(Dated: August 27, 2018)

The lacunar spinel GaV₄S₈ was recently suggested to be a prototype multiferroic material hosting skyrmion lattice states with a sizeable polarization \( P \) coupled to magnetic order. We explain this phenomenon on the microscopic level. On the basis of density functional theory, we construct an effective model describing the behavior of magnetically active electrons in a weakly coupled lattice formed by molecular orbitals of the \((\text{V}_4\text{S}_8)^{5+}\) clusters. By applying superexchange theory combined with the Berry-phase theory for \( P \), we derive a compass model relating the energy and polarization changes with the directions of spins \( e_i \) in magnetic bonds. We argue that, although each skyrmion layer is mainly formed by superexchange interactions in the same plane, the spin-dependence of \( P \) arises from the stacking misalignment of such planes in the perpendicular direction, which is inherent to the lacunar spinel structure. We predict a strong competition of isotropic, \( \sim e_i e_j \), and antisymmetric \( \sim e_i \times e_j \), contributions to \( P \) that explains the experimentally observed effect.

\[ P \sim \text{compass model} \]

**Introduction.** In recent years, magnetic skyrmions [1, 2], topologically protected spin textures, have attracted high levels of interest due to their various potentials in the emerging field of spintronics [3]. In most cases, they are stabilized by Dzyaloshinskii-Moriya (DM) interactions in compounds in which inversion symmetry is macroscopically broken [4, 5]. Owing to their topology and nanometer-size, skyrmions behave like particle objects that can be moved over macroscopic distances by applying low-density electric currents [6, 7] making them suitable candidates for applications in low-power nanoelectronics and data storage [8].

Skyrmionic states have been theoretically predicted to occur in crystals belonging to certain crystallographic classes, which can be either polar or non-polar [1]. Being mostly observed in non-polar chiral structures, skyrmions in polar crystals are also of great interest due to their interplay with electric polarization, giving rise to fascinating multiferroic properties. Until recently, Cu₂OSeO₃ was the only known multiferroic material hosting a skyrmionic state [9, 10]. Shortly after its first observation, an electric-field control of the skyrmion lattice in Cu₂OSeO₃ has been reported indicating that many emergent properties of the skyrmion state can be tailored to the properties of a host material [11, 12]. Overall, multiferroicity may give rise to many new prospects in a non-dissipative electric-field control of magnetic objects, and the existence of skyrmionic states in insulating magneto-electric materials holds many potential applications for new-generation electronic devices.

Recently, a novel host material has been reported to exhibit these properties [13]. GaV₄S₈ is a member of the lacunar spinel family with a non-centrosymmetric non-polar cubic \( F43m \) structure, with which at 38 K undergoes a structural transition to the polar rhombohedral \( R3m \) phase [14], giving rise to the ferroelectric polarization \( \sim 6000 \ \mu C/m^2 \) along the rhombohedral direction \( z \parallel [111] \) [15]. A complex phase diagram comprising paramagnetic, ferromagnetic, skyrmion and cycloidal states has been demonstrated, where the spin-driven excess polarization was assigned in each magnetic phase with the total value of \( \sim 100 \ \mu C/m^2 \), which is almost two orders of magnitude larger than that of Cu₂OSeO₃ [15].

The existence of multiple ferroelectric phases in GaV₄S₈ indicates a complex interplay of charge, spin, and lattice degrees of freedom making their theoretical description extremely important. Nevertheless, a rigorous theory of magneto-electric coupling in skyrmion materials is lacking. It remains largely unknown what mechanisms are responsible for this coupling, what aspects of the crystal structure play an essential role and how a spin texture contributes to electric polarization in each ferroelectric phase. Thus, the purpose of this Letter is to fill this gap and explain the multiferroic properties of GaV₄S₈ on a microscopic level, through the rigorous Berry-phase theory of electric polarization combined with a realistic modeling approach.

**Electronic model.** According to electronic structure calculations within local-density approximation (LDA) [16], as implemented in the VASP [17] and Quantum-ESPRESSO [18] packages, the group of bands near the Fermi level is dominated by the V 3\( d \) states (Fig. 1a), which strongly hybridize within each of the \((\text{V}_4\text{S}_8)^{5+}\) cluster, thus forming the molecular-type orbitals. The hybridization between these molecular orbitals is considerably weak and leads to the weakly dispersive bands. In the \( F43m \) phase, the molecular states belong to the \( a'_{1} \), \( e' \) and \( t_2 \) representations and are filled with seven electrons. Thus, the low-lying \( a'_{1} \) and \( e' \) states are double-occupied and do not contribute to magnetism, while the highest 3-fold degenerate \( t_2 \) level accommodates one unpaired electron. The rhombohedral distortion in the \( R3m \) phase lifts the degeneracy of the \( t_2 \) level splitting it into a single \( a_1 \) and 2-fold degenerate \( e \) states.

[arXiv:1808.08008v1 [cond-mat.str-el] 24 Aug 2018]
FIG. 1. a) Bands located near the Fermi level as calculated within LDA including spin-orbit coupling for the low-temperature GaV$_4$S$_8$. b) Wannier functions representing the high-lying $a_1$ and $e$ states; c) Density of states as obtained from LDA and Hartree-Fock calculations; d) Schematic view of the V$_4$ clusters with nearest neighbors.

Carrying a local $S = \frac{1}{2}$ moment, the (V$_4$S$_4$)$_{5+}$ clusters can be regarded as magnetic building blocks, and the corresponding molecular $a_1 \oplus e$ orbitals associated with the lattice of the V$_4$ tetrahedra can be chosen as a proper basis for the low-energy electronic model. In this regard, conventional band-structure methods may fail to properly include the electronic correlations between these composite molecular orbitals. Moreover, the complexity of skyrmion lattices, including hundreds of magnetic sites, is beyond the current abilities of ab-initio methods, is beyond the current abilities of ab-initio methods. In this regard, conventional band-structure methods may fail to properly include the electronic correlations between these composite molecular orbitals. Moreover, the complexity of skyrmion lattices, including hundreds of magnetic sites, is beyond the current abilities of ab-initio methods. Thus, our first goal is to construct an effective Hubbard-type model while taking the full advantage of ab-initio calculations in the Wannier basis

\[ \hat{H}^{el} = \hat{H}_{kin} + \hat{H}_{CF} + \hat{H}_{SO} + \hat{H}_U. \]  

The kinetic energy, \( \hat{H}_{kin} = \sum_{i \neq j} \sum_{a \sigma} \epsilon_{ia}^a c_{ia}^\dagger c_{ia} \), crystal-field splitting, \( \hat{H}_{CF} = \sum_{i,a \sigma} \Delta \epsilon_{ia}^a c_{ia}^\dagger c_{ia} \), and spin-orbit coupling (SOC) terms are identified through the matrix elements of LDA Hamiltonian in the basis of molecular-type Wannier orbitals [19, 20]; \( \epsilon_{ia}^a \) are the corresponding creation (annihilation) operators of an electron with spin \( \sigma \) at site \( i \) and orbital \( a \) (\( a = 1 \) stands for the \( a_1 \) and \( d_{xy} \) orbital, and \( a = 2 \) and \( 3 \) stand for, respectively, \( e = d_{xy} \) and \( d_{x^2-y^2} \) orbitals, carrying also some weight of the \( yz \) and \( xz \) symmetry [21], as shown in Fig. 1b).

The full set of model parameters is presented in Supplemental Material [22]. The polar rhombohedral distortion gives rise to the crystal-field splitting \( \Delta = 98.1 \) meV. The site-diagonal part of \( \hat{H}_{SO} \) includes a conventional “spherical” term and the Rashba-type (R) contribution arising from the distortion, \( \hat{H}_{SO} = \zeta_{SO} \sum_i \mathbf{S}_i \cdot \hat{S}_i - \zeta_{SO}^R \sum_i \left( \hat{L}_i^x \hat{S}_i^z + \hat{L}_i^z \hat{S}_i^x \right) \), where the angular momentum operator is given in a compact form in terms of the antisymmetric Levi-Civita symbol as \( \hat{L}_i^a)^{ab} = -i \epsilon_{2ab} \), \( \hat{L}_i^y)^{ab} = -i \epsilon_{3ab} \), and \( \hat{L}_i^z)^{ab} = \epsilon_{1ab} \), and the calculated SOC constants are \( \zeta_{SO} = 23.0 \) meV and \( \zeta_{SO}^R = 1.3 \) meV. The superexchange theory (SE) utilizes only those hopping parameters that involve the occupied \( a_1 \) orbital, \( \hat{t}_{ij} = (t_{1ij}^1, t_{1ij}^2, t_{1ij}^3) \). For the in-plane bonds (\( j = 1-6 \) in Fig. 1d) these parameters are given by \( \hat{t}_{ij} = \left( -1 \right)^j |t_{ij}^1| \left( 0, \sin \frac{\theta_j}{2}, \cos \frac{\theta_j}{2} \right) + |t_{ij}^3| \left( \frac{\pi}{4}, \theta_j, \cos \frac{\theta_j}{2}, -\sin \frac{\theta_j}{2} \right) \), where \( t_{ij}^S = -25 \) meV and \( t_{ij}^A = -16 \) meV stand for symmetric and antisymmetric parts, respectively, and \( \theta_j = 0.25 \). For the out-of-plane bonds (\( j = 1'-6' \) in Fig. 1d) we have \( \hat{t}_{ij} = \left( -1 \right)^j |t_{ij}^1| \left( 0, -\sin \frac{\theta_j}{2}, \cos \frac{\theta_j}{2} \right) + \left| t_{ij}^3 \right| \left( \frac{\pi}{4}, \theta_j, -\sin \frac{\theta_j}{2}, \cos \frac{\theta_j}{2} \right) \), where \( t_{ij}^{S'} = -23 \) meV, \( t_{ij}^{A'} = -22 \) meV, and \( \theta_j = 0.15 \). Finally, the screened on-site Coulomb interactions

\[ \hat{H}_U = \frac{1}{2} \sum_{i} \sum_{\sigma \sigma'} \sum_{a b c d} U_{abcd} \epsilon_{ia}^a \epsilon_{ib}^b \epsilon_{ic}^c \epsilon_{id}^d \epsilon_{ia}^\dagger \epsilon_{ib}^\dagger \epsilon_{ic}^\dagger \epsilon_{id}^\dagger, \]  

were evaluated by using constrained random-phase approximation (cRPA) [23]. The fitting of \( U \) in terms of Kanamori parameters [24] yields the intraorbital Coulomb interaction \( U = 0.86 \) eV and the exchange interaction \( J = 0.09 \) eV. These values are not particularly strong because the molecular \( t_2 \) orbitals are rather extended in space considerably reducing the bare interactions compared to their regular atomic values. Furthermore, the bare interactions are efficiently screened in cRPA due to proximity of the target \( t_2 \) bands to the occupied \( a_1 \) and \( e' \) bands of the same \( V 3d \) character [25]. Nevertheless, the Coulomb \( U \) remains the largest parameter of the model that justifies the use of SE theory for the construction of the spin model in the limit \( \hat{t}_{ij} < U \) [26].

The electronic model (1) can be solved in the mean-field Hartree-Fock approximation [25], and the FM state with the indirect band gap of 0.15 eV is found to be the ground state for the low-temperature phase of GaV$_4$S$_8$ (Fig. 1c). Given the large hopping parameters between occupied \( a_1 \) and empty \( e \) states, the FM ground state is also favoured by the Goodenough-Kanamori rule [27, 28].

**Spin model.** In the atomic limit, a single \( t_2 \) electron resides at the lowest Kramers doublet of \( \hat{H}_{CF} + \hat{H}_{SO} \). The corresponding Wannier function at site \( i \), \( \left| w_i \right> \propto \left| \alpha_i \right> \), specifies the direction of spin as \( e_i = \left\langle \alpha_i \left| \sigma \right| \alpha_i \right\rangle / \left\langle \alpha_i \left| \alpha_i \right\rangle \right\rangle \). The inclusion of \( \hat{t}_{ij} \) will induce the tails \( \left| \alpha_{i \rightarrow j} \right> \) of \( \left| w_i \right> \) spreading to neighboring sites \( j \)

\[ \left| w_i \right> \approx \left| \alpha_i \right> + \left| \alpha_{i \rightarrow j} \right>, \]  

which can be evaluated to first order in \( \hat{t}_{ij} \) as \( \left| \alpha_{i \rightarrow j} \right> = \hat{M}_j \hat{t}_{ij} \left| \alpha_i \right> \), where

\[ \hat{M}_j = \sum_M \frac{\hat{P}_j \left< j \right| \hat{M}_j \left| j \right> \hat{P}_j}{E_{jM}}. \]

\( E_{jM} \) and \( \left| j \right> \) are, respectively, eigenvalues and eigenfunctions of the excited two-electron states at site \( j \),
given by $\hat{H}_{\text{CF}} + \hat{H}_{\text{SO}} + \hat{H}_{U}$, and $\hat{P}_j$ is the projector operator in the form of two-electron Slater determinants, constructed from the occupied orbital $|\alpha_j\rangle$ and basis orbitals at site $j$, thus enforcing the Pauli principle [29, 30]. Then, the kinetic energy gain can be expressed as $E_{\text{kin}} = \sum_{(ij)} (\langle \alpha_i | \hat{t}_{ij} | \alpha_j \rangle + i \leftrightarrow j)$. By considering all possible combinations of $|\alpha_i\rangle$ and $|\alpha_j\rangle$, corresponding to $x$, $y$, and $z$ directions of spins at sites $i$ and $j$, $E_{\text{kin}}$ can be mapped onto the spin model $\mathcal{H}^S = \sum_{(ij)} e_i \hat{S}_{ij} e_j$, which is further rearranged as

$$\mathcal{H}^S = \sum_{(ij)} \left(-J_{ij} e_i e_j + D_{ij} e_i \cdot e_j + e_i \hat{\Gamma}_{ij} e_j\right),$$  \hspace{1cm} (4)$$

in terms of the isotropic exchange constants $J_{ij}$, antisymmetric DM vectors $D_{ij}$, and the traceless symmetric anisotropic tensors $\hat{\Gamma}_{ij}$. Using parameters of the electronic model (1), we obtain: $J_{ij} = 0.180$ meV and $J_{ij} = 0.217$ meV for the nearest-neighbor in-plane ($j = 1$-6 in Fig. 1d) and out-of-plane ($j = 1'$-6') interactions, respectively. The corresponding Curie temperature $T_C \approx 10$ K estimated in random phase approximation [31] is close to the experimental value of 13 K. The resulting DM interactions can be written in a compact form as $D_{0j} = d_{||}(\sin \frac{\pi}{3}, \cos \frac{\pi}{3}, (1)^J\delta)$ for $j = 1$-6, where $d_{||} = 0.073$ meV and $\delta = 0.137$, and $D_{0j} = d_{||}(\cos \frac{\pi}{3}, \sin \frac{\pi}{3}, 0)$ for $j = 1'$-6', where $d_{||} = 0.057$ meV. The parameters of $\hat{\Gamma}_{ij}$ are found to be small and do not play a decisive role [22].

**Electric polarization.** Such theory of SE interactions is well established and constitutes the basis of the so-called anisotropic compass model for electric polarization. The rigorous Berry-phase theory relates the polarization change with expectation values of the position operator, calculated in the Wannier functions basis for the occupied states [33]

$$P = -\frac{e}{V} \sum_{i} \langle w_i | r | w_i \rangle,$$  \hspace{1cm} (5)$$

where $-e$ and $V$ is the electron charge and the unit cell volume, respectively. By this definition, all spin dependencies of $P$ are incorporated in $|w_i\rangle$, so one needs to evaluate the change in the distribution of $|w_i\rangle$ caused by the change of magnetic order. In the lattice model, this change can be described by the tails of Wannier functions, $|\alpha_{i-\alpha}\rangle$, spreading to neighboring sites. Then, substituting Eq. (3) in Eq. (5), electric polarization can be expressed as a sum of bond contributions

$$P = \sum_{(ij)} P_{ij},$$

where

$$P_{ij} = \frac{e}{V} \tau_{ji} \left(\langle \alpha_{j-\alpha_i} | \alpha_{j-i} \rangle - \langle \alpha_{i-\alpha} | \alpha_{i-j} \rangle\right),$$  \hspace{1cm} (6)$$

and $\tau_{ji} = R_j - R_i$ is the bond vector connecting neighbouring sites [35–37]. The quantity $\langle \alpha_{i-\alpha} | \alpha_{i-j} \rangle$, which is nothing else but the Wannier weight transfer from site $i$ to site $j$, can be obtained in the framework of SE theory as $\langle \alpha_{i-j} | \alpha_{i-\alpha} \rangle = \langle \alpha_{i-j} | \mathcal{M}^2_{ij} | \alpha_{i} \rangle$. By considering different combinations of $|\alpha_i\rangle$ and $|\alpha_j\rangle$, the spin-driven part of electric polarization can be written as

$$P = \sum_{(ij)} e_{ij} \left(\epsilon_i \hat{\sigma}_{ij} e_j\right)$$

or

$$P = \sum_{(ij)} e_{ij} \left(P_{ij} e_i e_j + \mathcal{P}_{ij} e_i \times e_j + e_i \hat{\Pi}_{ij} e_j\right),$$  \hspace{1cm} (7)$$

where $e_{ij} = \tau_{ji}/|\tau_{ji}|$. This is an analogue of Eq. (4), where $e_{ij} P_{ij}$, $e_{ij} \mathcal{P}_{ij}$, and $e_{ij} \hat{\Pi}_{ij}$ stand for isotropic, antisymmetric, and anisotropic symmetric contributions, respectively [38]. Importantly, since $P_{ij} \parallel e_{ij}$, only the out-of-plane bonds can contribute to the polarization change along $z$.

In order to clarify the microscopic origin of electric polarization in GaV$_2$S$_8$, it is useful to consider an analytical expression for $P_{ij}$, which can be easily obtained in the absence of SOC. To first order in $J/(U + \Delta)$, it yields [22]:

$$P_{ij} \approx (e \tau_{ji}/V) T_{ij} / (U + \Delta),$$

where $T_{ij} = \Delta (t_{ij}^2 + (t_{ij}^3)^2 - (t_{ij}^1)^2 - (t_{ij}^2)^2)$ is the antisymmetric tensor $(\hat{T}_{ij} = -\hat{T}_{ji})$. Thus, in order to have finite $P_{ij}$, it is essential that (i) the Hund’s rule coupling $J$ should be finite; and (ii) inversion symmetry of the bond connecting neighbouring sites $i$ and $j$ should be crystallographically broken (otherwise, $T_{ij} = T_{ji}$ and, therefore, $T_{ij} = 0$, as indeed happens in the high-temperature $F4\bar{3}m$ phase). These two properties hold even in the presence of SOC. Particularly, if $J = 0$, the entire tensor $\mathcal{P}_{ij}$ is identical to zero, as confirmed by our calculations. Furthermore, for equivalent bonds in the positive (+) and negative (−) directions of $z$, we have $T = -T^*$, which is the direct consequence of translational invariance and the antisymmetry of $T_{ij}$. In combination with $e_{ij} = -e_{ij}$, it results in a finite contribution to $P$.

The calculated parameters for $j = 1'$-6' are $P_{0j} = (1)^{-1}P_{\perp}$ and $\mathcal{P}_{0j} = (-1)^{j}P_{\perp}$, where $P_{\perp} = -362 \mu$C/m$^2$ and $p_{\perp} = 41 \mu$C/m$^2$. As we will see below, they are mainly responsible for the magnetic state dependence of $P^z$. The corresponding polarization in the FM phase is calculated from Eq. (7) as $P^z = 3\epsilon_{0\perp} P_{\perp} = 889 \mu$C/m$^2$ (where $\epsilon_{0\perp} = 0.819$ [14]), while its thermal average in the paramagnetic state yields $P^z = 0$. As a result, we expect a large spin-driven excess polarization in the FM phase. The effect is very generic and can readily take place in other polar magnets [39, 40]. For the in-plane bonds $j = 1$-6, we have $P_{||} = 0$ and $\mathcal{P}_{0j} = (-1)^{j}p_{\parallel} \cos (\pi \frac{a}{3} - \sin \frac{\pi}{3}, 0)$, where $p_{\parallel} = 30 \mu$C/m$^2$. Since $\epsilon_{0\perp} = 0$, these bonds do not contribute to $P^z$. Nevertheless, $p_{\parallel}$ can give rise to small $P^{z-g}$, provided that the symmetry is lowered by magnetic order, as in the proper-screw spin spiral [35, 41]. Finally, in the multidomain samples [13] the value of $P^z$ will be deteriorated: in the domains [111], [111], and
[\{\bar{1}11\}], \textbf{P} is parallel to the corresponding rhombohedral axes, whose \(z\) component is opposite to the one of the main domain [111]. Moreover, since \(P_1 = 0\), there are no other contributions to \(P^z\) coming from the domains [111], [\{\bar{1}11\}], and [1\bar{1}1]. This can explain a relatively small value of spin-driven polarization (\(\sim 100 \mu C/m^2\)) observed experimentally [15], in comparison with the results of our theoretical calculations.

**Phase diagram.** We perform classical Monte-Carlo calculations for the spin model (4) with an applied magnetic field \(h \parallel z\) by using a heat-bath algorithm combined with overrelaxation [22, 42]. The results shown in Fig. 2a nicely reproduce the main sequence of cycloidal \(\rightarrow\) skyrmionic \(\rightarrow\) FM states in the phase diagram of GaV\(_4\)S\(_8\) with the increase of \(h\) [15]. Furthermore, in the cycloidal and skyrmion phases, the two-dimensional spin patterns in the \(xy\) plane tend to stack ferromagnetically along \(z\), that is naturally explained by the FM coupling \(J_{\perp}\). However, in the GaV\(_4\)S\(_8\) structure, this stacking is misaligned by the rhombohedral translations, so that the adjacent skyrmionic layers experience an additional shift in the \(xy\) plane. Therefore, there will always be some noncollinearity of spins between the adjacent layers, which according to Eq. (7) will contribute to the spin-excess polarization.

In order to describe this effect quantitatively, we evaluate the total and partial contributions to \(P^z\) by using Eq. (7) and the distribution of spins \(\{e_i\}\) obtained in Monte-Carlo calculations. The results are summarized in Fig. 2c. Particularly, we note a strong competition of the isotropic (\(\sim e_i e_j\)) and antisymmetric (\(\sim e_i \times e_j\)) contributions, while the anisotropic symmetric part (\(\sim e_i \vec{\Pi}_{ij} e_j\)) is negligibly small. As expected, the antisymmetric contribution decreases with the increase of \(h\) and vanishes in the collinear FM state. On the contrary, the isotropic contribution takes its maximal value in the FM state and is further reduced by a noncollinear alignment of spins. Since the change of \(e_i \times e_j\) and \(e_i e_j\) is proportional to \(\phi_{ij}\) and \(\phi_{ij}^2\), respectively (with \(\phi_{ij}\) being the angle between \(e_i\) and \(e_j\), which is induced by DM interactions and proportional to \(\zeta_{SO}\)), both the isotropic and antisymmetric mechanisms are of the 2nd order in \(\zeta_{SO}\), while the change of \(e_i \vec{\Pi}_{ij} e_j\) is only of the 3rd order. This naturally explains the hierarchy of partial contributions to \(\Delta P^z\) in Fig. 2c. Furthermore, the antisymmetric mechanism dominates when the skyrmions are large and the spin texture slowly varies in space. In this region, electric polarization decreases with \(h\), in agreement with the experimental observation [15]. The corresponding polarization change of about 4 \(\mu C/m^2\) is also consistent with the experimental data [15]. Finally, our conclusion clearly differs from the phenomenological analysis presented in [15], arguing that the antisymmetric DM interactions are solely needed to stabilize the cycloidal and skyrmion phases, while the corresponding polarization change is driven by the isotropic and anisotropic symmetric terms. In fact, we also expect a small region in the phase diagram, where the magnetization is nearly saturated (Fig. 2b) and the skyrmion size is small, so the polarization change is mainly governed by the isotropic mechanism and is expected to increase with \(h\). Overall, the \(h\)-dependence of spin-driven polarization in the skyrmion phase depends on the skyrmion size and the way a skyrmion lattice is packed leading to different competing scenarios.

**Conclusion.** We have presented the microscopic theory of spin-driven electric polarization in GaV\(_4\)S\(_8\). Based on the realistic model derived from first-principles electronic structure calculations, we have shown that the spin-excess polarization along the rhombohedral \(z\) axis associated with the ferromagnetic, skyrmionic and cycloidal states, is given by the interlayer electron transfer and originates from the strongly competing isotropic and antisymmetric contributions. The proposed theory is very general and can be applied to other multiferroic materials, including those hosting skyrmionic states.

FIG. 1. Crystal structure of GaV$_4$S$_8$ visualised by VESTA software [1]: a) unit cell, and b,c) planes along the [111] direction.

FIRST-PRINCIPLES CALCULATIONS

In our studies, we adopt the experimental crystallographic data of GaV$_4$S$_8$ shown in Table I and Fig. 1. Electronic structure calculations were performed within the conventional local-density approximation (LDA) [2] and projected augmented wave [3] formalisms, as implemented in the Vienna ab-initio simulation package (VASP) [4]. Band structure calculations including spin-orbit coupling (LDA+SO) were carried out by using norm-conserving pseudopotentials as implemented in the Quantum-ESPRESSO package (QE) [5]. The plane wave cutoff was set to 1360 eV, the Brillouin zone was sampled by a 16×16×16 Monkhorst-Pack k-point mesh [6], and the convergence criteria for the total energy calculations was 10$^{-9}$ eV. To calculate hopping parameters, we employed the maximally localized Wannier functions as implemented in the Wannier90 package [7, 8]. The resulting electronic structures and model parameters calculated in VASP and QE without spin-orbit coupling are in good agreement.

The on-site Coulomb parameters were calculated within constrained random-phase approximation defined in the Wannier functions basis [9, 10]:

$$U_i^{\alpha\beta\gamma\delta} = \int dr dr' w_i^\alpha(r) w_i^\beta(r) U(r, r') w_i^\gamma(r') w_i^\delta(r') = \langle w_i^\alpha w_i^\gamma | U | w_i^\beta w_i^\delta \rangle,$$

where the Greek superscript takes on the number of orbitals. Here, $U(r, r')$ is the partially screened Coulomb interaction for the target bands comprising the low-energy model:

$$U = W(1 + P_d W)^{-1}$$

and

$$W = (1 - \nu P)^{-1} \nu,$$

where $\nu$ and $W$ are the bare and fully screened Coulomb interactions, respectively; $P$ is the total polarization including transitions between all states $\{\psi_i, \varepsilon_i\}$:

$$P(r, r') = 2 \sum_{n \text{occ}} \sum_{n' \text{unocc}} \psi_n^*(r) \psi_{n'}(r) \psi_{n'}^*(r') \psi_n(r') \left\{ \frac{1}{\varepsilon_n - \varepsilon_{n'} + i\delta} - \frac{1}{\varepsilon_{n'} - \varepsilon_n - i\delta} \right\}$$
that can be further divided into $P = P_r + P_d$, so that $P_d$ includes only transitions between the target bands, and $P_r$ is the rest of the polarization. This method was implemented in VASP.

**EFFECTIVE ELECTRONIC MODEL**

The nonmagnetic electronic band structures calculated for the high- and low-temperature phases of GaV$_4$S$_8$ are presented in Fig. 2a. The group of bands located near the Fermi level is dominated by metal-metal bonding states of the V$_4$ cluster generated by the V 3$d$ orbitals. In the high-temperature cubic phase (point group $T_d$), these states are split into $a_1$, $e$ and $t_2$ levels filled with seven electrons in such a way that the highest 3-fold degenerate $t_2$ level contains one unpaired electron. At 38 K GaV$_4$S$_8$ undergoes a cubic-to-rhombohedral structural phase transition driven by the cooperative Jahn-Teller distortion [11] which lifts the degeneracy of the $t_2$ level and splits it into a low-lying single $a_1$ and double degenerate $e$ states (point group $C_{3v}$), as shown in Fig. 2b. Since each V$_4$ cluster carries a local moment $S = 1/2$ formed by three bands located near the Fermi level, these states can be chosen as a basis for the effective low-energy model to describe magnetic properties of GaV$_4$S$_8$. The corresponding Wannier functions obtained by projecting these states onto atomic-like orbitals are shown in Fig. 2c. As seen, the resulting Wannier functions are well defined and localized, but have a complicated structure representing metal-metal bonding in the V$_4$ cluster.

For the high-temperature phase, the effective Hubbard-type model can be constructed in the following way:

\[
\hat{H}_{HT} = \hat{H}_{\text{kin}} + \hat{H}_{SO} + \hat{H}_U, \tag{5}
\]

the hopping parameters and spin-orbit coupling are given by:

\[
\hat{H}_{\text{kin}} = \sum_{\langle ij \rangle \atop mm', \sigma} t_{ij}^{mm'} c_{im}^{\dagger \sigma} c_{jm'}^{\sigma}, \tag{6}
\]

and

\[
\hat{H}_{SO} = \frac{\zeta_{SO}}{2} \sum_{i,mm'\sigma\sigma'} c_{im}^{\dagger \sigma} \left( \begin{array}{ccc} 0 & -i\sigma_z & i\sigma_x \\ i\sigma_z & 0 & -i\sigma_y \\ -i\sigma_x & i\sigma_y & 0 \end{array} \right) c_{im'}^{\sigma}, \tag{7}
\]

respectively. Here, $c_{im}^{\dagger \sigma}$($c_{im}^{\sigma}$) is the creation (annihilation) operator of an electron with spin $\sigma$ at site $i$, $m$ is the orbital index in the following order $\{d_{xy}, d_{yz}, d_{xz}\}$; $t_{ij}^{mm'}$ is the hopping parameter, and $\zeta_{SO}$ is the spin-orbit coupling...
FIG. 2. a) Bands located near the Fermi level as obtained from LDA and LDA+SO calculations for the high-temperature \( F\bar{4}3m \) (left) and low-temperature \( R3m \) (right) phases of GaV\(_4\)S\(_8\); b) Crystal-field splitting of molecular orbitals in the V\(_4\) cluster; c) Wannier functions as obtained from LDA calculations for the high-temperature \( F\bar{4}3m \) (up) and low-temperature \( R3m \) (down) phases of GaV\(_4\)S\(_8\). Coordinates of the high-symmetry \( k \)-points are W = (1/4, 3/4, 1/2), L = (1/2, 1/2, 1/2), X = (0, 1/2, 1/2), and K = (3/8, 3/4, 3/8) for the \( F\bar{4}3m \) space group, and Z = (1/2, 1/2, 1/2), F = (1/2, 1/2, 0), and L = (1/2, 0, 0) for the \( R3m \) space group.

For the cubic symmetry, the on-site Coulomb interactions can be parametrized in the Hubbard-Kanamori form [12]:

\[
\hat{H}_U = \sum_{i,m} U \hat{n}_{im}^\sigma \hat{n}_{im}^{\bar{\sigma}} + \sum_{i,(mm')\sigma} (U - 2J) \hat{n}_{im}^\sigma \hat{n}_{im'}^{\bar{\sigma}} + (U - 3J) \hat{n}_{im}^\sigma \hat{n}_{im'}^\sigma,
\]

where \( \hat{n}_{im}^\sigma = \hat{c}_{im}^{\dagger \sigma} \hat{c}_{im}^{\sigma} \) is the density operator, \( U \) and \( U' \) are the intraorbital and interorbital Coulomb interactions, respectively, and \( J \) is the interorbital exchange interaction.
TABLE II. Nearest neighbour hopping parameters (in meV) calculated for the \( t_2 \) model of the high-temperature \( F\bar{4}3m \) \( GaV_4S_8 \).

The corresponding lattice translations are \( a_1 = a(1, 1, 0) \), \( a_2 = a(1, 0, -1) \), and \( a_3 = a(0, 1, -1) \), where \( a = 4.8305 \text{ Å} \).

\[
\begin{align*}
\hat{t}_{011} &= \begin{pmatrix} 18.06 & 7.42 & -13.96 \\ 7.42 & 18.06 & 13.96 \\ 13.96 & -13.96 & -36.37 \end{pmatrix}, & \hat{t}_{011} &= \begin{pmatrix} 18.06 & 7.42 & 13.96 \\ 7.42 & 18.06 & -13.96 \\ -13.96 & 13.96 & -36.37 \end{pmatrix}, & \hat{t}_{110} &= \begin{pmatrix} 18.06 & -13.96 & -7.42 \\ -13.96 & 18.06 & -13.96 \\ -7.42 & 13.96 & 18.06 \end{pmatrix}, \\
\hat{t}_{110} &= \begin{pmatrix} 18.06 & -13.96 & 7.42 \\ -13.96 & 18.06 & 7.42 \\ -7.42 & 13.96 & 18.06 \end{pmatrix}, & \hat{t}_{010} &= \begin{pmatrix} -36.37 & 13.96 & -13.96 \\ 13.96 & 18.06 & 7.42 \\ 13.96 & 7.42 & 18.06 \end{pmatrix}, & \hat{t}_{001} &= \begin{pmatrix} 18.06 & -13.96 & 7.42 \\ -13.96 & 18.06 & 7.42 \\ -7.42 & 13.96 & 18.06 \end{pmatrix}, \\
\hat{t}_{001} &= \begin{pmatrix} 18.06 & 7.42 & 13.96 \\ 7.42 & 13.96 & 18.06 \end{pmatrix}, & \hat{t}_{100} &= \begin{pmatrix} 18.06 & -7.42 & -13.96 \\ -7.42 & 18.06 & -13.96 \\ 13.96 & 13.96 & -36.37 \end{pmatrix}, & \hat{t}_{100} &= \begin{pmatrix} 18.06 & -7.42 & 13.96 \\ -7.42 & 18.06 & 13.96 \\ 13.96 & 13.96 & -36.37 \end{pmatrix}.
\end{align*}
\]

\[
U = \frac{1}{N} \sum_{m=1}^{N-3} U_{mmm'm'},
\]

\[
U' = \frac{1}{N(N-1)} \sum_{m \neq m'}^{N-3} U_{mmm'm'},
\]

\[
J = \frac{1}{N(N-1)} \sum_{m \neq m'}^{N-3} U_{mm'm'm'},
\]

and \( U' = U - 2J \). Here, we neglect the spin-flip and pair-hopping interactions on account of their smallness. The calculated hopping parameters and Coulomb interactions for the high-temperature phase are given in Tables II and IV, respectively. The calculated value for the spin-orbit coupling parameter is \( \zeta_{SO} = 22.6 \text{ meV} \).

The corresponding Hubbard-type model for the \( a_1 \oplus e \) states of the low-temperature phase has the following form:

\[
\hat{H}_{LT} = \hat{H}_{\text{kin}} + \hat{H}_{\text{CF}} + \hat{H}_{\text{SO}} + \hat{H}_U,
\]

the hopping parameters and crystal-field splitting are given by:

\[
\hat{H}_{\text{kin}} = \sum_{ij \leftarrow \rightarrow \sigma \leftarrow \sigma} t_{ij}^{mm'} c_{im}^{\sigma} c_{jm}^{\sigma},
\]

and

\[
\hat{H}_{\text{CF}} = \sum_{i, m \in \sigma} \Delta_i c_{im}^{\sigma} c_{im}^{\sigma}.
\]
TABLE III. Coulomb interaction parameters (in eV) calculated for the \( t_2 \) model of the high-temperature \( F\bar{4}3m \) GaV\(_4\)S\(_8\).

|                  | Bare Coulomb | Fully screened Coulomb | Partially screened Coulomb |
|------------------|-------------|------------------------|---------------------------|
| \( v^{mmm'm'} \) | \( \begin{pmatrix} 6.905 & 6.680 & 6.680 \\ 6.680 & 6.905 & 6.680 \\ 6.680 & 6.680 & 6.905 \end{pmatrix} \) | \( \begin{pmatrix} 0.176 & 0.046 & 0.046 \\ 0.046 & 0.176 & 0.046 \\ 0.046 & 0.046 & 0.176 \end{pmatrix} \) | \( \begin{pmatrix} 0.684 & 0.509 & 0.509 \\ 0.509 & 0.684 & 0.509 \\ 0.509 & 0.509 & 0.684 \end{pmatrix} \) |
| \( v^{mmm'm'm} \) | \( \begin{pmatrix} 6.905 & 0.235 & 0.235 \\ 0.235 & 6.905 & 0.235 \\ 0.235 & 0.235 & 6.905 \end{pmatrix} \) | \( \begin{pmatrix} 0.176 & 0.065 & 0.065 \\ 0.065 & 0.176 & 0.065 \\ 0.065 & 0.065 & 0.176 \end{pmatrix} \) | \( \begin{pmatrix} 0.684 & 0.087 & 0.087 \\ 0.087 & 0.684 & 0.087 \\ 0.087 & 0.087 & 0.684 \end{pmatrix} \) |
| \( v^{mmm'm'm'} \) | \( \begin{pmatrix} 6.905 & 0.235 & 0.235 \\ 0.235 & 6.905 & 0.235 \\ 0.235 & 0.235 & 6.905 \end{pmatrix} \) | \( \begin{pmatrix} 0.176 & 0.065 & 0.065 \\ 0.065 & 0.176 & 0.065 \\ 0.065 & 0.065 & 0.176 \end{pmatrix} \) | \( \begin{pmatrix} 0.684 & 0.087 & 0.087 \\ 0.087 & 0.684 & 0.087 \\ 0.087 & 0.087 & 0.684 \end{pmatrix} \) |

Hubbard-Kanamori parameters: \( U = 0.684, U' = 0.509, J = 0.087 \)

where \( m \) runs over the orbitals in the following order \{ \( d_{z^2}, d_{xy}, d_{x^2-y^2} \) \}; \( \Delta \) is the crystal-field splitting between the \( a_1 \) and \( e \) orbitals. The spin-orbit coupling term is expressed as:

\[
\hat{H}_{SO} = \frac{\zeta_{SO}}{2} \sum_{i,mm'\sigma\sigma'} \tilde{c}_i^{\sigma \sigma'} c_{i,m}'^{\sigma \sigma'} - \frac{\zeta_{SO}^R}{2} \sum_{i,mm'\sigma\sigma'} \epsilon_{i,m}'^{\sigma \sigma'} c_{i,m}'^{\sigma \sigma'} c_{i,m}'^{\sigma \sigma'},
\]

(12)

where the second term comes from the Jahn-Teller distortion of the \( V_4 \) cluster along the \( z \) axis and has a Rashba-type form. The first (spherical) term can be presented in the form \( \zeta_{SO} \hat{L} \cdot \hat{S} \), which can be used to derive matrix elements of the angular momentum operator \( \hat{L} \) in the Wannier basis. The matrix elements of the angular momentum operators can be written in a compact form in terms of the Levi-Civita symbol, \( (\hat{L}_i^a)^{ab} = -i\varepsilon_{2ab}, (\hat{L}_i^a)^{ab} = -i\varepsilon_{3ab}, \) and \( (\hat{L}_i^a)^{ab} = i\varepsilon_{1ab} \). Finally, the Hubbard term is written as:

\[
\hat{H}_U = \sum_{i,\sigma} U^{mm'} \hat{n}_{im}^{\sigma} \hat{n}_{im}^{\sigma} + \sum_{i,\sigma} (U^{mm'} - J^{mm'}) \hat{n}_{im}^{\sigma} \hat{n}_{im}^{\sigma},
\]

(13)

where \( U^{mm'} = U^{mmm'm'} \) and \( J^{mm'} = U^{mmm'm'm'} \) are the on-site Coulomb and exchange interactions. The calculated hopping parameters and Coulomb interactions for the low-temperature phase are presented in Tables III and V, respectively. The calculated value of the crystal-field splitting is \( \Delta = 98.1 \) meV. The spin-orbit coupling parameters are \( \zeta_{SO} = 23.1 \) meV and \( \zeta_{SO}^R = 1.2 \) meV. Finally, on-site matrix elements of the position operator in the constructed basis are \( \langle \hat{r}^z \rangle^{11} = 7.5329 \) Å, \( \langle \hat{r}^z \rangle^{22} = \langle \hat{r}^z \rangle^{33} = 7.3772 \) Å, and \( \langle \hat{r}^z \rangle^{ij} = \langle \hat{r}^y \rangle^{ij} \approx 0 \). According to our results, the on-site Coulomb interactions are not particularly strong but still remain the largest parameters in the model. This can be understood as follows. First, the resulting Wannier orbitals are rather extended (the calculated spread is \( \approx 8.5 \) Å\(^2\)). Therefore, the bare Coulomb and exchange interactions in the Wannier basis, \( U = 6.91 \) eV and \( J = 0.24 \) eV, are already considerably reduced compared to their atomic values for real \( d \) orbitals, \( U^A \) and \( J^A \). Since the interatomic exchange integrals are small, the main contribution to \( J \) is due to the bare intraatomic interaction, \( J^A \approx 1 \) eV. Assuming that the Wannier orbitals are equally distributed over the four atomic sites in the \( V_4 \) cluster, \( J \) can be evaluated as \( J \sim \frac{1}{4} J^A \), which is consistent with the calculated value. Second, the bare interactions are efficiently screened due to proximity of the target \( t_2 \) bands to the low-lying \( a_1 \) and \( e \) states of the \( V_4 \) cluster.
TABLE IV. Nearest neighbour hopping parameters (in meV) calculated for the $a_1 \oplus e$ model of the low-temperature $R3m$ GaV$_4$S$_8$. The corresponding lattice translations are $a_1 = a(\sqrt{3}/2, -1/2, 1.4251)$, $a_2 = a(0, 1, 1.4251)$, and $a_3 = a(-\sqrt{3}/2, -1/2, 1.4251)$, where $a = 3.9255 \text{ Å}$.

HARTREE-FOCK APPROXIMATION

The effective low-energy models allow us to go beyond conventional first-principles calculations, especially when treating electronic correlations. In particular, they come in handy when dealing with exotic systems, like GaV$_4$S$_8$, where the properties of interest are featured by complex molecular orbitals, so that the use of ordinary methods implemented for atomic-like orbitals (for example, LDA+U) may be questionable.
FIG. 3. a) Density of states and b) on-site level splitting of the ferromagnetic state in the low-temperature phase as obtained in the Hartree-Fock approximation with and without spin-orbit coupling (HF+SO and HF, respectively).

There is a large variety of different techniques used to deal with the Hubbard model:

\[
\hat{H} = \sum_{ij} t_{ij} c_{i\sigma}^\dagger c_{j\sigma'} + \frac{1}{2} \sum_{i} U_{\sigma\sigma'} c_{i\sigma}^\dagger c_{i\sigma'}^\dagger c_{i\sigma'} c_{i\sigma}. \tag{14}
\]

In the simplest way this model can be solved by expressing the correlation term as:

\[
\hat{c}_{i\sigma}^\dagger \hat{c}_{i\sigma'}^\dagger \hat{c}_{i\sigma'} \hat{c}_{i\sigma} \approx \hat{c}_{i\sigma}^\dagger \hat{c}_{i\sigma} \langle \hat{c}_{i\sigma'}^\dagger \hat{c}_{i\sigma'} \rangle + \hat{c}_{i\sigma'}^\dagger \hat{c}_{i\sigma'} \langle \hat{c}_{i\sigma}^\dagger \hat{c}_{i\sigma} \rangle - \hat{c}_{i\sigma}^\dagger \hat{c}_{i\sigma} \langle \hat{c}_{i\sigma'}^\dagger \hat{c}_{i\sigma'} \rangle - \hat{c}_{i\sigma'}^\dagger \hat{c}_{i\sigma'} \langle \hat{c}_{i\sigma}^\dagger \hat{c}_{i\sigma} \rangle, \tag{15}
\]

so that higher-order quantum fluctuations are neglected. Here, \(\langle ... \rangle\) stands for an average over the ground state. By using symmetry properties of the Coulomb matrix, we obtain the following one-electron Hamiltonian [13]:

\[
\hat{H}^{\text{HF}} = \sum_{ij} \sum_{\alpha\beta} t_{ij}^{\alpha\beta} c_{i\alpha}^\dagger c_{j\beta} + \sum_{i} \sum_{\alpha\beta\gamma\delta} V_{\alpha\beta\gamma\delta} c_{i\alpha}^\dagger c_{i\gamma}^\dagger c_{i\delta} c_{i\beta}. \tag{16}
\]

where:

\[
V_{\alpha\beta\gamma\delta} = \sum_{\gamma\delta} U_{\alpha\beta\gamma\delta} (n_{\gamma\delta}^{\uparrow\uparrow} + n_{\gamma\delta}^{\downarrow\downarrow}) \delta_{\sigma\sigma'} - U_{\alpha\beta\gamma\delta} n_{\gamma\delta}^{\sigma\sigma'}. \tag{17}
\]

and

\[
n_{\gamma\delta}^{\sigma\sigma'} = \langle \hat{c}_{\gamma\delta}^\sigma \hat{c}_{\gamma\delta}^{\sigma'} \rangle. \tag{18}
\]

In the reciprocal space, it is equivalent to solving the Hartree-Fock equations:

\[
(\hat{t}_{k} - \hat{V})|\varphi_{nk}\rangle = \varepsilon_{nk}|\varphi_{nk}\rangle, \tag{19}
\]

where \(\hat{t}_{k}^{\alpha\beta}\) is the Fourier image of \(\hat{t}_{ij}\). Iterative solution of the Hartree-Fock equations is obtained self-consistently with respect to the total energy:

\[
E^{\text{HF}} = \sum_{k} \sum_{n} \varepsilon_{nk} - \frac{1}{2} \sum_{i} \text{Tr} \{\hat{V}_{i} \hat{n}_{i}\}. \tag{20}
\]

The results of Hartree-Fock calculations are shown in Fig. 3.
For the low-temperature phase of GaV$_4$S$_8$, the electronic model, Eq. (9), can be mapped onto the classical spin model:

$$\mathcal{H}^S = -\sum_{\langle ij \rangle} J_{ij} \mathbf{e}_i \cdot \mathbf{e}_j - \sum_{\langle ij \rangle} D_{ij} \cdot \mathbf{e}_i \times \mathbf{e}_j,$$

(21)

where the first and second terms stand for the isotropic Heisenberg and anisotropic Dzyaloshinskii-Moriya exchange interactions, respectively, and $\mathbf{e}_i$ is the unit magnetic moment at site $i$. Below, we consider two approaches for calculating exchange parameters.

The Green's functions approach

The exchange parameters can be derived from a collinear configuration obtained in Hartree-Fock calculations without spin-orbit coupling by considering a perturbation $\delta \hat{v}_p^i$ caused by applying the spin-orbit coupling potential at one site while rotating the magnetic moment at another site. The corresponding rotation is given by another perturbation,

$$\delta \hat{v}_r^j = \hat{b}_j \delta \mathbf{e}_j \cdot \hat{\sigma},$$

where $\hat{b}_j = \frac{1}{2}(\hat{\mathbf{V}}_j^\uparrow - \hat{\mathbf{V}}_j^\downarrow)$ is the exchange splitting field at site $j$. Having employed Lloyd’s formula [14] to express the change in the single-particle energy to second order with respect to the applied potentials, the exchange parameters are obtained from the force $f_i = -\partial E/\partial \mathbf{e}_i$ rotating the magnetic moment at site $i$, which for the spin model given above is written as [15]:

$$f_i = \sum_j f_i^j = \sum_j J_{ij} \mathbf{e}_j + D_{ij} \times \mathbf{e}_j,$$

(22)

where

$$J_{ij} = \frac{2}{\pi} \int_\infty^{\varepsilon_F} dE \text{Tr}_L \{ \hat{G}^\uparrow_{ij}(E) \hat{b}_j \hat{G}^\downarrow_{ji}(E) \hat{b}_i \}$$

(23)

and

$$\frac{1}{2}(f_i^j - f_j^i) = \frac{1}{\pi} \int_\infty^{\varepsilon_F} dE \text{Tr}_L \{ \hat{\sigma} (\hat{G}^\uparrow_{ij}(E) \delta \hat{v}_p^j \hat{G}^\downarrow_{ji}(E) \hat{b}_i - \hat{G}^\downarrow_{ij}(E) \hat{b}_j \hat{G}^\uparrow_{ji}(E) \delta \hat{v}_p^i) \}.$$

(24)

Here, the unperturbed Green’s function is defined as:

$$\hat{G}_{ij} = \begin{pmatrix} \hat{G}^\uparrow_{ij} & 0 \\ 0 & \hat{G}^\downarrow_{ij} \end{pmatrix}$$

(25)

and

$$\hat{G}^\sigma_{ij}(E) = \sum_{nk} \frac{|\varphi_{nk}^\sigma\rangle\langle \varphi_{nk}^\sigma|}{E - \varepsilon_{nk} + i\delta} e^{ik\cdot(R_j - R_i)}.$$  

(26)

The effect of spin-orbit coupling is included perturbatively within self-consistent linear response theory [15], where the change of the density matrix with respect to an external perturbation $\delta \hat{v}^{ext} = \hat{H}_{SO}$ is given by:

$$\delta \hat{n} = \hat{R} \delta \hat{v}^{ext},$$

(27)

TABLE VI. Exchange parameters (in meV) for the spin model, Eq. (21), as obtained from the mean-field Hartree-Fock calculations (HF) and superexchange theory (SE). See Fig. 4a for details.

|       | HF                      | SE                      |
|-------|-------------------------|-------------------------|
|       | Intraplane              |                          |
| $J_{||}$ | 0.202                  | 0.180                   |
| $D_{01}$ | (0.138, 0.080, 0.010)  | (0.063, 0.036, -0.010)  |
| $D_{02}$ | (0.138, -0.080, -0.010) | (0.063, -0.036, 0.010)  |
| $D_{03}$ | (0.0, -0.159, 0.010)    | (0.0, -0.073, -0.010)   |
| $D_{04}$ | (-0.138, -0.080, -0.010) | (-0.063, -0.036, 0.010) |
| $D_{05}$ | (-0.138, 0.080, 0.010)  | (-0.063, 0.036, -0.010) |
| $D_{06}$ | (0.0, 0.159, -0.010)    | (0.0, 0.073, 0.010)     |
|       | Interplane              |                          |
| $J_{\perp}$ | 0.363                  | 0.217                   |
| $D_{01\prime}$ | (-0.021, -0.036, 0.0)  | (0.029, 0.049, 0.0)     |
| $D_{02\prime}$ | (0.021, -0.036, 0.0)   | (-0.029, 0.049, 0.0)    |
| $D_{03\prime}$ | (0.041, 0.0, 0.0)      | (-0.057, 0.0, 0.0)      |
| $D_{04\prime}$ | (0.021, 0.036, 0.0)    | (-0.029, -0.049, 0.0)   |
| $D_{05\prime}$ | (-0.021, 0.036, 0.0)   | (0.029, -0.049, 0.0)    |
| $D_{06\prime}$ | (-0.041, 0.0, 0.0)     | (0.057, 0.0, 0.0)       |

and the response matrix is defined as:

$$\tilde{\mathcal{R}}^{\sigma\sigma'} = \sum_{n} \sum_{n'} \sum_{k} \left( \frac{\langle \phi^{\sigma}_{nk} | \phi^{\sigma'}_{n'k} \rangle \langle \phi^{\sigma'}_{n'k} | \phi^{\sigma}_{nk} \rangle}{\varepsilon^{\sigma}_{nk} - \varepsilon^{\sigma'}_{n'k}} - \frac{\langle \phi^{\sigma}_{n'k} | \phi^{\sigma'}_{nk} \rangle \langle \phi^{\sigma'}_{nk} | \phi^{\sigma}_{n'k} \rangle}{\varepsilon^{\sigma'}_{n'k} - \varepsilon^{\sigma}_{nk}} \right).$$

(28)

Combining the corresponding change of the Hartree-Fock potential $\delta \tilde{v}$ with $\delta \tilde{v}^{\text{ext}}$, the problem is solved self-consistently giving the total perturbation $\delta \tilde{v}^{p} = \delta \tilde{v}^{\text{ext}} + \delta \tilde{v}$, so that:

$$\delta \tilde{v} = \tilde{\mathcal{R}} \delta \tilde{v}^{p}. \quad (29)$$

The calculated exchange parameters are given in Table VI. As can be seen from Fig. 4b, these parameters obey the $C_{3v}$ point group and are in agreement with Moriya rules. Clearly, because the mirror planes pass along the bonds
connecting nearest neighbours in the adjacent [111] planes, the anisotropic exchange parameters should be perpendicular to the corresponding bonds and lie in the xy plane. At the same time, the mirror planes are perpendicular to the in-plane bonds connecting nearest neighbours, and the corresponding Dzyaloshinskii-Moriya interactions lie within the plane with an alternating z component.

**Superexchange theory**

Superexchange interaction is regarded as the kinetic energy gain acquired by an electron centering at one site in the process of virtual hoppings into the subspace of unoccupied states at neighboring sites (and vice versa) [16, 17]. Starting from the atomic limit, this energy gain can be obtained to second order with respect to the hopping processes as [18, 19]:

$$
\mathcal{T}_{ij} = - \left( \mathcal{G}_{ij} \left| \hat{t}_{ij} \left( \sum_{M} \frac{\hat{P}_{j}|jM \rangle \langle jM|\hat{P}_{j}}{E_{jM}} \right) \hat{t}_{ji} + (i \leftrightarrow j) \right| \mathcal{G}_{ij} \right).
$$

(30)

Here, $\mathcal{G}_{ij}$ is the ground-state wavefunction for the bond $ij$ defined in the atomic limit. Since each atomic site accommodates 1 electron, one can start from the one-electron approximation and express $\mathcal{G}_{ij}$ in the form of Slater determinants constructed from the occupied orbitals $\phi_i$ at sites $i$ and $j$:

$$
\mathcal{G}_{ij}(1, 2) = \frac{1}{\sqrt{2}} [\phi_i(1)\phi_j(2) - \phi_i(2)\phi_j(1)].
$$

(31)

These orbitals correspond to the lowest Kramers doublet obtained by diagonalising $\hat{H}_{\text{CF}} + \hat{H}_{\text{SO}}$ and taken as their linear combinations to diagnose the Pauli matrices (that corresponds to the maximal projection of the pseudospin moment in a given direction). $E_{jM}$ and $|jM \rangle$ stand for the true eigenvalues and eigenvectors of the excited two-electron configurations at site $j$, and $\hat{P}_{j}$ is a projector operator that enforces the Pauli principle and suppresses any hoppings into the subspace of occupied orbitals. In practice, $\hat{P}_{j}$ projects $|jM \rangle$ onto the subspace of Slater determinants in the form:

$$
\hat{P}_{j}|jM(1, 2)\rangle = \frac{1}{\sqrt{2}} [\psi_j(1)\phi_j(2) - \psi_j(2)\phi_j(1)],
$$

(32)

where $\phi_j$ is the occupied orbital at site $j$, and $\psi_j$ is an unoccupied orbital at site $j$ reached through the hopping processes $\hat{t}_{ij}$. For the $t_2$ model, each $|jM \rangle$ is expressed in the basis of $6 \times 5/2 = 15$ Slater determinants, and the
FIG. 6. Skyrmion lattices as obtained from Monte Carlo simulations at temperature $T = 0.1J_1$ with an applied magnetic field $h || [111]$ by using two sets of exchange parameters derived from Hartree-Fock calculations (HF) and superexchange theory (SE).

corresponding two-electron Hamiltonian is constructed from $\hat{H}_{CF} + \hat{H}_{SO} + \hat{H}_{U}$ by using Slater-Condon rules. In this sense this superexchange theory goes beyond the conventional mean-field approximation. The calculated two-electron levels $E_{jM}$ are shown in Fig. 5.

In the case of a perfect cubic environment (when $\hat{H}_{CF} + \hat{H}_{SO}$ is neglected), the two-electron states are split into three groups: $^3T_1$, degenerate $^1T_2$ and $^1E$, and $^1A_1$ with the energy levels $(U-5J)$, $(U-3J)$, and $U$, respectively, as shown in Fig. 5 [20]. This property can be used to derive averaged Kanamori parameters [21] for the $R3m$ phase of GaV$_4$S$_8$: $U = 0.858$ eV and $J = 0.087$ eV.

To construct $\hat{T}_{ij}$, we consider all possible spin projections along $\pm x$, $\pm y$, and $\pm z$ at sites $i$ and $j$, and $\hat{T}_{ij}$ is mapped onto the spin model [18, 19]:

$$\hat{H}^S = \sum_{(ij)} e_i \hat{T}^S_{ij} e_j,$$

$$\mathcal{J}^{ab}_{ij} = \frac{1}{2} (\mathcal{T}^{ab}_{ij} - \mathcal{T}^{\bar{a}\bar{b}}_{ij}),$$

where $e_i = \langle \phi_i | \hat{\sigma} | \phi_i \rangle / \langle \phi_i | \hat{\sigma} | \phi_i \rangle$, $a$ and $\bar{b}$ run over $\{x, y, z\}$, and $\bar{a}$ stands for the opposite direction of $a$. The anisotropic and symmetric parts can be rewritten as $e_i \hat{T}^S_{ij} e_j = D_{ij} \cdot (e_i \times e_j)$ and $e_i \hat{\mathcal{J}}^{S}_{ij} e_j = -J_{ij} e_i \cdot e_j + e_i \hat{\Gamma}_{ij} e_j \approx J_{ij} (e_i^x e_j^x + e_i^y e_j^y) + (J_{ij} + \delta J_{ij}) e_i^z e_j^z$, respectively. The resulting parameters are summarized in Table VII. The calculated values of $\delta J$ are 0.021 meV and 0.032 meV for the intraplane and interplane bonds, respectively, and can be neglected on account of their smallness.

**Monte Carlo calculations**

Based on the calculated model parameters, we performed Monte Carlo simulations with an external magnetic field:
\[ \mathcal{H} = \mathcal{H}^S - \hbar \sum_i e_z \]  

by using a heat-bath algorithm combined with overrelaxation. In these calculations, supercells of \( N = 72 \times 72 \times 3 \) spins with periodic boundary conditions were used, and a single run contained \((1.0 - 5.0) \times 10^6\) Monte Carlo steps. For initial relaxation, the system was gradually cooled down from higher temperatures. As shown in Fig. 6, the resulting skyrmions are in agreement for two sets of exchange parameters.

**ELECTRIC POLARIZATION**

**Berry-phase formalism**

Starting from the Hartree-Fock approximation, electric polarization can be calculated by using the Berry-phase formalism [24, 25]:

\[ P_a = -\frac{1}{V} \frac{N_a}{N_1N_2N_3|G_a|} \gamma_a, \]  

where \( V \) is the unit cell volume, and the Berry phase \( \gamma_a \) is computed on a discrete mesh of \( N_1 \times N_2 \times N_3 \) \( \mathbf{k} \)-points in the first Brillouin zone with the reciprocal lattice vectors \( \{G_a\} \):

\[ k_{s_1,s_2,s_3} = \frac{s_1}{N_1} G_1 + \frac{s_2}{N_2} G_2 + \frac{s_3}{N_3} G_3, \]  

and

\[ \gamma_1 = -\sum_{s_2=0}^{N_2-1} \sum_{s_3=0}^{N_3-1} \text{Im} \ln \prod_{s_1=0}^{N_1-1} \text{det} \hat{S}(k_{s_1,s_2,s_3},k_{s_1+1,s_2,s_3}), \]  

where \( S_{n\alpha'}(\mathbf{k},\mathbf{k}') = \langle \varphi_{n\mathbf{k}}|\varphi_{\alpha'|\mathbf{k}'} \rangle \) is an overlap matrix between occupied states at two neighbouring \( \mathbf{k} \)-points; \( \gamma_2 \) and \( \gamma_3 \) are obtained by cyclic permutation of \( \{s_1, s_2, s_3\} \). The on-site contribution to electric polarization can be calculated as:

\[ P_{\text{on-site}} = -\frac{e}{V} \text{Tr}[\hat{n}\hat{r}], \]  

where \( \hat{r} \) is the position operator defined in the Wannier function basis, and the trace is over site, orbital, and spin indices.

The calculated values of electric polarization \( P^z \) along \( z \parallel [111] \) are 0.0107 and 0.0111 C/m² for the ferromagnetic solution with and without spin-orbit coupling, respectively.

In the presence of spin-orbit coupling, we reveal a small change of electric polarization when the ferromagnetic moment is rotated away from the easy axis \( z \parallel [111] \). Moreover, there is a strong anisotropy of orbital angular momentum in the direction perpendicular to the easy axis. It is worth noting that this fact is properly included in the following consideration of electric polarization in the framework of superexchange theory, where projections of the pseudospin state are constructed from the Kramers doublet \( |\phi_i\rangle \) by diagonalising \( \langle \phi_i|\hat{\sigma}|\phi_i\rangle \). As seen from the band structure shown in Fig. 7a for two ferromagnetic solutions with different directions of the magnetization, the occupied band changes on the F–L path, which goes along the boundary of the Brillouin zone that corresponds to the change of electron transfer between interplane nearest neighbours. Nevertheless, this change of electric polarization alongside with the on-site contribution is found to be small (Fig. 7b) and can be neglected in further considerations for magnetic textures with a slowly varying magnetization profile.

Finally, we have performed Hartree-Fock calculations for the ferromagnetic and spin spiral states to calculate the change of electric polarization. The resulting magnetic textures are shown in Fig. 7c, and the corresponding change of electric polarization between the ferromagnetic and spin spiral states is 10.4 and 12.1 \( \mu \text{C/m}^2 \) for supercells \( 1 \times 9 \times 3 \) and \( 1 \times 12 \times 3 \).
FIG. 7. a) Band structures of the ferromagnetic configuration with \( \theta = 0^\circ \) and \( \theta = 90^\circ \) (\( \phi = 0^\circ \)) as obtained in the Hartree-Fock approximation. b) Angle dependence of the total energy, orbital angular momentum, electric polarization for the ferromagnetic configuration obtained in the Hartree-Fock approximation. c) Spin and orbital (scaled for clarity) angular momenta of a spin spiral state obtained in the Hartree-Fock approximation with the propagation vector \( \mathbf{q} = q(0, 1, 0) \) and supercell \( 1 \times 20 \times 3 \).

Analytical expression without spin-orbit coupling

The spin-dependent part of electric polarization can be described within perturbation theory [27, 28]. To this end, let us consider a ferromagnetic state in the low-temperature phase, where a single \( d_{z^2}^\uparrow \) state is occupied, and neglect spin-orbit coupling. Since all the calculated parameters of the corresponding low-energy model are close to those of the high-temperature phase, we can discard their orbital dependence, so that the on-site Hamiltonian is written as:

\[
\hat{\mathcal{H}}_0 = \hat{\mathcal{H}}_{\text{CF}} + \hat{\mathcal{H}}_U,
\]

where the crystal-field splitting between the \( a_1 \) and \( e \) states and the Hubbard term are given by:

\[
\hat{\mathcal{H}}_{\text{CF}} = \sum_{i, m \in e, \sigma} \Delta c_{i m \sigma}^\dagger c_{i m \sigma}
\]

and

\[
\hat{\mathcal{H}}_U = \sum_{i, m} U \hat{n}_{i m \sigma}^\dagger \hat{n}_{i m \sigma} + \sum_{i, (m m') \sigma} (U - 2J) \hat{n}_{i m \sigma}^\dagger \hat{n}_{i m' \sigma} + (U - 3J) \hat{n}_{i m \sigma}^\dagger \hat{n}_{i m' \sigma}^\dagger,
\]

respectively. The corresponding level splitting at each site is readily obtained: \( \varepsilon_i^\sigma = \{0; U; U - 3J + \Delta; U - 2J + \Delta; U - 3J + \Delta; U - 2J + \Delta \} \) for the states \( \{d_{z^2}^\uparrow, d_{x^2-y^2}^\uparrow, d_{x^2-y^2}^\downarrow, d_{x^2-y^2}^\uparrow, d_{x^2-y^2}^\downarrow \} \), respectively. As seen from Fig. 3b, where the
level splitting obtained from Hartree-Fock calculations are shown, the atomic limit is a good starting approximation. Next, we make use of a general definition of electric polarization expressed in terms of the Wannier functions:

\[
P = -\frac{e}{V} \sum_{i=1}^{occ} \int \frac{r}{V} |w_i^\alpha(r)|^2 dr,
\]

(42)

Here, we assume that all \(w_i^\alpha(r)\) are well localized at the lattice points \(i\), so their tales at the neighbouring sites \(j\) are proportional to the corresponding transfer integrals from occupied to unoccupied orbitals and can be obtained within perturbation theory:

\[
|w_i^\alpha(r)|^2 = w_{ii}^\alpha \delta(r - R_i) + \sum_j w_{ij}^\alpha \delta(r - R_j + R_i),
\]

(43)

where \(w_{ii}^\alpha\) is the on-site Wannier density, and \(w_{ij}^\alpha\) is the corresponding Wannier weight transfer from site \(i\) to site \(j\):

\[
w_{ij}^\alpha = \sum_{\beta} \frac{|t_{ij}^{\alpha\beta}|}{\epsilon_i^\alpha - \epsilon_j^\beta}.
\]

(44)

Consequently, electric polarization \(P\) can be represented as the sum of bond contributions:

\[
P = \sum_{(ij)} P_{ij},
\]

(45)

where

\[
P_{ij} = -\frac{e}{V} \tau_{ji} \sum_\alpha (w_{ij}^\alpha - w_{ji}^\alpha),
\]

(46)

and \(\tau_{ji} = R_j - R_i\). In the case of the low-temperature GaV\(_4\)S\(_8\) with one occupied orbital \(d_{xz}^\uparrow\), \(w_{ij}^\alpha\) can be expressed as:

\[
w_{ij} = |\xi_{ij}^{\uparrow\uparrow}|^2 \frac{(t_{ij}^{12})^2 + (t_{ij}^{13})^2}{(U - 3J + \Delta)^2} + |\xi_{ij}^{\uparrow\downarrow}|^2 \frac{(t_{ij}^{12})^2 + (t_{ij}^{13})^2}{(U - 2J + \Delta)^2} + |\xi_{ij}^{\downarrow\downarrow}|^2 \frac{(t_{ij}^{11})^2}{U^2},
\]

(47)

with

\[
|\xi_{ij}^{\uparrow\uparrow}|^2 = |\xi_{ij}^{\uparrow\downarrow}|^2 = \frac{1}{2} (1 + e_i \cdot e_j),
\]

\[
|\xi_{ij}^{\downarrow\downarrow}|^2 = |\xi_{ij}^{\downarrow\uparrow}|^2 = \frac{1}{2} (1 - e_i \cdot e_j),
\]

(48)

and the spin-dependent part of electric polarization is written as:

\[
P_{ij} = -\frac{e \tau_{ji}}{2V} \left( \frac{1}{(U - 3J + \Delta)^2} - \frac{1}{(U - 2J + \Delta)^2} \right) \left( (t_{ij}^{12})^2 + (t_{ij}^{13})^2 - (t_{ij}^{12})^2 - (t_{ij}^{13})^2 \right) e_i \cdot e_j.
\]

(49)

As follows, without spin-orbit coupling \(P_{ij}\) is entirely isotropic. This analysis leads to some important conclusions on the microscopic origin of electric polarization in GaV\(_4\)S\(_8\). On the one hand, \(P_{ij}\) is given by the asymmetric electron transfer between nearest neighbors as a result of inversion symmetry breaking. On the other hand, \(P_{ij}\) requires a nonzero value of \(J\). The corresponding values of \(P_{ij}\) are obtained by using the model parameters given in Tables IV and V: for the intraplane bonds \(j = 1 - 6\) (Fig. 4a) \(P_{01} = 0\), \(P_{02} = -4.4 \mu C/m^2\), \(P_{04} = P_{05} = 4.4 \mu C/m^2\), and \(P_{03} = P_{06} = 0\), for the interplane bonds \(j = 1' - 6'\) (Fig. 4a) we have \(P_{ij} = (-1)^j P_\perp\), where \(P_\perp = 463.5 \mu C/m^2\). Thus, when summing over all nearest neighbors, the intraplane contributions cancel out, while the interplane contributions enter with opposite signs for the lower and upper planes and give the resulting spin-dependent polarization.
TABLE VII. Electric polarization tensors (in μC/m²) calculated within superexchange theory for the $a_1 \oplus e$ model of the low-temperature GaV$_4$S$_8$. The corresponding lattice translations are $a_1 = a(\sqrt{3}/2, -1/2, 1.4251)$, $a_2 = a(0, 1, 1.4251)$, and $a_3 = a(-\sqrt{3}/2, -1/2, 1.4251)$, where $a = 3.9255$ Å.

Intraplane

$\mathbf{\hat{P}}_{101} = \begin{pmatrix} 0.0 & 9.22 & -0.60 \\ 9.22 & 0.0 & 30.13 \\ -0.60 & -30.13 & 0.0 \end{pmatrix}$

$\mathbf{\hat{P}}_{101} = \begin{pmatrix} 0.0 & -9.22 & 0.60 \\ -9.22 & 0.0 & 30.13 \\ 0.60 & -30.13 & 0.0 \end{pmatrix}$

$\mathbf{\hat{P}}_{110} = \begin{pmatrix} -7.63 & 4.36 & -26.20 \\ 4.36 & 8.31 & -14.68 \\ 26.20 & 14.68 & -0.35 \end{pmatrix}$

Interplane

$\mathbf{\hat{P}}_{001} = \begin{pmatrix} -364.48 & -6.91 & -36.94 \\ -6.22 & -356.96 & -21.27 \\ 34.86 & 20.19 & -360.89 \end{pmatrix}$

$\mathbf{\hat{P}}_{100} = \begin{pmatrix} -364.48 & 6.91 & 36.94 \\ 6.22 & -356.96 & -21.27 \\ -34.86 & 20.19 & -360.89 \end{pmatrix}$

$\mathbf{\hat{P}}_{001} = \begin{pmatrix} 364.48 & 6.22 & -34.86 \\ 6.91 & 356.96 & -20.19 \\ 36.94 & 21.27 & 360.89 \end{pmatrix}$

$\mathbf{\hat{P}}_{100} = \begin{pmatrix} 353.99 & 0.0 & 0.0 \\ 0.0 & 369.16 & 39.88 \\ 0.0 & 42.87 & 361.84 \end{pmatrix}$

$\mathbf{\hat{P}}_{010} = \begin{pmatrix} 0.0 & -369.16 & -42.87 \\ -353.99 & 0.0 & 0.0 \\ 0.0 & -369.16 & -42.87 \end{pmatrix}$

$\mathbf{\hat{P}}_{010} = \begin{pmatrix} 0.0 & 369.16 & -42.87 \\ -353.99 & 0.0 & 0.0 \\ 0.0 & -369.16 & -42.87 \end{pmatrix}$

Superexchange theory

Following the idea of superexchange theory for exchange interactions, we can consider hopping processes of a single occupied electron to the excited two-electron levels at neighbouring sites to construct the Wannier weight transfer in Eq. (44):

$$\hat{w}_{ij} = \left< \hat{G}_{ij} | \hat{\tau}_{ij} \left( \sum_{M} \hat{P}_j | jM \rangle \langle jM | \hat{P}_j \right) \right> \hat{G}_{ij},$$

so that the spin-dependent part of electric polarization in Eq. (45) can be written as:

$$\mathbf{P}_{ij} = \frac{\mathbf{e}_i \mathbf{\hat{P}}_{ij} \mathbf{e}_j}{|\mathbf{\hat{P}}_{ij}|},$$

where $|\mathbf{\hat{P}}_{ij}|$ contains isotropic $P_{ij}$, antisymmetric $\mathbf{P}_{ij}$, and anisotropic $\mathbf{\hat{P}}_{ij}$ components. The resulting tensors $\mathbf{\hat{P}}_{ij}$ calculated from the multiplet structure with $\hat{H}_{CF} + \hat{H}_{SO} + \hat{H}_U$ (Fig. 5) are given in Table VII. When taking into account the effects of crystal field and Coulomb interactions and neglecting spin-orbit coupling (the multiplet structure with $\hat{H}_{CF} + \hat{H}_U$ in Fig. 5), $\mathbf{\hat{P}}_{ij}$ is diagonal and is in good agreement with the analytical one-electron approach: for the intraplane bonds
FIG. 8. a) Spiral and skyrmionic textures in the continuum limit. b) Change of electric polarization as a function of the skyrmionic radius calculated for the supercell $30 \times 30 \times 3$ with respect to the ferromagnetic state. c) Spatial profile of electric polarization in the skyrmionic phase.

$j = 1 - 6$ (Fig. 4a) $P_{0j} \approx 0$, and for the interplane bonds $j = 1' - 6'$ (Fig. 4a) $P_{0j} = (-1)^j P_\perp$, where $P_\perp = 381.1 \mu C/m^2$.

To supplement the results of Monte Carlo calculations presented in the main text, we use the continuum limit for magnetic textures, which is valid owing to their large spatial modulation. A skyrmionic texture can be defined as:

$$S_R = \frac{1}{2} \left( c_0 S_0 + c_1 \sum_{n=1}^{3} \text{Re} \left\{ S_n e^{i q_n \cdot R} \right\} \right),$$  \hspace{1cm} (53)

where $S_n = S_0 + i q_n / q$ with $S_0 = (0, 0, 1)$, the propagation vectors of a skyrmionic texture are $q_1 = q(0, 1, 0)$, $q_2 = q(\sqrt{3}/2, -1/2, 0)$, and $q_3 = q(-\sqrt{3}/2, -1/2, 0)$ with $q = 2\pi / R_{SK}$, $R_{SK}$ is the skyrmion radius. For a spin spiral, we take:

$$S_R = \frac{c_1}{2} \text{Re} \left\{ S_n e^{i q_n \cdot R} \right\}. \hspace{1cm} (54)$$

Generally, the coefficients $c_0$ and $c_1$ depend on temperature and applied magnetic fields. In accordance with Monte Carlo calculations, we consider supercells with a minimal periodicity along the $z \parallel [111]$ axis, as shown in Fig. 8a. The resulting change of spin-driven polarization as a function of $c_1 / c_0$ is shown in Fig. 8b and demonstrates a strong competition of isotropic and compass-type antisymmetric contributions. The corresponding spatial profile of electric polarization in the skyrmionic phase is shown in Fig. 8c and indicates a strong modulation of spin-driven polarization in the vicinity to the skyrmionic core, in agreement with Ref. 23.
