(Dated: September 14, 2020)

We compute the effects of strong Hubbardlike local electronic interactions on three-dimensional four-component massless Dirac fermions, which in a noninteracting system possess a microscopic global U(1)⊗SU(2) chiral symmetry. A concrete lattice realization of such chiral Dirac excitations is presented, and the role of electron-electron interactions is studied by performing a field theoretic renormalization group (RG) analysis, controlled by a small parameter $\epsilon$ with $\epsilon = d - 1$, about the lower-critical one spatial dimension. Besides the noninteracting Gaussian fixed point, the system supports four quantum critical and four bicritical points at nonvanishing interaction couplings $\sim \epsilon$. Even though the chiral symmetry is absent in the interacting model, it gets restored (either partially or fully) at various RG fixed points as emergent phenomena. A representative cut of the global phase diagram displays a confluence of scalar and pseudoscalar excitonic and superconducting (such as the $s$-wave and $p$-wave) mass ordered phases, manifesting restoration of (a) chiral U(1) symmetry between two excitonic masses for repulsive interactions and (b) pseudospin SU(2) symmetry between scalar or pseudoscalar excitonic and superconducting masses for attractive interactions. Finally, we perturbatively study the effects of weak rotational symmetry breaking on the stability of various RG fixed points.

I. INTRODUCTION

Dirac fermions offer a universal language to explore various territories of modern physics that include baryonic matters at high energies [1], topological phases of matter [2, 3], and scale invariant quantum critical phenomena in fermionic systems, to name a few. While in the context of high-energy physics massless Dirac fermions are realized in the ultraviolet regime, in solid state systems they are found as emergent sharp quasiparticle excitations at sufficiently low energies (the infrared regime) [4, 5]. The prominent representatives of such infrared nodal Dirac materials are the two-dimensional carbon-based honeycomb membrane or graphene [6], and three-dimensional strong spin-orbit coupled Cd$_3$As$_2$ [7] and Na$_3$Bi [8]. Here we focus on the minimal building block of a three-dimensional strong spin-orbit coupled gapless Dirac liquid, constituted by four-component massless Dirac fermions, that besides the fundamental discrete parity ($P$), time-reversal ($T$) and charge-conjugation ($C$) symmetries, also enjoy a microscopic continuous U(1)⊗SU(2) global chiral symmetry. The present discussion unfolds the role of strong momentum-independent Hubbardlike or local electronic interactions among massless chiral Dirac fermions.

The central outcomes of this study are captured by a representative cut of the global phase diagram, shown in Fig. 1. It displays realizations of and competitions among four chiral symmetry breaking mass orders for sufficiently strong local electronic interactions, which we demonstrate via a controlled, but leading-order renormalization group (RG) analysis. Even though the interacting Hubbardlike model does not possess the chiral U(1)⊗SU(2) symmetry at the bare level, the resulting phase diagram and the RG fixed points manifest its restoration (at least partially) as emergent phenomena.

Indeed “more is different” [9]. We now present a synopsis of our main findings.

A. Summary of results

Here we show that a collection of isotropically dispersing massless chiral Dirac fermions, interacting via Hubbardlike local or short-range interactions, is described only in terms of four linearly independent four-fermion or quartic terms. By performing a one-loop or leading-order RG analysis on such an interacting model, controlled by a small parameter $\epsilon$ with $\epsilon = d - 1$, about the lower-critical one spatial dimension ($d = 1$), we show that the system altogether sustains eight interacting fixed points, see Table I. All the fixed points are located at coupling constants $\sim \epsilon$, and can be grouped into following three categories, depending on the emergent chiral symmetry therein. Fixed points (1) possessing a partial U(1) or pseudospin SU(2) chiral symmetry, (2) enjoying the full U(1)⊗SU(2) chiral symmetry, and (3) transforming into each other under the chiral U(1) rotation. We arrive at these conclusions by computing the scaling dimensions of all symmetry allowed particle-hole or excitonic and particle-particle or superconducting orders, see Table II at various RG fixed points, see Table III. Otherwise, among eight RG fixed points four are quantum critical points (QCPs), while the remaining ones are bicritical points (BCPs). All the QCPs are characterized by the dynamic scaling exponent $z = 1$ and the correlation length exponent $\nu = \epsilon^{-1}$. Therefore, at the upper-critical three spatial dimensions we recover the exact mean-field value of the exponent $\nu = 1/2$ [10, 11], from a leading order $\epsilon$ expansion.

Some of these fixed points also play prominent roles on the global phase diagram of interacting Dirac fermions, a
FIG. 1: A representative phase diagram of a three-dimensional interacting isotropic Dirac semimetal in a two-dimensional subspace of interaction couplings. Here $g^s_2$ and $g^p_2$ are the coupling constants in scalar and pseudoscalar excitonic mass channels, respectively, measured in units of $\epsilon = d - 1$. Their positive (negative) values correspond to repulsive (attractive) interactions. Together, these two masses form a U(1) vector under the chiral U(1) rotation. The scalar s-wave and pseudoscalar p-wave superconducting masses (denoted by $s\mathrm{SC}$ and $p\mathrm{SC}$, respectively) also constitute a U(1) chiral vector. The emergent chiral symmetry manifests through the mirror symmetry of the phase diagram about the $g^s_2 = g^p_2$ line (the diagonal dashed line). Under the mirror transformation the components of the chiral U(1) mass orders transform into each other. The Dirac semimetal-excitonic mass quantum phase transition (blue boundary) is governed by the U(1) symmetric quantum critical point (QCP) C1. The scalar and pseudoscalar excitonic masses are degenerate along the red phase boundary between them, where the ordered state represents a P and T symmetry breaking axionic insulator [12–14]. The phase transitions across the black and purple boundaries are governed by the pseudospin SU(2) symmetric QCPs C2 and C3, respectively. Each excitonic mass is degenerate with the adjacent superconducting mass along the 135° diagonal (orange and pink lines), where they constitute pseudospin SU(2) chiral vectors, see Fig. 3. The basins of attraction of C1 and C2 (C1 and C3) are separated by the bicritical point B2 (B1), see Table I. The transitions through the bicritical points are also continuous, as they are accessed by holding one of the unstable directions fixed [15].

**Table I: Locations of four quantum critical points (QCPs) [C1, · · · , C4] and four bicritical points (BCPs) [B1, · · · , B4] in the four-dimensional space of coupling constants, measured in units of $\epsilon$, where $\epsilon = d - 1$ and $d$ is the spatial dimension of the system. Each QCP (BCP) possesses one (two) unstable direction(s). Note C1 and C4 are chiral U(1) symmetric QCPs, since $g^s_C = g^p_C$ therein. On the other hand, C2 and C3 are chiral U(1) partners, as their locations transform into each other under U(1) chiral rotation $g^s_C \leftrightarrow g^p_C$. Similarly, two pairs of BCPs, namely (1) (B1,B2), and (2) (B3,B4) are chiral U(1) partners. In addition, three QCPs C2, C3 and C4, and two BCPs B3 and B4 individually possess pseudospin SU(2) chiral symmetry. The emergent chiral symmetries can be anchored by comparing the scaling dimensions of fermion bilinears, tabulated in Table II at various fixed points, see Table III. In particular, the scaling dimensions of fermion bilinears that are related to each other by chiral U(1) [pseudospin SU(2)] chiral rotations are identical at the U(1) [pseudospin SU(2)] symmetric fixed points. By contrast, the scaling dimensions of two fermion bilinears that form a U(1) vector under the chiral U(1) rotations, are interchanged between two fixed points that are chiral partners of each other. Finally, the scaling dimension of chiral U(1) scalar fermion bilinears remain unchanged between two chiral partner fixed points. Only the fully U(1)@SU(2) symmetric QCP C4 becomes unstable even against weak rotational symmetry breaking, see Sec. III E.**

![Table I: Locations of Four Quantum Critical Points](image)

---

representative cut of which is displayed in Fig. 1. It shows a competition and confluence of four mass orders for chiral Dirac fermions, namely (1) the scalar excitonic mass, (2) the pseudoscalar excitonic mass, (3) the scalar s-wave pairing and (4) the pseudoscalar odd-parity p-wave pairing. Transformations of each mass order under various discrete ($P$, $T$ and $C$) and continuous symmetries are summarized in Table I. The fixed points (both critical and bicritical) controlling the continuous quantum phase transitions out of a Dirac semimetal into various broken symmetry phases for finite interactions across different segments of the phase boundary are also highlighted in Fig. 1. Most importantly, we find that the U(1) chiral symmetry of the noninteracting system manifests in the phase diagram as a reflection about the 45° diagonal (dashed) line under which the scalar excitonic and pairing masses transform into the pseudoscalar masses. Along this high symmetry line the chiral U(1) symmetry between scalar and pseudoscalar excitonic masses gets restored in the ordered phase (red line), which describes an axionic insulator [12–14]. Furthermore, the phase diagram supports another high symmetry line, the 135° diagonal, along which the pseudospin SU(2) symmetry between the scalar (pink line) and pseudoscalar (orange line) excitonic and pairing masses gets restored.

Finally, we address the stability of various interacting fixed points against weak breakdown of the spatial rotational symmetry. Such a rotational symmetry breaking introduces an anisotropy between the Fermi velocities in the $xy$ plane and along the $z$ direction, for example. Here we show that all but one RG fixed points, reported in Table IV for the isotropic system, retain their character in a weakly anisotropic Dirac semimetal. Only one QCP,
### TABLE II: Various local (momentum independent) orderings with their conjugate fields (CFs) (first column), the corresponding matrix \( \eta_\alpha \Gamma_{\mu\nu} \) (second column) associated with the fermion bilinears \( \Psi_{\alpha}^\dagger \Gamma_{\mu\nu} \Psi_{\alpha} \) in the Nambu basis \( \Psi_{\alpha} \), defined in Eq. (12). Fermion bilinears transforming as components of four pseudospin (PS) SU(2) vectors are marked as I, II, III and IV in the eighth column, see Fig. 3. The rest of the fermion bilinears transform as scalars under the pseudospin rotations, as they all commute with PS, see Eq. (14).

### TABLE III: Scaling dimensions (in units of \( \epsilon \)) of various particle-hole (first eight rows) and particle-particle (last four rows) order parameters (see Table I) at the eight nontrivial fixed points (see Table I). At the chiral U(1) symmetric fixed point C1 any two orders transforming as chiral U(1) vector (see Table I) seventh column) possess identical scaling dimensions. By contrast, their scaling dimensions switch between two fixed points that are chiral U(1) partners of each other, namely (1) (C2,C3), (2) (B1,B2), and (3) (B3,B4). At four pseudospin SU(2) chiral symmetric fixed points (C2, C3, B3, B4) all components of each pseudospin SU(2) vector (see Table II) possess identical scaling dimension. At the fully U(1)⊗SU(2) chiral symmetric fixed point C4, all components of chiral U(1) and pseudospin SU(2) vectors acquire equal scaling dimensions. In the phase diagram shown in Fig. 1 we highlight the role of these fixed points. At three QCPs (C1, C2, and C3) and two BCPs (B1 and B2) the mass orders possess the largest scaling dimensions (shown in bold). Therefore, C1 controls the transition to scalar and pseudoscalar excitonic mass orders. By contrast, C2 (C3) controls transition to pseudoscalar (scalar) excitonic and superconducting masses. On the other hand, when the role of C1 and C3 (C1 and C2) switch, the continuous transition to the scalar (pseudoscalar) excitonic mass is controlled by the BCP B1 (B2).

## II. NON-INTERACTING SYSTEM

In this section we introduce a noninteracting gapless Dirac system, possessing a genuine microscopic continuous chiral symmetry. First we promote the continuum or low-energy description of such system, and discuss its invariance under various discrete and continuous symmetries. Subsequently, we propose a lattice realization of a genuine chiral Dirac semimetal.
even though our results are insensitive to it. Nonetheless, for the sake of concreteness we organize the four-component spinor basis as \( \Psi_k = (c_{\uparrow}, c_{\downarrow}^{-1}, c_{-,\uparrow}^{-1}, c_{-,\downarrow}^{-1})^\top (k) \), where \( c_{\mu}(k) \) are the fermion annihilation operators with parity \( p = \pm \), spin projections \( s = \uparrow, \downarrow \), and momentum \( k \). The \( \Gamma \) matrices are then given by \( \Gamma_j = \Gamma_{1j} \) for \( j = 1, 2, 3 \), with \( \Gamma_{\mu\nu} \equiv \tau_\mu \otimes \sigma_\nu \). Two sets of Pauli matrices \( \{ \tau_\mu \} \) and \( \{ \sigma_\nu \} \) operate on parity and spin indices, respectively, and \( \tau_0 \) and \( \sigma_0 \) are the two-dimensional identity matrices. The model in Eq. (1) then describes the mixing of different parity states with unit angular momentum difference. To close the anticommuting Clifford algebra, which contains five elements in the space of four-dimensional Hermitian matrices, we define \( \Gamma_4 = \Gamma_{30} \) and \( \Gamma_5 = \Gamma_{20} \).

Unless mentioned, throughout the paper we set \( v_x = v_y = v_z = v \) (say), which brings Eq. (1) into a fully rotationally symmetric form \( \hat{h}(k) = v \Gamma_1 k \), where the summation over the repeated spatial indices is assumed, and \( h(k) \) describes an isotropic, doubly Kramers degenerate Dirac cone centered at the \( \Gamma = (0, 0, 0) \) point [see Sec. III B]. The generators of rotations about the \( x \)-, \( y \)- and \( z \)-axis are respectively \( \Gamma_{01} \), \( \Gamma_{02} \), and \( \Gamma_{03} \). For example, a rotation by an angle \( \theta \) about the \( j \)th axis is generated by \( \Gamma_j(\theta) = \exp[i\theta \Gamma_{0j}/2] \). Specifically, when \( \theta = \pi/2 \) and \( j = z \), \( k \rightarrow (k_y, -k_x, k_z) \), such that \( \Gamma_z(\pi/2) \hat{h}(k) \Gamma_z^{-1}(\pi/2) = \hat{h}(k) \) in an isotropic system. Therefore, the noninteracting Hamiltonian remains invariant under the four-fold \((C_4)\) rotation about the \( z \)-axis. Similarly, under the \( C_4 \) rotations about the \( x \) and \( y \) axes \( k \rightarrow (k_x, k_z, -k_y) \) and \( (-k_x, k_y, k_z) \), respectively. It is then straightforward to show that \( \hat{h}(k) \) remains invariant under \( O(3) \) rotations.

The \( O(3) \) rotational symmetry of the low-energy model is only plausible when the underlying lattice structure possesses a cubic symmetry. The isotropic Fermi velocity in a low-energy theory is then \( v = v \), where \( v \) is the hopping amplitude and \( \tau \) is the lattice constant. However, known Dirac materials often exhibit tetragonal symmetry [7, 8], with elongated (or shortened) lattice constant along one of the three principle axes, for example. In a tetragonal environment this results in the breakdown of the \( O(3) \) rotational symmetry down to an in-plane \( O(2) \) one about the \( z \)-axis. In other words, \( v_x = v_y \neq v_z \) in a tetragonal Dirac material. In Sec. III C we discuss the effects of weak rotational symmetry breaking on interacting chiral Dirac fermions in a perturbative manner.

The gapless chiral Dirac system is invariant under the discrete parity transformation \((P)\), reversal of time \((T)\), and charge conjugation \((C)\). In our representation of the four-component spinor \( \Psi_k \) and the \( \Gamma \) matrices, the above transformations are realized as \( P \Psi_k = \Gamma_{30} \Psi_{-k} \), \( T \Psi_k^\dagger T = -\Gamma_{02} \Psi_{-k} \) and \( C \Psi_k C = -i \Gamma_{12} \Psi_k \). The time-reversal operator is antunitary and can be written as \( T = U^\dagger K \), where \( U = \Gamma_{02} \) is the unitary part and \( K \) is complex conjugation, such that \( T^2 = -1 \), yielding Kramers degenerate Dirac bands.

The noninteracting system remains invariant also under a continuous global \( U(1) \) chiral rotation \((\theta_{ch})\), under which \( \Psi_k \rightarrow \exp[i\theta_{ch} \Gamma_{10}] \Psi_k \), where the matrix \( C = \Gamma_{10} \) is the generator of the chiral rotation. We note that two mass matrices, namely \( \Gamma_4 \) and \( \Gamma_5 \), that anticommute with \( \hat{h}(k) \), break the global \( U(1) \) chiral symmetry of the massless Dirac Hamiltonian. While the scalar mass \((\Gamma_4)\) only breaks the continuous chiral symmetry, the pseudoscalar mass \((\Gamma_5)\) in addition breaks the discrete \( P \) and \( T \) symmetries. Furthermore, the noninteracting Hamiltonian \( \hat{h}(k) \) possesses a pseudospin \( SU(2) \) chiral symmetry, which only becomes visible once we Nambu double the spinor basis, as shown in Sec. III C. Therefore, the noninteracting gapless chiral Dirac system enjoys a \( U(1) \otimes SU(2) \) chiral symmetry.

The imaginary time \((\tau)\) Euclidean action for such a collection of noninteracting chiral Dirac fermions reads

\[
S_0 = \int d\tau \int d^d x \, \Psi_{+,x}^\dagger \left[ \partial_{\tau} + \hat{h}(k) \rightarrow -i \nabla \right] \Psi_{+,x},
\]

where \( d \) is the number of spatial dimensions. The absence of a chemical potential term implies the fine tuning of the Fermi energy to the band touching Dirac point, whereby the Fermi surface shrinks to just one point at the center of the Brillouin zone (see, however, Ref. 13). While constructing the interacting theory, besides the spatial rotational symmetry, we impose \( P \), \( T \) and \( C \) symmetries separately. But, we do not enforce invariance under \( U(1) \) chiral rotations or pseudospin \( SU(2) \) rotations explicitly. Instead, we demonstrate restoration of the chiral symmetry as an emergent phenomena at various RG fixed points that can be accessed by tuning the strength of interactions among Dirac fermions. For the time being however our noninteracting single-flavor model is chiral symmetric, which at first glance seems to be at odds with the Nielsen-Ninomiya “no-go” theorem 17, when it comes to constructing a corresponding lattice model. We proceed with pointing at a possible way out of this conundrum. Readers solely interested in the field theoretic results may wish to skip the following section. Nevertheless, given that two-dimensional genuine chiral Dirac-Hubbard model on a square lattice 13, and three-dimensional Dirac-Hubbard on a cubic lattice 19 have been studied recently using quantum Monte Carlo simulations, a concrete lattice realization of three-dimensional massless chiral Dirac fermions should facilitate future numerical investigations of this system, where our results can be scrutinized.

## B. Lattice model

In this paper we consider a single flavor of four-component massless chiral Dirac fermions in a continuum theory, the translation of which to a lattice model is, however, a nontrivial task. The challenge originates from constructing a lattice version of the derivative operator while taking \( k \rightarrow -i \nabla \) in Eq. (1). Nevertheless,
symmetrizing the derivative from basic calculus as
\[
\frac{df(x)}{dx} = \lim_{a \to 0} \frac{f(x + a) - f(x - a)}{2a}
\]  
(3)

proffers a tempting lattice version, in which one treats \(a\) as the lattice constant, and arrives at the nearest neighbor description, where in one dimension the eigenenergies are \(\epsilon_k \sim t \sin(ka)\), the blue squares in Fig. 2. Here \(k\) is the discrete valued lattice momentum and \(t\) is a hopping amplitude, setting the energy scale. However, this construction results in so-called fermion doublers at the edges of the Brillouin zone \((k = \pm \pi/a)\). In fact in \(d\) dimensions one finds \(2^d\) number of low-energy Dirac points compared to the continuum theory \([24]\). A common remedy to this problem is the introduction of a momentum-dependent Wilson mass, which gaps the doublers, but vanishes at the desired \(\Gamma\) point \([21, 22]\). But, such a construction comes with its own intricacies. As such adding another discrete symmetry \((\mathcal{P}, \mathcal{T}, \mathcal{C})\) preserving anticommuting mass matrix \((\mathcal{G}_4)\) spoils the genuine microscopic chiral symmetry of Dirac fermions. Even though the resulting higher order in momentum \((\propto k^2)\) terms are irrelevant in the RG framework, yielding an emergent chiral U(1) symmetry, the nucleation of \(\mathcal{P}, \mathcal{T}\) and \(\mathcal{C}\) symmetric, but chiral U(1) symmetry breaking scalar mass \((\mathcal{G}_4)\) at strong coupling then takes place through a fluctuation driven first-order transition, as it does not break any bonafide microscopic symmetry \([25]\). So, we seek for a lattice realization of single flavored massless Dirac fermions with genuine microscopic chiral symmetry.

The doubler problem can also be overcome by extending the nearest neighbor derivative to next nearest neighbor \([20]\), with hopping parameters \(t_1 = (1 + \mu)/(2\mu)\) and \(t_2 = (\mu - 1)/(4\mu)\) between the first and second neighbors, respectively. Here \(\mu\) is a tuning parameter that recovers the nearest neighbor limit for \(\mu = 1\). The corresponding spectrum is then given by
\[
\epsilon_k = t_1 \sin(ka) + t_2 \sin(2ka).
\]  
(4)

Upon sending \(\mu \to 0\), the Fermi velocity of the doublers gets pushed to infinity, and due to the finite sampling of the \(k\) axis there will be no additional low-energy mode in the Brillouin zone, see red diamonds in Fig. 2. However, this construction results in much of the spectral weight being pushed to high energies \(\epsilon_k \gg \pi t\).

The aforementioned complications are solved by using the Stanford Linear Accelerator (SLAC) lattice derivative \([21]\), a pedagogic construction of which is provided in Ref. [25]. The three main ingredients of the SLAC construction are the following. (i) Identifying the (continuum) derivative operation with convolving a function \(f(x)\) with the negative derivative of the Dirac delta function \(f'(x) = -\delta'(x) * f(x)\). (ii) Applying a low-pass filter to the continuum formalism to restrict it in momentum space to the first Brillouin zone. (iii) Finally, sampling the resulting operator on a lattice. Since the Fourier transform of the Dirac delta function is unity, and the ideal low-pass filter in position space is \(\sin(\pi x/a)/(\pi x)\), steps (i) and (ii) can be summarized as
\[
-(\delta_{\text{filt}}(x))' = a \sin(\frac{\pi x}{a}) - \pi x \cos(\frac{\pi x}{a}) \frac{\pi}{a x^2},
\]  
(5)

where \(\delta_{\text{filt}}(x)\) is the filtered Dirac delta operator that has Fourier components only in the first Brillouin zone. By performing the Taylor expansion we find that \(\delta_{\text{filt}}(x)'\) vanishes linearly around \(x = 0\), and the SLAC construction does not have an on site component. The ideal lattice derivative is then obtained by sampling the expression from Eq. [5] at the lattice points \(x = na\), multiplied by the lattice spacing \((a)\), yielding
\[
\Delta(n) = \begin{cases} 0, & \text{if } n = 0 \\ (-1)^n a, & \text{otherwise.} \end{cases}
\]  
(6)

FIG. 2: Spectrum of the one-dimensional Hamiltonian \(\hat{h}_{1D} = \frac{-i t_0}{2a}(d/dx)\) for three different choices for the lattice derivative. The blue squares show the simplest, nearest neighbor approach [see Eq. [3]], which results in doublers around \(k = \pm \pi/a\). The red diamonds correspond to the next nearest neighbor spectrum from Eq. [4] for \(\mu = 0.12\). Notice that the Fermi velocity of the doubler around \(k = \pm \pi/a\) in this case is greater than that near the center of the Brillouin zone \((k = 0)\). This effect is exacerbated by further decreasing \(\mu\), which eventually gets rid of the doublers, but pushes much of the spectral weight to high energies \((\epsilon_k \gg \pi t)\). The black dots represent the ideal derivative, the spectrum of which is devoid of doublers and remains linear in the entire Brillouin zone, thereby yielding a genuine chiral symmetry at the microscopic level. Notice that around \(k \approx 0\) all three constructions recover \(k\)-linear dispersion. This construction can be generalized to realize three-dimensional massless Dirac fermions with microscopic chiral symmetry, see Eq. [7].
By identifying the position space derivative with convolution from Eq. (3), we get rid of the doublers, but pay the price of our operator now being non-local, albeit only along the principal axes.

The resulting tight binding Hamiltonian which corresponds to Eq. (1) on a three-dimensional cubic lattice with linear dimension \( L = 2N + 1 \) in each direction reads

\[
h_{\text{latt}} = -i \sum_{\mathbf{R}} \sum_{j=1}^{3} \sum_{n=1}^{N} \Delta(n) \Psi_{\mathbf{R}+n\hat{\mathbf{e}}(j)}, \quad (7)
\]

where \( \mathbf{R} \) denotes the position of the lattice sites and \( \hat{\mathbf{e}}(j) \) is a vector of length \( a \) in the \( j \)th principal direction. While the locality of the SLAC derivative on a conceptual level can be subject to debate, the long-range behavior under the tuning of non-thermal parameters, such as the strength of the local interactions in this case. To proceed we introduce a hard ultraviolet momentum cutoff \( \Lambda \sim 2\pi/a \), which replaces the cubic Brillouin zone by a spherical one. Here \( a \) bears the dimension of the lattice constant. In the RG procedure we then gradually decrease \( \Lambda \) by repeatedly integrating out a thin Wilsonian momentum-shell defined as \( \Lambda^{-1} < |\mathbf{k}| < \Lambda \), where

These three discrete symmetries permit only 12 terms with \( \mu \nu \neq \rho \lambda \) and 16 quartic terms with \( \mu \nu = \rho \lambda \). The spatial O(3) rotational symmetry eliminates the former set of quartic terms, and organizes remaining 16 terms of the form \( (\Psi^\dagger \Gamma_{\mu\nu} \Psi)^2 \) into eight distinct interaction channels. For a detailed derivation see Appendix A. The interacting Lagrangian containing all symmetry allowed local quartic terms is then given by

\[
L_{\text{int}} = \sum_{\mu=0}^{3} g_{\mu}^s (\Psi^\dagger \Gamma_{\mu0} \Psi)^2 + \sum_{\mu=0}^{3} g_{\mu}^t \left( \sum_{j=1}^{3} (\Psi^\dagger \Gamma_{\mu j} \Psi)^2 \right). \quad (8)
\]

The four-fermion interactions with coupling constants \( g_{\mu}^s \) and \( g_{\mu}^t \) for \( j = 1, 2, 3 \) correspond to spin-independent (spin-dependent) mixing of even and odd parity states. By contrast, \( g_{\mu}^s \) corresponds to short-range density-density (ferromagnetic) interaction. Notice that we did not enforce chiral U(1) symmetry on \( L_{\text{int}} \) at the bare level. Consequently, the components of chiral U(1) vectors appear as independent quartic terms in Eq. (8). Namely, two terms containing \( \Gamma_{20} \) and \( \Gamma_{10} \) (\( \Gamma_{2j} \) and \( \Gamma_{3j} \)) acquire two separate coupling constants \( g_{s}^j \) and \( g_{t}^j \) (\( g_{s}^j \) and \( g_{t}^j \)), respectively, at the microscopic level. On other hand, in Weyl semimetals the chiral U(1) symmetry is associated with the translational symmetry in the continuum limit [37, 38]. Therefore, the interacting theory must preserve the chiral U(1) symmetry in Weyl semimetals.

However, the number of linearly independent four-fermion terms is only four due to the existence of the Fierz identity [39] (see Appendix B). We choose them to be the ones appearing with the coupling constants \( \{g_{s}^j\} \). The corresponding interacting Euclidean action reads

\[
S_{\text{int}} = \int d\tau \int d^4x \left( \sum_{\mu=0}^{3} g_{\mu}^s (\Psi^\dagger \Gamma_{\mu0} \Psi)^2 \right). \quad (9)
\]

Notice that eight quartic terms appearing in \( L_{\text{int}} \) can be decomposed into two sectors, the ones transforming as scalars (three-component vectors) under spatial O(3) rotations and appearing with coupling constants \( g_{s}^j \) (\( g_{t}^j \)), for \( \mu = 0, \cdots, 3 \). Consequently, we can choose four quartic terms in the singlet channel as the independent ones. Next we study the interacting model \( S_0 + S_{\text{int}} \) within the framework of Wilsonian momentum-shell RG analysis.

### A. Renormalization group analysis

To study the quantum critical properties of this system, we examine its low-energy and long-wavelength behavior under the tuning of non-thermal parameters, such as the strength of the local interactions in this case. To proceed we introduce a hard ultraviolet momentum cutoff \( \Lambda \sim 2\pi/a \), which replaces the cubic Brillouin zone by a spherical one. Here \( a \) bears the dimension of the lattice constant. In the RG procedure we then gradually decrease \( \Lambda \) by repeatedly integrating out a thin Wilsonian momentum-shell defined as \( \Lambda^{-1} < |\mathbf{k}| < \Lambda \), where
$\ell > 0$ is the logarithm of the RG scale. Finally, we restore the Euclidean action $(S_0 + S_{\text{int}})$ into its original form, but in terms of the renormalized quantities.

The scaling of various quantities appearing in the action relative to $k$ is of crucial importance as we gradually lower the ultraviolet cutoff. The scaling dimensions of momentum and frequency are respectively $|k| = 1$ and $|\omega| = z$, where the dynamic scaling exponent $z = 1$ for linearly dispersing Dirac fermions. The scale-invariance of $S_0$ requires that $[\Psi] = d/2$, from which we obtain the scaling dimension of the quartic coupling constants to be $[g^s_\mu] = z - d$. Therefore, local interactions in three-dimensional Dirac systems are irrelevant in the RG sense and the Dirac cone remains stable as long as they are sufficiently weak. On the other hand, strong enough local interactions can drive the system through quantum phase transitions into various broken symmetry phases. The scaling of various quantities appearing in the action relative to $k$ is of crucial importance as we gradually lower the ultraviolet cutoff. The scaling dimensions of momentum and frequency are respectively $|k| = 1$, whereas interactions become marginal when $d$ is of order $1$. Note that vanishing density requires that $[\Psi] = 0$ is the logarithm of the RG scale. Finally, we restore the Euclidean action $(S_0 + S_{\text{int}})$ into its original form, but in terms of the renormalized quantities.

Evaluating the relevant Feynmann diagrams up to one-loop order [10], we arrive at the following leading-order RG flow equations for the coupling constants

$$
\frac{dg^s_\mu}{d\ell} = -\epsilon g^s_\mu - (g^s_\mu g^s_\nu + g^s_\nu g^s_\mu + 2g^s_\mu g^s_\nu),
$$

$$
\frac{dg^1_\mu}{d\ell} = -\epsilon g^1_\mu + g^1_\mu g^s_\nu + g^s_\nu g^1_\mu - 4g^1_\mu g^s_\nu,
$$

$$
\frac{dg^2_\mu}{d\ell} = -\epsilon g^2_\mu + 3(g^1_\mu)^2 - 2(g^s_\mu g^s_\nu + g^s_\nu g^s_\nu - g^s_\mu g^s_\nu),
$$

$$
\frac{dg^3_\mu}{d\ell} = -\epsilon g^3_\mu + 3(g^s_\nu)^2 - 2(g^s_\mu g^s_\nu + g^s_\nu g^s_\nu - g^s_\mu g^s_\nu),
$$

$$
\frac{dg^4_\mu}{d\ell} = +3g^1_\mu (g^s_\mu - g^s_\nu).
$$

Here we made the substitution $\Delta_{\mu \nu} g^s_\mu \rightarrow g^s_\mu$, such that the flow equations are expressed in terms of dimensionless couplings. Note that the flow equations are symmetric under the exchange of $g^s_\mu$ and $g^s_\nu$, manifesting the chiral U(1) symmetry of the noninteracting system.

### B. Fixed points and critical exponents

We examine the quantum critical phenomena by analyzing the fixed point structure of the RG flow equations from Eq. (10), which from now we denote as $\beta_{g^s_\mu} = d^2 g^s_\mu/d\ell^2$. A fixed point $g^s_\mu$ in the four-dimensional coupling constant space is found by simultaneously solving $\beta_{g^s_\mu}(g^s_\mu) = 0$, where $\mu = 0, \cdots , 3$ and $g^s = (g^s_0, g^s_1, g^s_2, g^s_3)$. Each fixed point is characterized by linearizing the RG flow around it. To this end we construct a four-dimensional stability matrix ($M$) and compute its eigenvalues at various fixed points. The elements of the stability matrix are explicitly given by

$$
M_{\mu+1,\nu+1} = \frac{d^2 \beta_{g^s_\mu}}{d^2 g^s_\nu},
$$

where $\mu, \nu = 0, \cdots , 3$. A negative (positive) eigenvalue of $M$ corresponds to a stable (unstable) eigendirection, and the number of unstable directions characterizes a given fixed point. For example, a QCP (BCP) has one (two) unstable direction(s).

We find all together nine fixed points [33], of which the trivial one at $g^s = (0, 0, 0, 0)$ is the fully attractive noninteracting Gaussian fixed point. It describes a stable Dirac semimetal for sufficiently weak, but generic short-range interactions. The rest of the eight fixed points at nontrivial strength of the coupling constants are reported in Table I. Four of them are QCPs (C1, . . . , C4) and the remaining four are BCPs (B1, . . . , B4). The existence of BCPs is necessary for the continuity of the RG flow trajectories. As such they separate the basins of attraction of various QCPs. All fixed points are located at $g^s \sim \epsilon$, which can be seen from Eq. (10).

The dynamic scaling exponent $z = 1$ at all four QCPs. On the other hand, the inverse of the positive eigenvalue of the stability matrix ($M$) determines the correlation length exponent ($\nu$) at each QCP. To the leading order in the $\epsilon$ expansion we obtain $\nu^{-1} = \epsilon$, and $\nu = 1/2$ in $d = 3$. The mean-field value of the correlation length exponent is an exact result, as the system resides at the upper-critical three spatial dimensions [10, 11].

From the locations of the fixed points we can conclude the following. Two QCPs C1 and C4 are chiral symmetric, where the couplings of the two components of the U(1) chiral vector $g^s_\mu$ and $g^s_\nu$ are identical. The remaining two QCPs, namely C2 and C3, are chiral partners of each other and their locations transform into one another under the chiral rotation $g^s_\mu \leftrightarrow g^s_\nu$. On the other hand, the four BCPs form two such pairs of chiral partners, namely under $g^s_\mu \leftrightarrow g^s_\nu$ (1) B1 $\leftrightarrow$ B2 and (2) B3 $\leftrightarrow$ B4. To further anchor the restoration of chiral symmetry at various RG fixed points next we compute the scaling dimension of all symmetry allowed fermion bilinears.

### C. Nambu doubling and emergent chiral symmetry

Sufficiently strong local electronic interactions destabilize a gapless Dirac liquid and drive the system through quantum phase transitions into various broken symmetry phases. Here we consider all such symmetry allowed particle-hole (or excitonic) and particle-particle (or superconducting or pairing) orders. To bring both sectors under a unified framework we extend the Dirac spinor following the Nambu doubling

$$
\Psi_k \rightarrow \Psi_{\text{Nam}} = \left[ \begin{array}{c} \Psi_k \\ \Gamma_{20} \Psi_{-k} \end{array} \right].
$$

Note that in the lower block we absorb the unitary part of the time-reversal operator (T), such that Ψ_{Nam} transform as Ψ_{L} under all symmetry operations [11]. The noninteracting Hamiltonian from Eq. (1) in this basis reads
\[
\hat{h}_{\text{Nam}}(k) = \eta_3 \sum_{j=1}^{3} v_j \Gamma_j k_j.
\]

The newly introduced set of Pauli matrices \{η_{\mu}\} operate on the Nambu or particle-hole indices, with \(\mu = 0, \ldots, 3\). The generator of the chiral U(1) symmetry in this basis becomes \(C = \eta_3 \Gamma_{10}\). Furthermore, the Nambu doubling allows us to unveil the *psuedospin* SU(2) chiral symmetry of the noninteracting system, generated by
\[
\mathbf{PS} = \{ \eta_1 \Gamma_{30}, \eta_2 \Gamma_{30}, \eta_3 \Gamma_{00} \},
\]
since \(\hat{h}_{\text{Nam}}(k), \mathbf{PS} = 0\). Specifically, \(\mathbf{PS}_3 = \eta_3 \Gamma_{00}\) is the number operator. Therefore a collection of noninteracting four-component massless Dirac fermions enjoys U(1)⊗SU(2) chiral symmetry, since \([C, \mathbf{PS}] = 0\). Previously, the pseudospin SU(2) symmetry has been discussed in the context of two-dimensional Hubbard model [13] [12] [14]. But, its imprints on three-dimensional interacting systems remained unexplored so far.

To appreciate the imprint of the enlarged chiral symmetry in the presence of interactions, next we consider all symmetry allowed fermion bilinears describing different orders in the Nambu doubled basis. The effective action containing all (excitonic and pairing) symmetry allowed local terms reads as
\[
S_{\text{local}} = \int dt \int d^3r \Psi_{\text{Nam}}^\dagger \hat{h}_{\text{exc}} + \hat{h}_{\text{pair}} \Psi_{\text{Nam}},
\]
where
\[
\hat{h}_{\text{exc}} = \Delta_0 \eta_3 \Gamma_{00} + \Delta_1 \eta_3 \Gamma_{10} + \Delta_2 \eta_0 \Gamma_{20} + \Delta_3 \eta_0 \Gamma_{30} + \sum_{j=1}^{3} \left[ \Delta_0^a \eta_0 \Gamma_{0j} + \Delta_1^a \eta_0 \Gamma_{1j} + \Delta_2^a \eta_3 \Gamma_{2j} + \Delta_3^a \eta_0 \Gamma_{3j} \right],
\]
and
\[
\hat{h}_{\text{pair}} = (\eta_1 \cos \phi + \eta_2 \sin \phi) \times \left[ \Delta_0^p \Gamma_{00} + \Delta_1^p \Gamma_{10} + \Delta_2^p \sum_{j=1}^{3} \Gamma_{2j} + \Delta_3^p \Gamma_{30} \right],
\]

with \(\phi\) as the U(1) superconducting phase. The real (imaginary) component of any pairing order corresponds to \(\phi = 0\) (\(\pi/2\)). Here \(\Delta^a_{\mu}\) is the conjugate field of the corresponding fermion bilinear.

The bilinears, their physical meanings together with the corresponding matrices and their transformations under various symmetry operations (discrete and continuous) are summarized in Table II. The two fully gapped phases in the particle-hole subspace are the scalar and pseudoscalar masses, which form a U(1) vector under the chiral U(1) rotation generated by \(C = \eta_3 \Gamma_{10}\). The Nambu basis accommodates two additional massive orders in the particle-particle sector, the scalar s-wave and pseudoscalar p-wave pairings [13] [20]. They form two copies of U(1) chiral vector, where the doubling is due to the gauge redundancy in the internal U(1) degree of freedom associated with the superconducting phase (\(\phi\)). Furthermore, the two tensor bilinears (coupled with the conjugate fields \(\Delta_s^a\) and \(\Delta_p^a\)) form other three copies of two-component chiral U(1) vector, where the threefold redundancy stems from the spatial O(3) symmetry. Additionally, there exist four three-component orders, each of which is a composite of a particle-hole and...
a particle-particle order and transforms as a vector under the pseudospin SU(2) chiral rotations, generated by $\mathbf{PS}$ [see Eq. (14)], as shown in Fig. 3.

To extract the scaling dimension of various fermion bilinears, first we compute the RG flow equations for the corresponding source terms or conjugate fields $\Delta_{\mu}^a$, where $\mu = 0, \cdots, 3$ and $a = s, t, p$. After evaluating the relevant Feynmann diagrams up to the one-loop order [40], we arrive at the following leading-order $\beta$ functions for $\Delta_{\mu}^a$:

$$\beta_{\Delta^a_0} = 0, \quad \beta_{\Delta^1_t} = 0, \quad \beta_{\Delta^2_p} = -\frac{3}{2}(g_s^a - g_1^a - 3g_2^a - g_s^a),$$

$$\beta_{\Delta^0_s} = -\frac{3}{2}(g_s^a - g_1^a - g_2^a - 3g_s^a),$$

$$\beta_{\Delta^1_s} = -g_s^a - g_1^a - g_2^a - g_s^a, \quad \beta_{\Delta^1_t} = -g_s^a - g_1^a + g_2^a + g_s^a,$$

$$\beta_{\Delta^1_p} = \frac{1}{2}(-g_0^a + g_1^a + g_2^a + g_s^a),$$

$$\beta_{\Delta^2_p} = 3 \left( g_0^a + g_1^a + g_2^a + g_s^a \right), \quad \beta_{\Delta^2_s} = \frac{3}{2}(g_s^a + g_1^a + g_s^a - g_2^a),$$

$$\beta_{\Delta^2_t} = g_0^a - g_1^a - g_2^a - g_s^a, \quad \beta_{\Delta^0_t} = 0,$$  \hspace{1cm} (18)

where $\beta_{\Delta^a} = d\ln \Delta_{\mu}^a/df - 1$. The right hand side of each equation corresponds to the one-loop corrections to the scaling dimension of the corresponding order parameter or fermion bilinear, which we compute at various RG fixed points (see Table I) and their values are reported in Table II.

Computation of one-loop corrections to the scaling dimensions for all excitonic and pairing orders reveals the emergent chiral symmetry at various RG fixed points. First we note that the bilinears that commute with $h_{\text{NNam}}(k)$, the fermionic density, chiral density and temporal vector pairing, do not receive any correction to their bare scaling dimension. The matrices associated with these bilinears are also the generators of U(1)⊗SU(2) chiral symmetry of the noninteracting system.

One can construct three chiral U(1) vectors by combining (1) the scalar and pseudoscalar excitonic masses, (2) two tensor order parameters, and (3) the scalar s-wave and pseudoscalar p-wave pairing masses, see Table II. Two components of any chiral U(1) vector acquire identical scaling dimensions at C1 and C4, while their scaling dimensions are exchanged between (a) C2 and C3, (b) B1 and B2, and (c) B3 and B4. Therefore, only C1 and C4 are chiral U(1) symmetric. On the other hand, the four-dimensional coupling constant space accommodates three chiral U(1) partner fixed points, namely (a) (C2,C3), (b) (B1,B2), and (c) (B3,B4), as we previously anticipated from their locations.

Also the possible restoration of the pseudospin SU(2) chiral symmetry can be anchored from the scaling dimensions of fermion bilinears at various RG fixed points. As such one can construct four three-component pseudospin SU(2) vectors by combining (1) the scalar excitonic and pairing masses, (2) the pseudoscalar excitonic and pairing masses, (3) fermion density and temporal vector pairing, and (4) Abelian current and spatial vector pairing, see Fig. 3. All components of each pseudospin vector acquire identical scaling dimensions at three QCPs, C2, C3 and C4, and at two BCPs, B3 and B4. Hence, these five fixed points are pseudospin SU(2) chiral symmetric. Therefore, while all the RG fixed points at least partially restore the chiral U(1)⊗SU(2) symmetry of the noninteracting system, it is fully restored only at the C4 QCP.

Even though the space of independent coupling constants is four-dimensional, the imprint of various chiral symmetric fixed points on the global phase diagram of interacting massless chiral Dirac fermions can be appreciated by focusing on its representative cut on the $(g_s^a; g_2^a)$ plane, as shown in Fig. [1] which we discuss next.

D. Phase diagram

Now we proceed to construct the phase diagram in the $(g_s^a; g_2^a)$ plane by numerically solving the $\beta$ functions of the coupling constants [see Eq. (10)] and the conjugate order parameter fields [see Eq. (18)]. We simultaneously run the flow equations for four coupling constants $(g_0^a)$ and all symmetry allowed source terms $(\Delta_{\mu}^a)$ for various choices of the bare coupling constants as a function of the RG time ($\ell$). Sufficiently weak but generic local interactions are irrelevant perturbation in three-dimensional Dirac semimetals due to the vanishing density of states ($\rho(E) \sim |E|^2$). Therefore, onset of any ordered phase takes place beyond a bare critical strength of interaction, which we identify from the divergence of at least one of the renormalized coupling constants as $\ell \rightarrow \infty$. At the same time at least one of the source terms diverges, which ultimately determines the pattern of the symmetry breaking in the ordered phase in an unbiased fashion. We pursue this approach to construct a representative cut of the global phase diagram for three-dimensional interacting massless chiral Dirac fermions, displayed in Fig. [1] which manifests an intriguing confluence of all four mass orders (the scalar and pseudoscalar excitonic and pairing masses), and the restoration of chiral and pseudospin symmetries among them. Note that at zero temperature nucleation of mass orders is energetically most favored as they isotropically gap the Dirac point and thereby optimally lower the free-energy (no competition with entropy [40]). Next we highlight the role of various RG fixed points on different segments of this phase diagram.

The chiral U(1) symmetric QCP C1 can be accessed for purely repulsive interactions $g_s^a, g_2^a > 0$ and it governs the continuous quantum phase transitions between Dirac semimetal and the two excitonic mass orders (the blue phase boundary in Fig. [1]). These two excitonic masses are degenerate along the $45^\circ$ red line, where we realize an axionic insulator [12][14]. A slight deviation from the red line in favor of $g_s^a (g_2^a)$ tips the balance in favor of the nucleation of pure scalar (pseudoscalar) excitonic mass.

The phase transitions out of the Dirac semimetal across the black phase boundary into the pseudoscalar excitonic and pairing (p-wave superconductor) masses is
governed by the SU(2) pseudospin symmetric QCP C2. In the absence of a Fermi surface, strong attractive interaction in at least one channel is required for the stability of a superconducting phase, which in this case occurs in the $g_z^s$ channel. These two orderings are degenerate along the 135° (orange) line. The basins of attraction of C1 and C2 are separated by the bicritical point B2, where the pseudoscalar exciton possesses the largest scaling dimension, see Table III. Still the transition to this ordered phase through B2 is continuous as it is accessed by holding one of its unstable directions fixed [15].

The rest of the phase diagram and the role of various fixed points therein can be appreciated by exploiting a mirror symmetry of the whole phase diagram, under which $g_z^s \leftrightarrow g_z^s$. Such a mirror symmetry is rooted in the underlying U(1) chiral symmetry and corresponds to a reflection about the 45° diagonal (dashed) line, defined by $g_z^s = g_z^s$, that brings the upper left triangle of the phase diagram onto its chiral partner, the bottom right triangle. Also note that the three-component scalar and pseudoscalar masses, constructed by combining the corresponding excitonic and pairing orders, can be rotated into each other by the generator of the chiral U(1) symmetry, see Table III. Still the transition to this ordered phase through B2 is continuous as it is accessed by holding one of its unstable directions fixed [15].

In summary and discussion

IV. SUMMARY AND DISCUSSION

Here we investigate the role of strong momentum-independent local or Hubbard-like electronic interactions among three-dimensional massless Dirac fermions that in the noninteracting system possess a global chiral U(1)$\otimes$SU(2) symmetry. We provide a lattice realization of such quasiparticle excitations in terms of the SLAC fermions, which should facilitate future numerical investigation of this subject using quantum Monte Carlo simulations [18,19], for example. We show that an isotropic interacting Dirac semimetal is described in terms of only four linearly independent local quasiparticle interactions. Besides studying the possible ordered or broken symmetry

E. Anisotropic Dirac semimetal

Finally, we address the breakdown of the O(3) rotational symmetry down to an in-plane O(2) invariance about the $z$-axis, which manifests through an anisotropy between the perpendicular and the $z$ components of the Fermi velocity, i.e., $v_x = v_y = v_\perp \neq |v_z|$. Due to such a reduced symmetry, all three-component four-fermion terms get split into the perpendicular and $z$ components, namely $g_\mu^s \rightarrow (g_\mu^0, g_\mu^s)$, where $\mu = 0, \cdots, 3$, see Eq. (8). The interacting Lagrangian then contains 12 quartic terms, out of which only five are linearly independent due to the Fierz constraint. See Appendix B for detailed derivation. To account for the reduced symmetry, we take the fifth independent quartic term to be $g_z^s(\psi^\dagger \Gamma_{13} \psi)^2$. Assuming sufficiently weak rotational symmetry breaking, we compute the one-loop renormalization of $g_z^s$ only up to linear order in $g_z^s$, yielding

$$\frac{dg_z^s}{d\ell} = (-\epsilon - g_0^s - 3g_z^0 - 2g_z^s - 2g_3^s) g_z^s + O ((g_z^s)^2).$$

(19)

Since we are interested in capturing the leading order effects of weak rotational symmetry breaking, all the Feynman diagrams are computed with isotropic Dirac kernel. The relevance of the rotational symmetry breaking can be estimated by computing the scaling dimension of $g_z^s$ at all the fixed points reported in Table III for the isotropic system. Evaluating the right hand side of Eq. (19) at the eight fixed points from Table III we find

$$\frac{\text{d} \ln g_z^s}{\text{d} \ell} \bigg|_{C1} = -1.251 \epsilon, \quad \frac{\text{d} \ln g_z^s}{\text{d} \ell} \bigg|_{C2/C3} = -1.594 \epsilon,$$

$$\frac{\text{d} \ln g_z^s}{\text{d} \ell} \bigg|_{C4} = \epsilon, \quad \frac{\text{d} \ln g_z^s}{\text{d} \ell} \bigg|_{B1/B2} = \frac{5}{3} \epsilon,$$

$$\frac{\text{d} \ln g_z^s}{\text{d} \ell} \bigg|_{B3/B4} = -0.155 \epsilon.$$

(20)

Therefore, slight distortion of the Dirac cone is an irrelevant perturbation in the close vicinity of all the fixed points, except C4. In other words, C4 turns into a BCP even for sufficiently weak breaking of the rotational symmetry. Therefore, this QCP cannot be found in general in a three-dimensional interacting Dirac system. We also note that the irrelevance of $g_z^s$ at the BCPs B3 and B4 is weak, in comparison to those near C1, C2, C3, B1 and B2. Therefore, it is conceivable that these two BCPs ultimately turn into tricritical points with three relevant directions in a strongly anisotropic Dirac semimetal, which we leave for a future investigation.
phases in this system, which set in through continuous quantum phase transitions, we also pay special attention to the restoration of partial and full chiral symmetry at various interacting fixed points. By performing a leading-order field theoretic RG analysis, controlled by a small parameter $\epsilon = d - 1$, about the lower-critical one spatial dimension $(d = 1)$, we find that an isotropic interacting chiral Dirac semimetal altogether supports nine RG fixed points. One of them corresponds to the noninteracting trivial Gaussian fixed point, describing a stable Dirac semimetal for sufficiently weak, but generic short-range interactions. On the other hand, the system also supports four quantum critical $(C)$ and four bicritical $(B)$ fixed points at finite interaction couplings $(\sim \epsilon)$, where $i = 1, 2, 3, 4$, see Table I.

Even though we do not impose (partial or full) chiral symmetry on the interacting theory $S_{\text{int}}$ at the bare level, two QCPs, namely C1 and C4, transform as chiral U(1) scalars, while the remaining six fixed points (C2,C3), (B1,B2) and (B3,B4) pairwise transform as three two-component vectors under the chiral U(1) rotations. In addition, the pseudospin SU(2) chiral symmetry gets restored at three QCPs (C2, C3 and C4) and two BCPs (B3 and B4). Therefore, only one fixed point, namely C4, enjoys the full chiral U(1)⊗SU(2) symmetry of the noninteracting systems, see Tables I, II and III.

The dynamic scaling exponent ($z$) and correlation length exponent ($\nu$) at all the QCPs are respectively $z = 1$ and $\nu^{-1} = \epsilon$. Together they determine the scaling of the transition temperature $T_c \sim \delta^z \nu$, of the ordered states (up to a logarithmic correction due to the breakdown of the hyperscaling hypothesis in $d = 3$), where $\delta$ is the reduced distance from a critical point. The value of $\nu = 1/2$ is an exact result as the system resides at the upper critical three spatial dimension [10, 11]. The momentum shell RG procedure although breaks the space-(imaginary)time Lorentz symmetry of the noninteracting system, it does not obscure the restoration of internal chiral symmetry at various RG fixed points.

We also demonstrate the imprints of some of these fixed points and emergent chiral symmetry among competing phases on a representative cut of the zero temperature global phase diagram, shown in Fig. I. This phase diagram displays an intriguing confluence of four competing mass orders, the scalar and pseudoscalar excitonic and superconducting masses, which are the energetically most favored ordered states at zero temperature as they uniformly and isotropically gap the Dirac point. In particular, we find high-symmetry lines in the phase diagram along which the chiral U(1) symmetry between two excitonic (scalar and pseudoscalar) masses and the pseudospin SU(2) symmetry among scalar or pseudoscalar excitonic and superconducting masses get restored. We also note that the phase diagram displays a chiral mirror symmetry about the 45° diagonal across which all the scalar and pseudoscalar mass orders transform into each other. Finally, it is worth pointing out that the arrangements among the competing and neighboring phases in the phase diagram are consistent with our previously proposed “selection rule and organization principle” in Ref. [10]. In particular, one can immediately verify the following. (1) A quartic interaction $(\Psi^\dagger_{\text{Nam}}\eta_{\mu}\Gamma_{\nu}\Psi_{\text{Nam}})^2$, written in the Nambu doubled basis $\Psi_{\text{Nam}}$ [see Eq. (12)], is conducive for the nucleation of an ordered state, represented by the fermion bilinear $\Psi^\dagger_{\text{Nam}}O\Psi_{\text{Nam}}$, only if (a) $O \equiv \eta_{\mu}\Gamma_{\nu}$ or (b) $\{O, \eta_{\mu}\Gamma_{\nu}\} = 0$. (2) Two ordered phases, represented by the fermion bilinears $\Psi^\dagger_{\text{Nam}}O_1\Psi_{\text{Nam}}$ and $\Psi^\dagger_{\text{Nam}}O_2\Psi_{\text{Nam}}$ reside next to each other only when $\{O_1, O_2\} = 0$.

Finally, we show that a weak anisotropy of the Dirac cone leaves the nature of various RG fixed points unchanged, except the fully U(1)⊗SU(2) chiral symmetric critical point C4. Specifically, this critical point gets converted into a bicritical point even in a weakly anisotropic Dirac system. A complete RG analysis, fixed point structure and the phase diagram in a three-dimensional anisotropic chiral Dirac semimetal is, however, left for a future investigation.

Here we address the role of electronic interactions and chiral symmetry restorations by performing a RG analysis about the lower-critical one spatial dimension. In the future, we will complement this analysis by performing an alternative RG analysis about the upper-critical three spatial dimension by accounting for order-parameter fluctuations within the framework of the Gross-Neveu-Yukawa theory [10]. The existing methodology only allows to demonstrate the restoration of high-symmetry among the dominant mass orders [37]. Therefore, a substantial generalization of the Gross-Neveu-Yukawa formalism is needed in order to demonstrate the restoration of partial or full chiral symmetry among all symmetry allowed fermion bilinears at RG fixed points, which therefore deserves a separate investigation.

Appendix A: Symmetry classification of four-fermion interaction

The momentum-independent local four-fermion interactions are captured by the quartic terms of the form $(\Psi^\dagger\Gamma_{\mu\nu}\Psi)(\Psi^\dagger\Gamma_{\rho\lambda}\Psi)$, where $\mu, \nu, \rho, \lambda = 0, \cdots, 3$. By imposing discrete parity ($\mathcal{P}$), time-reversal ($\mathcal{T}$), and charge conjugation ($\mathcal{C}$) symmetries, we reduce 136 possible interaction terms to the ones where both $\Psi^\dagger\Gamma_{\mu\nu}\Psi$ and $\Psi^\dagger\Gamma_{\rho\lambda}\Psi$ are either even or odd under $\mathcal{P}$, $\mathcal{T}$ and $\mathcal{C}$ separately, such that each quartic term is invariant under all three individual discrete symmetries. The classification of sixteen fermion bilinears under these three discrete symmetries is displayed in Table IV. As there are no two
identical rows in this table, there exists no interaction term that mixes any two different rows. Hence, the remaining four-fermion terms that are invariant under $\mathcal{P}$, $\mathcal{T}$ and $\mathcal{C}$ are

\[
\begin{align*}
\langle \Psi^\dagger (\Gamma_{\mu_0} \Psi)^2 & \quad (16 \text{ of them}), \quad \text{(A1)} \\
\langle \Psi^\dagger (\Gamma_{\mu_1} \Psi)(\Psi^\dagger \Gamma_{\mu_2} \Psi) & \quad (12 \text{ of them}), \quad \text{(A2)}
\end{align*}
\]

where $j \neq k = 1, 2, 3$.

The number of quartic terms is further reduced when we invoke the spatial rotational symmetry. First of all, all terms from (A2) get eliminated, as they do not transform as scalars nor as vectors under the O(3) spatial rotations. Furthermore, it organizes (A1) into four scalars (O(3) vectors) for $\Gamma_{\mu_0}$ ($\Gamma_{\mu_j}$), with $j = 1, 2, 3$. Therefore, the eight symmetry allowed four-fermion terms are of the form

\[
\langle \Psi^\dagger \Gamma_{\mu_0} \Psi \rangle^2 \text{ and } \sum_{j=1}^{3} \langle \Psi^\dagger \Gamma_{\mu_j} \Psi \rangle^2
\]

(A3)

In Eq. (8) the matrices $\Gamma_{\mu_0}$ and $\Gamma_{\mu_j}$ appear with couplings $g_0^2$, $g_j^2$ respectively. We note that each component of $\Gamma_{\mu_0}$ ($\Gamma_{\mu_j}$) for $\mu = 0, \cdots, 3$ transforms as scalar (three-component vector) under the spatial O(3) rotations, generated by $\{\Gamma_{01}, \Gamma_{02}, \Gamma_{03}\}$. As the O(3) group is isomorphic to SU(2), we can immediately conclude that the total number of linearly independent quartic terms in an isotropic Dirac semimetal is four, the dimensionality of the vectors $\Gamma_{\mu_0}$ and $\Gamma_{\mu_j}$. Furthermore, we can choose four O(3) scalar quartic terms ($\langle \Psi^\dagger \Gamma_{\mu_0} \Psi \rangle^2$ as the linearly independent four-fermion interactions. Next we explicitly demonstrate these outcomes using the Fierz identity.

### Appendix B: Fierz reduction of four-fermion interaction

Given a complete basis of Hermitian matrices, the Fierz identity allows us to express any four-fermion term ($\langle \Psi^\dagger \Gamma_{\mu_0} \Psi \rangle\langle \Psi^\dagger \Gamma_{\rho_0} \Psi \rangle$ as a linear combination of the others. Schematically, the Fierz relation can be written as

\[
\langle \Psi^\dagger \Gamma_{\mu_0} \Psi \rangle\langle \Psi^\dagger \Gamma_{\rho_0} \Psi \rangle = \frac{1}{16} \sum_{\alpha,\beta,\gamma,\delta} \langle \Psi^\dagger \Gamma_{\alpha_0} \Psi \rangle \langle \Psi^\dagger \Gamma_{\gamma_0} \Psi \rangle
\]

(B1)

where $\alpha, \beta, \gamma, \delta = 0, \cdots, 3$. Next we demonstrate the general principle to find linearly independent quartic terms in a given interacting model. For example, if $X$ is an array of the four-fermion terms, then the above Fierz relation can be cast as

\[
X = MX \Rightarrow (M - 1)X \Rightarrow FX = 0,
\]

(B2)

where $M$ contains the linear connections among the quartic terms due to Eq. (B1), and $F = M - 1$ is the Fierz matrix. The number of linearly independent four-fermion terms is equal to $D(F) - R(F)$, where $D(F)$ and $R(F)$ are respectively the dimension and rank of the square matrix $F$. Since the isotropic and anisotropic DSM are bestowed with different symmetries, the explicit forms of the corresponding Fierz matrices and the numbers of independent quartic terms in these two cases are distinct. Therefore, we present the two cases separately following the general approach outlined above.

1. Isotropic Dirac semimetal

For the isotropic Dirac semimetal there are eight symmetry allowed quartic terms, see Eq. (8), which can be organized into $X$ according to

\[
X^T = \begin{bmatrix}
\langle \Psi^\dagger \Gamma_{00} \Psi \rangle^2, & \langle \Psi^\dagger \Gamma_{10} \Psi \rangle^2, & \langle \Psi^\dagger \Gamma_{20} \Psi \rangle^2, & \langle \Psi^\dagger \Gamma_{30} \Psi \rangle^2, & \sum_{j=1}^{3} \langle \Psi^\dagger \Gamma_{0j} \Psi \rangle^2, & \sum_{j=1}^{3} \langle \Psi^\dagger \Gamma_{1j} \Psi \rangle^2, & \sum_{j=1}^{3} \langle \Psi^\dagger \Gamma_{2j} \Psi \rangle^2, & \sum_{j=1}^{3} \langle \Psi^\dagger \Gamma_{3j} \Psi \rangle^2
\end{bmatrix}.
\]

(B3)
The corresponding eight-dimensional Fierz matrix reads as

\[
F_{iso} = \begin{pmatrix}
5 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
1 & 5 & -1 & -1 & 1 & 1 & -1 & -1 \\
1 & -1 & 5 & -1 & 1 & -1 & 1 & -1 \\
1 & -1 & -1 & 5 & 1 & -1 & 1 & 1 \\
3 & 3 & 3 & 3 & 3 & -1 & -1 & 1 \\
3 & -3 & -3 & 3 & 3 & -1 & 3 & 1 \\
3 & -3 & -3 & -3 & -1 & 1 & 3 & 1 \\
3 & -3 & -3 & -3 & -1 & 1 & 1 & 3 \\
\end{pmatrix},
\]

with \( R(F_{iso}) = 4 \). Therefore, the number of independent coupling constants is \( D(F_{iso}) - R(F_{iso}) = 4 \). Without any loss of generality, we choose the four single-component quartic terms containing \( \Gamma_{\mu} \), each of which transforms as a scalar under spatial \( O(3) \) rotations, as the independent ones, see Eq. (9). The remaining four quartic terms containing \( \Gamma_{\mu j} \), which for any given \( \mu \) transform as a three-component vector under spatial \( O(3) \) rotations, can be expressed as

\[
\sum_{j=1}^{3} (\Psi^{\dagger} \Gamma_{0j} \Psi)^2 = -2(\Psi^{\dagger} \Gamma_{00} \Psi)^2 - (\Psi^{\dagger} \Gamma_{10} \Psi)^2 - (\Psi^{\dagger} \Gamma_{20} \Psi)^2 - (\Psi^{\dagger} \Gamma_{30} \Psi)^2,
\]

\[
\sum_{j=1}^{3} (\Psi^{\dagger} \Gamma_{1j} \Psi)^2 = - (\Psi^{\dagger} \Gamma_{00} \Psi)^2 + 2 (\Psi^{\dagger} \Gamma_{10} \Psi)^2 - (\Psi^{\dagger} \Gamma_{20} \Psi)^2 - (\Psi^{\dagger} \Gamma_{30} \Psi)^2,
\]

\[
\sum_{j=1}^{3} (\Psi^{\dagger} \Gamma_{2j} \Psi)^2 = - (\Psi^{\dagger} \Gamma_{00} \Psi)^2 + (\Psi^{\dagger} \Gamma_{10} \Psi)^2 - 2 (\Psi^{\dagger} \Gamma_{20} \Psi)^2 + (\Psi^{\dagger} \Gamma_{30} \Psi)^2,
\]

\[
\sum_{j=1}^{3} (\Psi^{\dagger} \Gamma_{3j} \Psi)^2 = - (\Psi^{\dagger} \Gamma_{00} \Psi)^2 + (\Psi^{\dagger} \Gamma_{10} \Psi)^2 + (\Psi^{\dagger} \Gamma_{20} \Psi)^2 - 2 (\Psi^{\dagger} \Gamma_{30} \Psi)^2.
\]

Therefore, whenever we generate any one of these quartic terms through the quantum loop corrections, it is expressed in terms of the four quartic terms appearing in Eq. (9). Furthermore, the fact that an interacting isotropic chiral Dirac semimetal can be described by only four linearly independent quartic terms is consistent with the existence of four independent superconducting orders, tabulated in Table II (last four rows).

2. Anisotropic Dirac semimetals

When we introduce an anisotropy between the in-plane \( (v_x, v_y) \) and the perpendicular or out of the plane \( (v_z) \) components of the Fermi velocity (germane in a tetragonal system), each three-component quartic term splits into two, with the corresponding coupling constants splitting as \( g_\mu \rightarrow (g_\mu^1, g_\mu^2) \) for \( \mu = 0, \cdots, 3 \), yielding the interacting Lagrangian

\[
F_{ani} = g_0^2 (\Psi^{\dagger} \Gamma_{00} \Psi)^2 + g_0^2 (\Psi^{\dagger} \Gamma_{10} \Psi)^2 + g_0^2 (\Psi^{\dagger} \Gamma_{20} \Psi)^2 + g_0^2 (\Psi^{\dagger} \Gamma_{30} \Psi)^2 + g_0^2 \sum_{j=1}^{2} (\Psi^{\dagger} \Gamma_{0j} \Psi)^2 + g_0^2 (\Psi^{\dagger} \Gamma_{03} \Psi)^2 +
\]

\[
g_1^2 \sum_{j=1}^{2} (\Psi^{\dagger} \Gamma_{1j} \Psi)^2 + g_1^2 (\Psi^{\dagger} \Gamma_{13} \Psi)^2 + g_2^2 \sum_{j=1}^{2} (\Psi^{\dagger} \Gamma_{2j} \Psi)^2 + g_2^2 (\Psi^{\dagger} \Gamma_{23} \Psi)^2 + g_3^2 \sum_{j=1}^{2} (\Psi^{\dagger} \Gamma_{3j} \Psi)^2 + g_3^2 (\Psi^{\dagger} \Gamma_{33} \Psi)^2.
\]

Hence the array \((X)\) containing all the quartic terms reads

\[
X^T = \left[ (\Psi^{\dagger} \Gamma_{00} \Psi)^2, (\Psi^{\dagger} \Gamma_{10} \Psi)^2, (\Psi^{\dagger} \Gamma_{20} \Psi)^2, (\Psi^{\dagger} \Gamma_{30} \Psi)^2, \sum_{j=1}^{2} (\Psi^{\dagger} \Gamma_{0j} \Psi)^2, (\Psi^{\dagger} \Gamma_{03} \Psi)^2, \right.
\]

\[
\sum_{j=1}^{2} (\Psi^{\dagger} \Gamma_{1j} \Psi)^2, (\Psi^{\dagger} \Gamma_{13} \Psi)^2, \sum_{j=1}^{2} (\Psi^{\dagger} \Gamma_{2j} \Psi)^2, (\Psi^{\dagger} \Gamma_{23} \Psi)^2, \sum_{j=1}^{2} (\Psi^{\dagger} \Gamma_{3j} \Psi)^2, (\Psi^{\dagger} \Gamma_{33} \Psi)^2 \right].
\]
The twelve-dimensional Fierz matrix then reads

\[
F_{\text{ani}} = \begin{pmatrix}
5 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
1 & 5 & -1 & -1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 & -1 \\
1 & -1 & 5 & -1 & -1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\
1 & -1 & -1 & 5 & 1 & 1 & 1 & -1 & -1 & 1 & 1 & -1 \\
2 & 2 & 2 & 2 & 4 & -2 & 0 & -2 & 0 & -2 & 0 & 2 \\
1 & 1 & 1 & 1 & -1 & 5 & -1 & 1 & -1 & 1 & 1 & 1 \\
2 & -2 & -2 & 0 & -2 & 4 & -2 & 0 & 2 & 0 & 2 & 2 \\
1 & -1 & -1 & -1 & 1 & -1 & 5 & 1 & -1 & 1 & -1 & 1 \\
2 & -2 & -2 & 2 & 0 & -2 & 0 & 2 & 2 & 4 & -2 & 4 & -2 \\
1 & -1 & 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 & -1 \\
\end{pmatrix}, \tag{B8}
\]

and now \( R(F_{\text{ani}}) = 7 \). Therefore, we have five linearly independent quartic terms. The additional coupling constant (besides \( g^a_{\mu} \) with \( \mu = 0, \cdots, 3 \)) can be chosen to be \( g^a_3 \), for example, see Sec.\[11\] \text{The remaining seven quartic terms are then given by}

\[
\begin{align*}
\sum_{j=1}^{2} (\Psi^\dagger \Gamma_{0j} \Psi)^2 &= -(\Psi^\dagger \Gamma_{10} \Psi)^2 + (\Psi^\dagger \Gamma_{13} \Psi)^2, \\
(\Psi^\dagger \Gamma_{03} \Psi)^2 &= -(\Psi^\dagger \Gamma_{10} \Psi)^2 - (\Psi^\dagger \Gamma_{13} \Psi)^2, \\
\sum_{j=1}^{2} (\Psi^\dagger \Gamma_{1j} \Psi)^2 &= -(\Psi^\dagger \Gamma_{0j} \Psi)^2 - 2(\Psi^\dagger \Gamma_{10} \Psi)^2 + (\Psi^\dagger \Gamma_{13} \Psi)^2, \\
(\Psi^\dagger \Gamma_{2j} \Psi)^2 &= -(\Psi^\dagger \Gamma_{0j} \Psi)^2 + (\Psi^\dagger \Gamma_{10} \Psi)^2 - (\Psi^\dagger \Gamma_{13} \Psi)^2, \\
(\Psi^\dagger \Gamma_{23} \Psi)^2 &= (\Psi^\dagger \Gamma_{10} \Psi)^2 - (\Psi^\dagger \Gamma_{13} \Psi)^2, \\
\sum_{j=1}^{2} (\Psi^\dagger \Gamma_{3j} \Psi)^2 &= -(\Psi^\dagger \Gamma_{0j} \Psi)^2 + (\Psi^\dagger \Gamma_{10} \Psi)^2 - (\Psi^\dagger \Gamma_{13} \Psi)^2, \\
\end{align*}
\tag{B9}
\]

The fact that an interacting anisotropic (tetragonal) Dirac semimetal is described by five linearly independent quartic terms can be justified from the fact that a Dirac system with reduced in-plane rotational symmetry supports five independent local pairings, as the three-component vector pairing \( \Delta^3 \) (see Table \[1\]) splits into the in-plane (with \( j = 1, 2 \)) and out of plane (with \( j = 3 \)) components. Similarly, one can show that in orthorhombic system (\( v_x \neq v_y \neq v_z \)), an interacting Dirac semimetal is described by six linearly independent local four-fermion interactions.
