Kansai Rosai Hospital Cardiovascular Center, Amagasaki, Hyogo, Japan

Very late stent thrombosis (VLST) is a potentially life-threatening complication in coronary angioplasty patients. The patient was a 95-year-old man who had been implanted with a durable polymer everolimus-eluting stent (DP-EES, 3.5 × 23 mm) at the restenosis site in the proximal part of the left descending artery using only plain balloon angioplasty for acute coronary syndrome (ACS) 27 months earlier. Final intravascular ultrasound (IVUS) evaluation had shown no stent malapposition and adequate stent expansion. However, he presented to our hospital due to vomiting and fatigue 89 months after the implantation. An electrocardiogram showed ST-elevation in V2-6 leads, we therefore suspected ACS and emergent coronary angiography (CAG) revealed total occlusion of DP-EES site, which was diagnosed as VLST. Percutaneous coronary intervention (PCI) was subsequently carried out and complete recovery of blood flow was obtained by thrombus aspiration. Optical coherence tomography (OCT) demonstrated uncovered struts, stent malapposition, and some thrombi in the proximal part of DP-EES. Yellow chemogram was not detected in the DP-EES site by near-infrared spectroscopy (NIRS). Coronary angioscopy (CAS) showed exposed stent struts with red thrombus adhesion in the proximal part of the DP-EES. Judging from intravascular images, the main cause of VLST was stent malapposition and uncovered struts. Here, we report a case with VLST due to late acquired stent malapposition and uncovered struts 89 months after DP-EES implantation.

Key words: very late stent thrombosis, percutaneous coronary intervention, durable polymer drug-eluting stent, late acquired stent malapposition

Introduction

Very late stent thrombosis (VLST) is a rare but potentially life-threatening complication after stent implantation. The incidence of VLST after second-generation drug-eluting stent (DES) implantation has decreased compared with that of first-generation DES implantation. However, VLST remains a major concern in the clinical setting. In this report, we present a case with VLST 89 months after implantation of durable polymer everolimus-eluting stent (DP-EES) due to late acquired stent malapposition and uncovered struts observed by optical coherence tomography (OCT), near-infrared spectroscopy (NIRS), and angioscopy.

Case Presentation

A 95-year-old man was transferred to our hospital due to vomiting and fatigue. He had a medical history of hypertension and paroxysmal atrial fibrillation (PAF) with an episode of acute myocardial infarction (AMI) approximately 116 months earlier and had undergone percutaneous coronary intervention (PCI) for total occlusion of the proximal part of the left anterior descending artery (LAD) with
collaterals from the left circumflex artery (Fig. 1A). After balloon dilation, the lesion had not been sufficiently dilated due to a severely calcified plaque (Fig. 1B). Therefore, the procedure had been terminated without stent implantation because blood flow was deemed acceptable and there was a concern about stent underexpansion if a stent was implanted. Follow-up coronary angiography (CAG) 27 months after the initial PCI had demonstrated severe stenoses at the proximal and middle part of the LAD (Fig. 1C). Therefore, he underwent an additional PCI for these lesions. Because of severe calcification of the lesion, rotational atherectomy with a 1.5-mm burr and a 1.75-mm burr had been performed. After performing rotational atherectomy, one DP-EES (Xience™, 2.5 × 15 mm, Abbott Vascular, Abbott Park, IL, USA) had been implanted in the middle part of LAD and another DP-EES (PROMUS™, 3.5 × 23 mm, Boston Scientific Co., Marlborough, MA, USA) had been implanted in the proximal part of LAD. Finally, excellent blood flow had been achieved demonstrated by angiography (Fig. 1D). We judged that intravascular ultrasound (IVUS) evaluation had shown no major stent malapposition with adequate stent expansion, although we did not perform contrast IVUS, coronary angiography (CAS), or OCT at that time (Fig. 2A–E). After the second PCI, he was free from angina. Although the duration of dual antiplatelet therapy was unknown, it was switched to single anticoagulant therapy using edoxaban (30 mg/day) which was appropriate dose for this patient.

On this admission (present report), although the abdominal computed tomography findings had led to the diagnosis of acute cholecystitis by a gastroenterologist, he was transferred to cardiovascular center because the electrocardiogram on admission showed ST-elevation in V2-6 leads. Acute coronary syndrome (ACS) was suspected, and emergent CAG was conducted. Emergent CAG revealed total occlusion of the DP-EES site in the proximal part of LAD, which was diagnosed as VLST (Fig. 1E). PCI was subsequently carried out and complete recovery of blood flow was achieved after thrombus aspiration (Fig. 1F). On pathological evaluation, the aspirated matter was composed of

Fig. 2 Images of IVUS immediately after stent implantation and at the time of VLST. (A–E) Image of IVUS immediately after stent implantation. EEM areas were 25.68 mm², 25.32 mm², 27.52 mm², 26.58 mm², and 26.14 mm² at 2 mm, 4 mm, 6 mm, 8 mm, and 10 mm distal to the proximal edge of the DP-EES, respectively. (F–J) Image of IVUS at the time of VLST. EEM area were 24.44 mm², 24.55 mm², 26.37 mm², 26.05 mm², and 25.89 mm² at 2 mm, 4 mm, 6 mm, 8 mm, and 10 mm distal sites to the proximal edge of the DP-EES, respectively. DP-EES: durable polymer everolimus-eluting stent; EEM: external elastic membrane; IVUS: intravascular ultrasound; VLST: very late stent thrombosis

Fig. 3 Histopathology of aspirated materials. H & E stain of the aspirated materials showing fresh mixed fibrin thrombi without plaque, eosinophils, or cholesterol cleft.

Fresh platelet thrombi with fibrin and without plaque, eosinophil, or cholesterol cleft (Fig. 3). Then, we evaluated the DP-EES site in the proximal part of LAD using intravascular imaging devices. OCT demonstrated uncovered struts, stent malapposition, and some thrombi in the proximal part of DP-EES site (Figs. 4C and 4D), although OCT showed homogeneous neointima in the distal part of DP-EES site (Fig. 4E). Yellow chemogram which represents lipid was not detected by NIRS in the proximal and distal part of DP-EES site (Figs. 4F–H and 4L). CAS showed that stent struts were exposed with red thrombus adhesion in the proximal part of DP-EES site (Figs. 4I and 4J), while stent struts were embedded by the neointima in the distal part of DP-EES site (Fig. 4K). We completed the procedure because we acquired an excellent angiographic result after thrombus aspiration. After PCI, the peak values of creatine kinase (CK) and CK-MB were 4741 U/L and 400 U/L, respectively. Low-density lipoprotein cholesterol level was 55 mg/dL. Dual antiplatelet therapy with aspirin and prasugrel started in addition to anticoagulant therapy with edoxaban. Although he gradually recovered in the early days, his respiratory condition got worse drastically because of acute interstitial pneumonia 12 days after the hospitalization. Despite maximum support including steroid pulse therapy, the patient died due to respiratory failure 20 days after the hospitalization.

Discussion

Here, we reported a case with VLST occurring 89 months after implantation of DP-EES observed by OCT, NIRS, and CAS. Although there was a possibility of embolization due to PAF, the pathological evaluation of the aspirated thrombus demonstrated fresh platelet thrombus with fibrin, suggesting that the thrombus was organized in the coronary artery rather than thromboembolism.

Previous OCT reports showed that stent malapposition, neoatherosclerosis, and uncovered struts are the main causes of VLST. Although neoatherosclerosis could not be considered as the cause of VLST because yellow chemogram which represents lipid was not detected by NIRS although CAS showed light yellow plaque. Therefore, since
calcification is sometimes detected as yellow color by CAS, yellow plaque in Figs. 4I and 4J may be calcification. On the other hand, OCT demonstrated uncovered struts and stent malapposition, and some thrombi in the proximal part of DP-EES site (C and D), although OCT showed homogenous neointima in the distal part of DP-EES site (E). (F–H) Images of NIRS-IVUS. NIRS-IVUS showed no yellow chemogram in DP-EES site (F, G, and H). (I–K) Images of CAS. CAS showed that stent struts were exposed with red thrombus adhesion in the proximal part of DP-EES site (I and J), while stent struts were embedded by the neointima in the distal part of DP-EES site (K). (L) Chemogram of NIRS. Yellow chemogram was not detected.

CAG: coronary angiography; CAS: coronary angioscopy; DP-EES: durable polymer everolimus-eluting stent; OCT: optical coherence tomography; NIRS-IVUS: near-infrared spectroscopy intravascular ultrasound; PCI: percutaneous coronary intervention; VLST: very late stent thrombosis.
addition, if stent malapposition is observed in the chronic phase, it may be necessary to perform additional balloon dilation to obtain adequate stent apposition.
