidation and consolidation only, the pooled sensitivities/specificities were 58% (48%–68%)/58% (41%–73%) and 49% (20%–78%)/56% (30%–78%), respectively. The diagnostic accuracy of radiographic findings could not be assessed due to small number of studies.

Conclusion: GGO on CT has the highest diagnostic performance for COVID-19 pneumonia, followed by GGO plus consolidation and consolidation only. However, the moderate to low sensitivity and specificity suggest that CT should not be used as the primary tool for diagnosis. Chest radiographic abnormalities are seen in half of the patients.

1. Introduction

World Health Organization (WHO) declared coronavirus disease 2019 (COVID-19) a “public health emergency” at the end of January 2020.1 The disease is highly infectious, and the reported modes of spread are via aerosol and feco-oral route.2 The initial symptoms are indistinguishable from other viral diseases. Pneumonia is the most frequent presentation and manifests as fever, cough, dyspnea. Although most patients have mild disease with complete recovery, patients with advanced age and underlying co-morbidities have higher mortality.3 There are no specific clinical or radiological features reliably distinguishing COVID-19 from other viral infections of the respiratory system.4 The definitive diagnosis of COVID-19 disease is based on the analysis of the respiratory specimens (expectorated sputum, nasopharyngeal, oropharyngeal or nasal swabs and/or bronchoalveolar lavage) by the reverse transcriptase polymer chain reaction (RT-PCR).5 The
Detection rates vary from 32 to 93% according to the site and method of obtaining the specimen. Bronchoalveolar lavage fluid specimen has the highest positivity rates followed by sputum, and nasal swabs.

Imaging is invaluable in the assessment of the COVID-19 patients. Standard frontal chest radiographs reveal ground-glass opacities (GGO) or consolidation. The most common CT finding is bilateral, peripheral GGO. Consolidation, combination of consolidation and GGO, and crazy paving pattern are the other commonly reported findings. The CT features of COVID-19 pneumonia depend on the duration of infection. CT may be normal in the early phase. The CT findings peak between 6 and 11 days and comprise mainly of GGO. Between 12 and 17 days, a mixed pattern of findings (GGO and consolidation) predominate. Majority of the patients have residual findings on CT at the time of discharge. Additionally, the CT findings may progress over time. In one study, worsening of GGO and progression to consolidation was reported in 85.7% of the patients. CT involvement scores, architectural distortion, and traction bronchiectasis may aid in evaluation of disease progression.

severity. Despite some reports of better diagnostic accuracy of chest CT compared with RT-PCR, the American College of Radiology (ACR) does not recommend the use of a CT chest for screening purposes. CT scans can be efficiently utilized in a selected group of hospitalized COVID-19 patients to assess the extent, severity, and prognosis of the disease and to detect associated complications. The visual as well as quantitative maps of the affected lungs, may provide an objective assessment of the severity of involvement.

Most of the published systematic reviews on the imaging findings in COVID-19 comprise studies conducted in the early period of the disease outbreak. The quantitative analyses were limited to pooled prevalence estimates. The present systematic review and meta-analysis is aimed to evaluate the pooled prevalence and the diagnostic accuracy of individual imaging findings on chest CT scans and radiographs in patients with COVID-19 pneumonia.

2. Materials and methods

This meta-analysis complied with the Preferred Reporting Items for Systematic reviews and Meta-Analysis guidelines.

2.1. Literature search

Two reviewers searched Pubmed and Embase and screened the titles and abstracts independently. The disagreement regarding the inclusion of a potential article was resolved in consensus. There was no language restriction for the search. The search was limited to the articles reporting COVID-19 infection only. The initial search was completed on 2nd April and again updated on 7th April 2020. The detailed search strategy is shown in Table 1. Studies were first screened by examining their titles and abstracts. Their references were also checked for other relevant publications. The full texts of potentially eligible studies were retrieved for review.

2.2. Inclusion and exclusion criteria

Criteria for inclusion of studies were as follows: (a) Confirmed COVID-19 based on positive RT-PCR on one of the respiratory specimens (b); Studies reporting the imaging findings in COVID-19 pneumonia on a baseline CT (c) the absolute numbers of patients with positive imaging findings should have been directly reported or was derivable and (d) more than ten patients should have been reported.

Review articles, case series (≤10), case reports, pictorial essays, letter to the editor (on already published papers), unpublished data, conference abstracts, and proceedings on the topic of interest were excluded.

2.3. Data extraction and quality assessment

The data was extracted on an excel sheet by two reviewers independently. The following details were obtained: type of study, country of origin, imaging modality (CT or chest radiograph); reference standard for diagnosis; patient demographic information (age, gender); numbers of true-positive (TP), true-negative (TN), false-positive (FP), and false-negative (FN); distribution of findings (central, peripheral, or both; unilateral or bilateral; upper lobe, middle or lower lobe); the interval from symptom onset to CT acquisition; the number of patients with normal CT scans; the number of patients with co-morbidities and number of patients requiring mechanical ventilation. The data entered by both the reviewers was matched, and any discrepancy was resolved after the re-evaluation of the paper in consensus.

Two reviewers assessed the methodologic and reporting quality of each study independently by using the NIH quality assessment tool for case series studies. This tool comprised nine questions. The responses to each of these questions were ‘yes’, ‘no’ or others (cannot determine, CD; not reported, NR; or not applicable, NA). The overall assessment was "good", "fair" or "poor".

2.4. Statistical analysis

The statistical analysis was performed using R statistical software (version 3.6.1). In addition to the base package, the additional packages used include meta, mada, and readxl. The studies providing the number of patients with individual imaging findings and the total number of patients were summarized as pooled prevalence. Studies reporting the sensitivity as well as specificity were used to extract TP, TN, FP, and FN for evaluating pooled sensitivity, specificity, and diagnostic odds ratio. The meta-analysis was done using the inverse variance method with logit transformation along with the Clopper-Pearson confidence interval for individual studies. The pooling of the diagnostic odds ratio was also computed by the inverse variance method. The Forest plots were constructed for pooled prevalence, sensitivity, specificity, and diagnostic odds ratio. For the pooled analysis, heterogeneity was quantified using the $I^2$ test statistic, including 95% CI. The $I^2$ statistic reports the percentage of total variation across studies that is due to heterogeneity rather than chance. A value of $I^2$ statistic greater than 50% implies heterogeneity. Wilson method was used for the calculation of CI for both pooled analysis as well as the summary results. A bivariate diagnostic random-effect model was used for computing the combined sensitivity and specificity. For the computation of the bivariate model, a minimum of 4 studies was essential. Hierarchical summary receiver operating plot (hsROC) with 95% predictive and calculated region was plotted, and area under the curve (AUC) was determined.

3. Results

3.1. Literature search and article selection

The study selection process is detailed in the flowchart (Fig. 1). The initial search yielded 16,438 articles in Pubmed and 20,543 articles in Embase. Manual restriction to articles reporting COVID-19 in 2020 resulted in 1136 articles in Pubmed and 1393 articles in Embase. After screening titles and abstracts, and removing duplicates, the full texts of 168 articles were reviewed. Finally, 56 articles were selected.

The details of these studies are given in Supplementary Table 1. There were four studies in the Chinese language. Most of the studies were from the Chinese population. Three studies were reported from the United States (n = 3) and one study each from Japan (n = 1) and Italy (n = 1).

3.2. Quality assessment

The results of the quality assessment are presented in Supplementary Table 2. Most of the studies were rated as “fair” by both the reviewers.

3.3. Pooled prevalence of the imaging findings

There were 6007 patients, with 2910 (48.5%) males and 2887 (48.1%) females. In a few studies, the number of males and females was not specifically reported. However, as the rest of the data was complete, these studies were included for analysis. Baseline CT scans were performed in 5762 patients and chest radiographs in 282 patients. The information regarding the laterality of involvement was reported in 30
studies (3141 patients). Unilateral disease was reported in 286 (9.1%) CT scans and bilateral disease in 1358 (44%) CT scans. The preferential involvement of peripheral vs. central lung was reported in 31 studies (1960 patients). Central, peripheral, and central plus peripheral involvement was reported in 314 (16%), 1147 (58.5%), and 382 (19.4%) CT scans, respectively. The mean interval from the onset of symptoms to CT acquisition was 1–8 days. Co-morbidities were reported in 773 patients (29.9%), and 232 (15.6%) patients required mechanical ventilation.

The pooled prevalence of GGO was 66.9% (95% CI 58.4–72.4%, $I^2$ 96%).
92%) (Fig. 2A), consolidation only was 32.1% (23.6–41.9%, $I^2$ 96%) (Fig. 2B), and GGO plus consolidation was 44.9% (38.7–51.3%, $I^2$ 83%) (Fig. 2C). The pooled prevalence of other CT abnormalities were 29.1% (19.6–40.8, $I^2$ 93%) for crazy paving, 23.6% (11.7–41.8, $I^2$ 93%) for halo sign, 8.9% (5.7–13.8, $I^2$ 65%) for nodules, 5.6% (4.2–7.4, $I^2$ 51%) for pleural effusion, and 2.7% (1.3–5.5, $I^2$ 84%) for lymphadenopathy (Supplementary Figs. 1 and 2).

Findings of chest radiographs were reported by five studies comprising 396 patients. The pooled prevalence of GGO and consolidation was 38.7% (22.2–58.3%, $I^2$ 83%) and 46.9% (29.7–64.9%, $I^2$ 84%), respectively (Supplementary Fig. 3). The diagnostic accuracy meta-analysis for radiographic abnormalities could not be conducted due to a limited number of studies.

3.4. Diagnostic performance evaluation of various imaging modalities

Pooled sensitivities and specificities of GGO on CT were 73% (71–80%, $I^2$ 96%) and 61% (41–78%, $I^2$ 94%) respectively. For GGO plus consolidation and consolidation only, the pooled sensitivities/ specificities were 58% (48–68%, $I^2$ 31%) / 58% (41–73%, $I^2$ 77%) and 49% (20–78%, $I^2$ 96%) / 56% (30–78%, $I^2$ 91%), respectively. The pooled diagnostic odds ratio of GGO, GGO plus consolidation, and consolidation only was 4.97 (2.36–10.35), 1.4 (0.99–1.97), and 0.82 (0.09–7.84), respectively. AUC for GGO was 0.728 compared with 0.575 for GGO plus consolidation and 0.472 for consolidation only (Figs. 3–5).

Table 2 shows the results of the pooled prevalence and diagnostic accuracy meta-analysis of CT findings. Table 3 shows the pooled prevalence of chest radiographic abnormalities.

4. Discussion

We reported a systematic review and meta-analysis of chest CT and radiographic findings in 5993 patients with COVID-19 pneumonia. We included 56 studies that reported the chest imaging findings at baseline. Besides evaluating the prevalence of various findings in COVID-19 pneumonia, we also conducted diagnostic accuracy meta-analysis for chest CT findings.

Table 3
Pooled prevalence of chest radiographic findings in COVID-19 pneumonia.

| Findings         | Pooled prevalence (95% CI) | $I^2$ |
|------------------|---------------------------|------|
| GGO              | 38.7% (22.2–58.3)         | 83%  |
| Consolidation    | 46.9% (29.7–64.9)         | 84%  |

GGO: ground glass opacity; CI: confidence interval.

GGO: ground glass opacity; CI: confidence interval, DOR: diagnostic odds ratio, AUC: area under the curve, *-Diagnostic accuracy meta-analysis not performed due to limited number of studies reporting these findings.

Fig. 5. Forest plots demonstrate the pooled sensitivity, specificity, diagnostic odds ratio and hROC of consolidation only on CT.
certain studies where the required data was available. We found that GGOs, GGO plus consolidation, and consolidation only were the frequent imaging findings in that order. The diagnostic odds ratio of GGO was the highest (4.97, 95% CI: 2.36–10.35) with the AUC of 0.728. Additionally, we found that on chest radiograph, consolidation was more frequently reported than GGOs (46.9%, 95% CI: 29.7–64.9% vs. 38.78%, 95% CI: 22.2–58.3%). Pooled prevalence of nodules, halo sign, crazy-paving, lymphadenopathy, and pleural effusion was also reported. Sensitivity, specificity, and diagnostic odds ratio could not be evaluated due to the paucity of studies specifically reporting these findings.

A few previous systematic reviews and meta-analyses have investigated the imaging findings in COVID-19 pneumonia. Among the specific imaging findings, GGOs was reported in 69.9% of the patients. The other commonly reported findings were “halo sign” (54.4%), air bronchogram (51.3%), bronchovascular bundle thickening (39.5%), grid form shadows (24.4%) and pleural effusion (18.5%). The bilateral findings were reported in 75.7% and unilateral findings in 23.4% of the included subjects. Some of the findings reported in this study e.g. grid form shadows and bronchovascular bundle thickening are not accepted as standard terminology and have not been recommended by the Radiological Society of North America expert consensus statement on reporting chest CT Findings related to COVID-19 [75].

In another systematic review and meta-analysis by Rodriguez-Morales et al., the imaging features were pooled from 10 studies [6]. The only specific imaging finding in this study was GGO reported in 68.5%. Unilateral and bilateral lung involvement was reported in 25% and 72.9%, respectively. The pooled prevalence of GGOs (66.9%) in our study was similar to the study by Rodriguez-Morales et al. However, bilateral involvement was less frequent in our study. Similarly, “halo sign” and pleural effusion was less frequent compared to the study by Cao et al. [14]. This difference is due to a greater number of studies as well as the exclusion of case reports and smaller case series in our meta-analysis. Another systematic review comprising 999 patients with COVID-19 pneumonia included 30 articles, most (21/30) of which were either case reports or small case series (<10 subjects). The screened articles were restricted to the earlier phase of the pandemic and included studies published in English language only. The largest included series comprised 167 patients. Like the other studies, GGO in the bilateral peripheral distribution was the most common findings. GGOs were reported in 88% of the patients with bilateral and peripheral distribution in 87.5% and 76%, respectively. This study did not report other findings, and meta-analysis was not performed. In the meta-analysis by Xu B et al., from 16 studies comprising 3186 patients was included. The authors reported the overall diagnostic accuracy of CT rather than the individual CT findings. The pooled sensitivity of CT was reported to be 92% while the pooled specificity was reported for only two studies (33% and 25%).

Our study is the one of the most updated and recent meta-analysis, including the studies published in English as well as non-English literature. We reported most of the findings recommended by the Radiological Society of North America in the context of COVID-19 pneumonia. We purposely excluded the case reports and smaller case series (<10 subjects) to avoid misinterpretation of the data. There were a few limitations to our study. First, we evaluated the findings of only the baseline CT scan and chest radiograph, and so could not assess the pattern of disease progression. However, the inclusion of a baseline CT scan matches well with the primary aim of our meta-analysis. Second, most of the studies were retrospective and included patients with varying degrees of disease severity. Thus, the results of our meta-analysis need to be reviewed carefully. Prospective and systematically conducted studies will strengthen our observations. However, considering the pandemic nature and global impact of this highly infectious viral disease, we believe that our results are timely and highly relevant despite these limitations.
