Asymptotically optimal appointment schedules with customer no-shows

Abstract

We consider the problem of scheduling appointments for a finite customer population to a service facility with customer no-shows, to minimize the sum of customer waiting time and server overtime costs. Since appointments need to be scheduled ahead of time we refer to this problem as an optimization problem rather than a dynamic control one. We study this optimization problem in fluid and diffusion scales and identify asymptotically optimal schedules in both scales. In fluid scale, we show that it is optimal to schedule appointments so that the system is in critical load; thus heavy-traffic conditions are obtained as a result of optimization rather than as an assumption. In diffusion scale, we solve this optimization problem in the large horizon limit. Our explicit stationary solution of the corresponding Brownian Optimization Problem translates the customer-delay versus server-overtime tradeoff to a tradeoff between the state of a reflected Brownian motion in the half-line and its local time at zero. Motivated by work on competitive ratios, we also consider a reference model in which an oracle provides the decision maker with the complete randomness information. The difference between the values of the scheduling problem for the two models, to which we refer as the stochasticity gap (SG), quantifies the degree to which it is harder to design a schedule under uncertainty than when the stochastic primitives (i.e., the no-shows and service times) are known in advance. In the fluid scale, the SG converges to zero, but in the diffusion scale it converges to a positive constant that we compute.

1 Introduction

We study the problem of determining an optimal appointment schedule for a finite number of customers at a service system that only accepts arrivals in a finite time horizon, but renders service to all arriving customers. Broadly, the objective here is to assign deterministic arrival epochs to a finite population such that the server is optimally utilized while the cumulative delay experienced by the customers is minimized. The optimization problem is stochastic in nature due not only

to the randomness in service times, but also to the fact that some arrivals do not show up. As opposed to typical stochastic control problems that appear in the literature, the schedule needs to be determined \textit{offline}, ahead of time, with no access to the realization of the stochastic primitives over time.

Our research is motivated by systems such as outpatient clinics that render service to a finite number of patients during a working day (7AM to 4PM, for instance). No patients are accepted for service if they arrive after the end of the horizon, but all patients that do arrive are rendered service. No-shows in outpatient care is a problem most clinics struggle with regularly. According to \cite{7} no-show rates may be up to 60\%, depending on the clinic specific characteristics. Patient overbooking has been proposed as an effective strategy to handle clinic under-utilization resulting from patient no-show \cite{19}. At the same time overbooking may lead to clinic overcrowding, that will intensify patient waiting time and doctor overtime. Our paper aims at determining effective appointment schedules that will minimize these wait- and over- times.

We model the service system as a single server queue with an infinite buffer. We assume that the service times are generally distributed IID non-negative random variables (RVs) with a finite second moment, and that the server is non-idling and operates according to a first-come-first-served discipline. The entire finite population needs to be provided with appointments, and these appointments are allowed to span the entire time horizon, but not beyond. The actual arrival process is thinned with probability $p$ due to no-shows from this deterministic appointment schedule.

Our optimization problem’s goal is to determine an appointment schedule to minimize the objective of a weighted sum of the expected cumulative wait time of all the customers that arrive in the (finite) arrival horizon and the expected overage time, defined as the amount of time it takes for the server to clear out the backlog after the end of the horizon. The appointment scheduling problem is reducible to a stochastic bin-packing problem making it NP-hard, and is generally solved using various heuristics (see \cite{11}).

Here, we introduce two large population limit regimes that lead to simpler optimization problems and yield exact solutions. We operate in a large population limit framework that reveals the fundamental complicating factors in the optimization problem. Our scaling regimes let the population size tend to infinity while simultaneously accelerating the service rate in proportion to the population size. In the fluid regime, the service time cost is scaled by the inverse of the population size. Customers are assigned arrival epochs according to a sequence of arbitrary schedules. In the limit, the fluid regime washes out the stochastic variation and captures the ‘mean’ or first order effects in the queue performance. We posit a variational fluid optimization problem (FOP) and solve it in Proposition 1 under an ‘overload’ condition that the aggregate available fluid service is less than the expected aggregate fluid arrivals, and thus the overtime cost is non-zero. The optimal cumulative fluid schedule function matches the cumulative service completions in the arrival horizon and schedules the remaining fluid at the end of the horizon. This result shows that the heavy-traffic critical-load condition emerges as a consequence of optimization as opposed to a postulated assumption. In Theorems 1 and 2 we prove that the value of the fluid optimization problem is asymptotically achievable by a carefully constructed sequence of simple finite population schedules.

While the FOP results in a simple and intuitive schedule, it only considers first-order effects and washes away stochastic fluctuations. In actuality, we expect the inherent stochasticity of the system to have a significant impact on system performance and thus on the design of the schedule. Indeed, one might ask, whether considering second-order terms will shed more light on the optimal
appointment schedule. Specifically, it is of interest to see how fluctuations of order of the square root of the population size about the fluid solution impact the schedule. To formalize this question we posit a Brownian optimization problem (BOP), assuming the same overload condition as in the fluid scale. The BOP is stated in terms of an equation driven by a Brownian motion and a control, obtained as a formal diffusion limit of the queue length in heavy traffic. This is in line with the fact that the fluid optimal schedule enforces criticality within the appointment horizon. The BOP is not a dynamic control problem, but one where the control trajectory has to be planned ahead of time zero. This makes insights, structure, and tools from dynamic programming irrelevant. While we are unable to obtain an explicit solution of the BOP when set on a fixed time horizon, we do derive an explicit solution to it in the large time horizon limit. In Proposition 3 we prove that the value of the BOP in the large horizon limit can be achieved by an RBM that has a constant negative drift. Equivalently, in this limit, the BOP is solved by a stationary RBM. We identify the optimal drift coefficient in Lemma 7. In Theorems 3 and 4 we prove that the value of the BOP is also asymptotically achievable by a carefully constructed sequence of finite population schedules.

There is, of course, a ‘price’ to be paid for having to schedule traffic at time zero without any stochastic information revealed ahead of time. We quantify this by introducing the notion of a stochasticity gap (SG), defined as the difference between the appropriately scaled finite population value and the value of the ‘complete information’ (CI) problem. In the CI problem an oracle reveals all stochastic primitives (or future events) to the optimizer at time zero. The CI problem is not completely trivial, but much easier than the original one. The CI and the fluid optimal schedules are similar in that they both schedule appointments such that customers arrive at (precisely or approximately, respectively) the time when they are ready to be served, and any excess jobs are scheduled at the end of the horizon. Indeed, Proposition 2 shows that in the fluid scale the asymptotic SG is zero. On the other hand, in diffusion scaling we calculate the SG and show in Proposition 4 that it is strictly positive. (The term SG has been used before in the robust optimization literature in relation to performance with and without information revealed by an oracle, but in a way that differs from our use of it, see eg. [3].)

To summarize, our main contributions are as follows:

(i) Under an overload condition, we identify explicitly computable asymptotically optimal schedules in the fluid and diffusion regimes. These constitute the first analytical results for the appointment scheduling problem with no-shows in the large population limit.

(ii) Most literature on queueing control problems in heavy traffic focuses on dynamic control. Our results differ from this literature in two fundamental ways. First, the queueing model problem is formulated as an optimization rather than a dynamic control problem. Second, a critical load condition, which sets the ground for a heavy traffic analysis at the diffusion scale, emerges because it is optimal to operate at criticality, rather than as an assumption.

(iii) The essence of the optimization problem is that it must be carried out without the randomness being revealed. We analyze the SG as a means of quantifying the cost associated with uncertainty. To the best of our knowledge, this is the first work to study the SG at any scaling limit.

The rest of the paper is organized as follows. We conclude this section with a brief overview of the relevant literature and notational convention. §2 provides the problem formulation and a summary of the main results. In §§3 and 4 we solve the problem under fluid and diffusion scaling,
respectively. We compute the corresponding SG in these sections as well. We conclude with final remarks and a discussion of future research directions in §5.

We now review some of the relevant results in the field. There is a vast literature on appointment scheduling in healthcare which we will not attempt to summarize here; we direct the reader to the comprehensive reviews in [6, 11, 12]. We note two that are particularly relevant to our study. A scheduling problem close to ours has been studied in [21]. The problem they consider is that of determining an optimal schedule for heterogeneous patients in the presence of no shows with the objective of minimizing waiting cost plus idling and overtime cost. Our model may be considered a special case of their model in that our patients are homogeneous, and our idling cost is zero. However, their model considers fixed appointment slots, while ours allows for appointment times to be a result of the optimization problem. For a finite and fixed patient population, the authors characterize structural properties of an optimal schedule. Explicit solutions are given for some special cases and are studied numerically for the more general problem. The authors observe that optimal solutions tend to front load (more overbooking towards the beginning of the day). The numerical solutions of [21] also show that some appointment slots should be overbooked but not all, with only up to a couple of patients scheduled per slot.

A second paper that is relevant is [14], which considers a similar problem definition. However, the model there assumes that service times are exponentially distributed and there is no fixed horizon in which the finite number of arrivals must be scheduled. The cost function again trades off the expected cumulative waiting time of the customers that show-up against the expected server time beyond the last scheduled arrival epoch. The authors provide extensive numerical analysis of the finite-population scheduling problem. In particular, they numerically compute the optimal schedule which shows that overbooking is possible for the first few and last few arrival epochs, and arrivals in the middle are almost uniformly spread out. Furthermore, they also contrast the value of their problem against that of an oracle problem akin to our CI problem, and note the fact that value of the latter is significantly lower.

Also relevant is [2] who consider finite population scheduled arrivals models with both no-shows and tardiness. Under the assumption of exponentially distributed service times, the authors derive exact expressions for various performance metrics.

The second relevant stream of literature is on the asymptotics of scheduled arrivals ([1]) and transitory queueing ([15, 16]). This stream considers limits of processes that are generated from a queue with an arrival process that is originated from a finite population. Closest to our model is §4.3 of [16], in which the authors consider scheduled arrivals with epoch uncertainty. Indeed, the asymptotic scaling and limiting regimes are similar to ours. The two main differences are that (i) the appointment times are given and are assumed a-priori to be equally spaced, and (ii) all customers are assumed to show up but they may be non-punctual.

**Notation** Let $\mathcal{D}[0, \infty)$ be the space of functions $f : [0, \infty) \to \mathbb{R}$ that are right continuous with left limits, equipped with the Skorohod $J_1$ topology. Let $\mathcal{D}^+(0, \infty) \subset \mathcal{D}[0, \infty)$ be the subset of non-negative non-decreasing functions. For a sequence $\{X_n\}$, $X$, of RVs, $X_n \Rightarrow X$ as $n \to \infty$ denotes convergence in law. For a sequence $\{X_n\}$, $X$, of stochastic processes with sample paths in $\mathcal{D}[0, \infty)$, $X_n \Rightarrow X$ denotes convergence in law in the $J_1$ topology. In this paper, all statements involving convergence of processes $X_n \Rightarrow X$ will be to processes $X$ that have a.s. continuous sample paths, thus these convergences can equivalently be understood as convergence in law in the uniformly on
2 Problem setting

2.1 Model

Consider a single server queue with an infinite waiting room. A finite number of jobs arrive at the queue over a finite time horizon, and are served on a first-come-first-served (FCFS) schedule. Jobs are given appointments at fixed times during the day (not necessarily uniformly spaced), and we assume that jobs that do turn up do so precisely at the appointment time; that is, we assume punctual arrivals but allow no-shows. We also assume that the service times are independent and identically distributed (IID) with finite second moments.

The RVs and stochastic processes are defined on a probability space \((\Omega, \mathcal{F}, \mathbb{P})\), and the symbol \(\mathbb{E}\) denotes expectation with respect to \(\mathbb{P}\). The number of requested appointments (or population size) is denoted as \(N\). Let \(H > 0\) denote the operating time horizon. A schedule is any deterministic, non-decreasing sequence \(\{T_i, i = 1, \ldots, N\}\) taking values in \([0, H]\). It represents scheduled arrival epochs. The collection of all schedules is denoted by \(\mathcal{T}\). We denote by \(E(t)\) the cumulative number of scheduled arrivals by time \(t\), that is, \(E(t) = \sum_{i=1}^{N} 1_{\{T_i \leq t\}}\). The function \(E\) is referred to as the scheduling function. Let \(\{\xi_i, i \in \mathbb{N}\}\) be IID Bernoulli RVs with mean \(p \in (0, 1]\). They are used as a model for actual arrivals, namely \(\xi_i = 1\) if and only if the \(i\)th scheduled job shows up. With these elements, the cumulative arrival process, \(A \in \mathcal{D}^+[0, H]\), is given by \(A(t) = \sum_{i=1}^{N} \xi_i 1_{\{T_i \leq t\}}\). Note that, with \(\Xi(k) = \sum_{i=1}^{k} \xi_i, k \in \mathbb{Z}_+\), one can express the above relation as

\[
A(t) = \sum_{i=1}^{E(t)} \xi_i = \Xi \circ E(t).
\] (1)

Let \(\{\nu_i\}\) be an IID sequence of non-negative RVs with mean \(\mu^{-1}\) and squared coefficient of variation \(C_3^2 \in (0, \infty)\). Assume that this sequence and the sequence \(\{\xi_i\}\) are mutually independent. These RVs are used to model service times in the following way. Let \(\{\nu_i, i \in \mathbb{N}\}\) be the service time of the \(i\)th served job. Let \(S(t) = \max\{m | \sum_{i=1}^{m} \nu_i \leq t\}\). Then \(S(t)\) is the cumulative number of service completions by the time the server is busy for \(t\) units of time.

Let \(Q\) denote the number-in-system process. Then the cumulative busyness process is given by \(B(\cdot) = \int_0^1 1_{\{Q(s) > 0\}} ds\). A simple balance equation for \(Q\) is

\[
Q = A - S \circ B.
\] (2)

2.2 Cost and optimization problem

Two primary performance measures of interest to us are the overall waiting time, or makespan, and the average time. The former is defined as

\[
W = \int_0^{\infty} (Q(s) - 1)^+ds,
\] (3)
and represents the sum, over all arriving jobs, of the job’s waiting time in the queue (not counting
the time of service). The overage time is the amount of time after the end of the horizon \([0, H]\)
it takes to complete the last arrival in \([0, H]\). If we denote by \(\tau\) the time when the last arrival in
\([0, H]\) departs from the server, then the overage time is given by
\[
O = (\tau - H)^+.
\] (4)

Note that \(\tau\) can be expressed in terms of the processes introduced earlier as
\[
\tau = \inf\{t : S \circ B(t) \geq \Xi(N)\},
\] (5)
for \(\Xi(N)\) is the total number of arrivals, and \(S \circ B(t)\) is the number of departures by time \(t\).

The goal of the system operator is to schedule the \(N\) jobs so as to minimize a combination of the
expected overall waiting time experienced by the jobs (makespan) and the expected overage time.
Thus we consider the finite population optimal-schedule problem (FPOP) defined by considering
the cost
\[
J(\{T_i\}) = c_wE[W] + c_oE[O], \quad \{T_i\} \in \mathcal{T},
\] (6)
and the value
\[
V = \inf_{\{T_i\} \in \mathcal{T}} J(\{T_i\}).
\] (7)

Here, \(c_w\) and \(c_o\) are non-negative constants. In general, solving the FPOP is formidable. Rather
than solve it directly, we solve fluid and diffusion scale problems and prove the existence of asymptotically optimal finite population schedules that approach the fluid- and diffusion-optimal solutions
in the large population limit.

The main objective of this work is to study the asymptotics of problem (6)–(7). Before we turn
to it we comment on another, related problem setting. Suppose that all the information on the
stochastic data is known to the decision maker when he selects the schedule at time zero. In this
version of the problem, that we refer to as the complete information (CI) problem, the selection of
schedule \(\{T_i\}\) may depend on the stochastic data \(\{\xi_i, \nu_i\}\). We do not consider it as a practically
motivated setting by itself, because in applications we have in mind these stochastic ingredients
are not known in advance. However, it is useful to regard it as a reference model, and to relate it
to our main problem (6)–(7).

For a precise formulation, let \(\Sigma\) denote the sigma-field generated by the collection \(\{\xi_i, \nu_i\}\).
An \(\Sigma\)-measurable RV \(\{\Theta_i\}\) taking values in \(\mathcal{T}\) is called a CI-schedule. Let \(\mathcal{T}^{CI}\) denote the collection
of all CI-schedules (note that schedules in \(\mathcal{T}^{CI}\) are not allowed to change the order
of the scheduled jobs). Then, analogously to (6), we let
\[
J^{CI}(\{\Theta_i\}) = c_wE[W] + c_oE[O], \quad \{\Theta_i\} \in \mathcal{T}^{CI},
\] (8)
\[
V^{CI} = \inf_{\{\Theta_i\} \in \mathcal{T}^{CI}} J^{CI}(\{\Theta_i\}),
\] (9)
where \(W\) and \(O\) correspond to the selection \(\{\Theta_i\}\). Clearly, one always has \(V \geq V^{CI}\). We refer to the
difference
\[
\gamma = V - V^{CI}
\]
as the stochasticity gap, as it quantifies the gap between performance with and without knowing
the stochastic ingredients.

Problem (8)–(9) is much easier than our main problem, and is in fact fully solvable. We devote
\(\S 2.5\) to present its solution.
2.3 Large-population asymptotic framework

Because the problem (5)–(7) is prohibitively difficult to solve exactly, we instead take a large-population asymptotic approach where we consider a sequence of systems where the number of scheduled jobs grows large and the cost is scaled to make the problem tractable. Specifically, we consider a sequence of systems indexed by \( n \in \mathbb{N} \), where the population size \( N_n \) satisfies

\[
N_n = \lceil \alpha n \rceil,
\]

where \( \alpha > 0 \) is a fixed parameter. A schedule in the \( n \)th system is a non-decreasing sequence \( \{T_{i,n}, i = 1, \ldots, N_n\} \) taking values in \([0, H]\), with the corresponding scheduling function defined as

\[
E_n(t) = \sum_{i=1}^{N_n} 1\{T_{i,n} \leq t\}, \quad A_n(t) = \sum_{i=1}^{E_n(t)} \xi_i = \Xi \circ E_n(t).
\]

The collection of all schedules for the \( n \)th system is denoted by \( \mathcal{T}_n \). Let

\[
S_n(t) = S(nt) = \max \left\{ m \mid \sum_{i=1}^{m} \nu_i \leq nt \right\} = \max \left\{ m \mid \sum_{i=1}^{m} \nu_{i,n} \leq t \right\}, \quad \nu_{i,n} = n^{-1} \nu_i.
\]

In parallel to (2), the resulting number-in-system process for the \( n \)th system may be expressed as

\[
Q_n = A_n - S_n \circ B_n,
\]

with \( B_n(\cdot) = \int_0^1 1\{Q_n(s) > 0\} \, ds \).

Under the large-population scaling, population is assumed to grow linearly with \( n \). One may interpret the scaling of the various processes a couple of different ways. Under one interpretation time is scaled by \( n \), the scheduling time horizon becomes \([0, nH]\), and service times are of order \( O(1) \). A second interpretation is that the scheduling time horizon remains as \([0, H]\), but the service times are scaled by \( 1/n \). That is, when the population grows, the server speeds up at a rate that is proportional to the population size. While these two interpretations are mathematically equivalent, we will provide intuition throughout the paper that is consistent with the second interpretation.

Paralleling (3), (4), and (5), we have that the makespan, the overage time, and the departure time of the last arrival, are respectively defined as:

\[
W_n = \int_0^{\infty} (Q_n(s) - 1)^+ \, ds,
\]

\[
O_n = (\tau_n - H)^+,
\]

and

\[
\tau_n = \inf \{ t : S_n \circ B_n(t) \geq \Xi(N_n) \}.
\]

Paralleling (6) and (7), the large population optimal-schedule problem (LPOP) defined by considering the cost

\[
J_n(\{T_{i,n}\}) = c_{w,n} E[W_n] + c_{o,n} E[O_n], \quad \{T_{i,n}\} \in \mathcal{T}_n,
\]

where \( c_{w,n} \) and \( c_{o,n} \) are appropriately scaled constants, and the value

\[
V_n = \inf_{\{T_{i,n}\} \in \mathcal{T}_n} J_n(\{T_{i,n}\}).
\]

Similarly, for the complete information case we have

\[
J_n^{CI}(\{\Theta_{i,n}\}) = c_{w,n} E[W_n] + c_{o,n} E[O_n], \quad \{\Theta_{i,n}\} \in \mathcal{T}^{CI}_n,
\]

and

\[
V_n^{CI} = \inf_{\{\Theta_{i,n}\} \in \mathcal{T}^{CI}_n} J_n^{CI}(\{\Theta_{i,n}\}).
\]
Finally, let
\[ \gamma_n = V_n - V_n^{CI}. \]

To see what is the appropriate scaling for the cost coefficients of \( J_n(\cdot) \), note that the leading (first-order) term in the expression for the number of jobs that the server can handle in the interval \([0, H]\) is \( n\mu H \) (recall that we assume that in the \( n \)th system the server works at a rate \( n\mu \)). Similarly, the leading term in the total number of jobs that arrive into the system in \([0, H]\) is \( p\alpha n \). To capture the case where the server incurs a non-negligible overage cost, we assume that the system is overloaded. That is, we assume that \( p\alpha n > n\mu H \), or equivalently,
\[ p\alpha > \mu H. \]  

Thus, regardless of the schedule, at time \( H \) the number of jobs present in the system is of order \( n \). Since the service rate is also of order \( n \), it takes a constant (order 1) time to handle these jobs. That is, the overage time is \( O(1) \). Along the same lines, notice that the number of arriving jobs is of order \( n \) and their individual waiting time is of order 1. Thus the total waiting time (makespan) is \( O(n) \). This suggests that in order to get a meaningful cost function \( J_n(\cdot) \), the cost parameter \( c_{w,n} \) should be scaled by \( n^{-1} \) and the cost parameter \( c_{o,n} \) should remain a constant. Thus, we assume for the rest of the paper that
\[ c_{w,n} = n^{-1}c_w, \quad c_{o,n} = c_o. \]  

We study this asymptotic problem under two scalings. The first is a fluid scaling (see §3) in which only first order deterministic effects are accounted for. The second is a diffusion scaling (see §4) under which a refinement of the fluid solution is considered to account for stochastic second-order terms.

### 2.4 Main results

Our paper focuses on solving the LPOP asymptotically under the large population limiting regime. Our first-order analysis uses a fluid-scaling and captures the deterministic elements of the system, not accounting for stochasticity. This type of analysis allows us to identify a simple near-optimal scheduling rule and gives us useful insights about the original finite-population problem. Our second-order analysis incorporates the stochastic elements back into the model and offers a solution that is asymptotically optimal under diffusion scaling for large time horizon \( H \). In both scaling regimes we also identify the SG defined as the appropriately scaled difference between our proposed solution and the solution under complete information.

#### 2.4.1 Fluid scale

Assume that the cost parameters are of the form postulated in (19), and recall that this form was selected in such a way that the two additive components of \( J_n(\cdot) \) in (14) are both of order \( O(1) \). In the fluid scaling, the stochastic variation is ‘washed out,’ ensuring that the stochastic optimization in (14) is approximated by a variational problem, in the large population asymptotic. This allows us to focus on the \( O(1) \) terms in the optimization.

Consider
\[ E_n^f(t) = \begin{cases} 1 + \left\lfloor \frac{n\mu t}{p} \right\rfloor & t < H, \\ N_n & t = H, \end{cases} \]  

(20)
and its corresponding schedule

\[ T^f_{i,n} = \min \left\{ \frac{p}{p_n \mu} (i - 1), H \right\}, \quad i = 1, \ldots, N_n, \quad n \in \mathbb{N}. \]  \hspace{1cm} (21)

Then, we establish that \( \{T^f_{i,n}\} \) is asymptotically optimal in the fluid scale. Specifically, we show that

\[ \lim_{n \to \infty} J_n \left( \{T^f_{i,n}\} \right) = \lim_{n \to \infty} V_n = \bar{V}. \]

The schedule \( \{T^f_{i,n}\} \) satisfies the following properties:

- The appointment times up to time \( H \) are at intervals of equal duration of \( \frac{p_n \mu}{n} \) time units.
- All patients who do not get appointments before time \( H \) are scheduled to arrive at that time.
- The arrival rate during \([0, H]\) is equal to the service rate of \( n \mu \). Thus, it is asymptotically optimal to operate the system at a critically loaded heavy-traffic regime. Note that heavy traffic is obtained here as a result of optimality and not as an assumption.
- The critically loaded regime implies that, in the fluid scale, the server idle-time is negligible compared to the average time, when all customers have been served, and that no customers wait during \([0, H]\).

In terms of SG, our results show that in the fluid scaling this gap vanishes in the limit. Specifically, we show that

\[ \lim_{n \to \infty} \gamma_n = \lim_{n \to \infty} (V_n - V_n^{CI}) = 0. \]  \hspace{1cm} (22)

This result implies that, at the fluid scaling, knowing whether customers will show or not and their actual service time is only marginally beneficial to the system manager. In particular, knowing these quantities on average is sufficient at the fluid level.

### 2.4.2 Diffusion scale

In diffusion scaling we are interested in fluctuations about the fluid solution that are of order \( O(1/\sqrt{n}) \). Specifically, we focus on the centered and scaled cost function

\[ \hat{J}_n (\{T_{i,n}\}) = \sqrt{n} \left( J_n (\{T_{i,n}\}) - \bar{V} \right), \]  \hspace{1cm} (23)

and its corresponding centered and scaled value function

\[ \hat{V}_n = \inf_{\{T_{i,n}\} \in T_n} \hat{J}_n (\{T_{i,n}\}). \]

Our diffusion scale results are for a large time horizon. To state these results we will add the time horizon \( H \) as a subscript to all relevant quantities. Consider the following scheduling function

\[ E^d_{n,H}(t) = \begin{cases} 1 + \left[ \frac{nt}{p} \left( \mu - \frac{\sigma}{\sqrt{n}} \right) \right] & t < H, \\ N_n & t = H, \end{cases} \]  \hspace{1cm} (24)

where \( c_H^* = \sqrt{\frac{c_w(p(1-p)+\mu^2\sigma^2)}{2(c_w(\bar{\tau}-H)+c_o/\mu)}} \), with \( \bar{\tau} = \frac{p\alpha}{\mu} \), and its corresponding schedule

\[
T^d_{i,n,H} = \min \left\{ \frac{p}{n(\mu - c_H^*/\sqrt{n})} (i-1), H \right\}, \quad i = 1, \ldots, N_n, \quad n \in \mathbb{N}.
\]

Then, we establish that \( \{T^d_{i,n,H}\} \) is asymptotically optimal in the diffusion scale. More precisely, under the assumption that the service times \( \nu_i \) possess a \( 3 + \varepsilon \) moment, we show that

\[
\lim_{H \to \infty} \limsup_{n \to \infty} \frac{1}{H} \hat{J}_{n,H} \left( \left\{ T^d_{i,n,H} \right\} \right) = \lim_{H \to \infty} \liminf_{n \to \infty} \frac{1}{H} \hat{V}_{n,H}.
\]

The schedule \( \{T^d_{i,n,H}\} \) satisfies the following properties:

- The appointment times up to time \( H \) are at intervals of equal duration of \( p/\left( n(\mu - c_H^*/\sqrt{n}) \right) \) time units. This interval duration deviates from the fluid schedule by a term of the order of \( O(1/\sqrt{n}) \).
- In the scaling limit, the queue length process converges to a reflected Brownian motion (RBM) on the half-line, with a constant negative drift \(-c_H^*\).
- The constant \( c_H^* \) is obtained by minimizing a cost with two additive terms; one that is proportional to \( c_H^* \), and represents that server idleness cost, plus a term that is inversely proportional to \( c_H^* \), that represents the holding cost.

In terms of SG, it turns out that while in the fluid scale the SG is negligible, it is strictly positive in the diffusion scale. Specifically, let \( \hat{\gamma}_{n,H} = \sqrt{n} \left( V_{n,H} - V^C_{n,H} \right) \). Then, we show that

\[
\lim_{H \to \infty} \liminf_{n \to \infty} \frac{1}{H} \hat{\gamma}_{n,H} = \lim_{H \to \infty} \liminf_{n \to \infty} \frac{1}{H} \hat{V}_{n,H} =: \hat{V}^* > 0,
\]

where \( \hat{V}^* \) is a constant.

### 2.5 Exact analysis of the CI problem

In the CI problem, all stochastic data are known to the decision maker. It thus can be treated, for each realization of these data, as a deterministic allocation problem. The number of show ups is given by \( \Xi(N) \), and the total amount of work associated with them is \( \tau^* := V(\Xi(N)) = \text{inf}\{t : S(t) \geq \Xi(N)\} \). Hence \( \tau^* \) is a lower bound on \( \tau \) for any CI-schedule. It is easy to see that there is no gain by allowing the system to be empty (thus the server idle) for some time prior to the time of completion of all jobs, \( \tau \). Indeed, if there is any interval \( [a,b) \) on which the system is empty, and there is still a job (or more) that will show up at time \( b \), then advancing all jobs scheduled at \( b \) or later by \( b-a \) units of time (so that the job originally scheduled at \( b \) arrives at \( a \), etc.) does not affect the waiting time of any of the jobs arriving at times \( t \geq a \), and it can only decrease the average time. Thus it suffices to consider only allocations for which \( B(t) = t \), (equivalently, \( Q(t) \geq 1 \)) for all \( t < \tau \). Moreover, for all such allocations, clearly \( \tau = \tau^* \). As a result, (2) gives

\[
Q = A - S \text{ on } [0, \tau^*].
\]
The sample path of \( A(t), t \in [0, \infty) \), can be any member of \( \tilde{D}[0, \infty) \) that is integer valued and satisfies
\[
A(t) = \Xi(N) \quad \text{for all } t \geq H. \tag{27}
\]
Now, in view of (26), the requirement \( Q(t) \geq 1 \) alluded to above implies
\[
A(t) \geq 1 + S(t) \quad \text{for all } t < \tau^*. \tag{28}
\]
Among all paths satisfying (27) and (28) there is one that is pointwise minimal, namely
\[
A^*(t) = \begin{cases} 
1 + S(t), & t < H, \\
\Xi(N), & t \geq H.
\end{cases}
\]
It corresponds to allocating the jobs in such a way that there are no waiting customers during \([0, H]\), and, in the event that \( \tau^* \geq H \), the remaining customers, that are \( \Xi(N) - (1 + S(H)) \) in number, are all scheduled at the very last moment, \( H \). By (3) and (26),
\[
W = \int_0^{\tau^*} (A(s) - S(s) - 1)^+ ds.
\]
Thus \( W \) is monotone in \( A \) in the following sense: If \( A(t) \geq \tilde{A}(t) \) for all \( t \in [0, \tau^*] \) then \( W \geq \tilde{W}^* \). We conclude that \( A^* \) minimizes \( W \), and since we have already mentioned that it minimizes \( \tau \), it also minimizes their weighted sum, in pathwise sense. Consequently, this CI-schedule minimizes the cost (5).

Finally, we can also compute this cost. On the event \( \tau^* < H \), \( W^* = 0 \); when \( \tau^* \geq H \),
\[
W^* = \int_H^{\tau^*} (\Xi(N) - S(s) - 1)^+ ds = \int_H^{\tau^*} (\Xi(N) - S(s) - 1) ds.
\]
We thus obtain
\[
V^{CI} = c_w E[W^*] + c_o E[(\tau^* - H)^+]
= c_w E\left[ \int_H^{\tau^*} (\Xi(N) - S(s) - 1) ds \right] + c_o E[(\tau^* - H)^+]. \tag{29}
\]

3 Large population asymptotics: fluid scale

This section studies our appointment scheduling model in fluid scale. By exploiting the stochastic regularity that emerges in this scaling limit, we identify a deterministic, first-order approximation to the FPOP that governs the limit behavior. We find an optimal solution to this limiting problem and show that the cost associated with this solution is asymptotically achievable in the fluid scale limit.

We start by stating and solving a formal fluid problem. Later we show that the optimal value of this fluid problem constitutes a lower bound on the fluid-scaled FPOP. Subsequently, we show that this value also constitutes an upper bound on the fluid-scaled FPOP shown by identifying a sequence of simple policies for the FPOP that asymptotically achieve this value. Thus, we establish that this sequence of policies is asymptotically optimal in the fluid scale.
3.1 Fluid Model

Let \( \{ E_n \} \) be an arbitrary sequence of scheduling functions. Following (1), the fluid-scaled cumulative arrival process is defined as:

\[
\bar{A}_n = \frac{1}{n} \Xi \circ nE_n,
\]

where \( \bar{E}_n = \frac{1}{n}E_n \) is the fluid-scaled schedule. The FLLN implies that, as \( n \to \infty \),

\[
\frac{1}{n} \Xi ([ne]) \Rightarrow pe,
\]

(30)

where \( e : \mathbb{R}_+ \to \mathbb{R}_+ \) is the identity map; note that here the convergence is u.o.c., even though the pre-limit processes are assumed to exist in the Skorokhod \( J_1 \) topology, since the limit process is continuous. This will be the case in the remainder of the discussion, unless noted otherwise. Throughout this section we use the notation \( \varepsilon_n \) for a generic sequence of stochastic processes that converge to the zero process in probability as \( n \to \infty \), as well as for a generic sequence of RVs that converges to zero in probability. It follows from (30) that

\[
\bar{A}_n = n^{-1} \Xi (nE_n) = p\bar{E}_n + \varepsilon_n.
\]

(31)

Also, the FLLN for renewal processes [8, Chapter 5] implies that, as \( n \to \infty \),

\[
\bar{S}_n := \frac{1}{n} S_n \Rightarrow \mu e.
\]

(32)

As a result, \( \bar{S}_n(B_n(t)) = \mu B_n(t) + \varepsilon_n \). In view of these identities, the fluid-scaled queue length process \( \bar{Q}_n := n^{-1}Q_n \), is given by

\[
\bar{Q}_n = \bar{A}_n - \bar{S}_n \circ B_n
\]

\[
= p\bar{E}_n - \mu e + \mu (e - B_n) + \varepsilon_n.
\]

The idleness process \( I_n := e - B_n \) is non-decreasing and is flat on excursions of \( \bar{Q}_n \) away from zero, and thus \( (\bar{Q}_n, \mu I_n) \) forms a solution to the Skorohod problem with data \( p\bar{E}_n - \mu e + \varepsilon_n \). That is,

\[
(\bar{Q}_n, \mu I_n) = (\Gamma_1(p\bar{E}_n - \mu e + \varepsilon_n), \Gamma_2(p\bar{E}_n - \mu e + \varepsilon_n)),
\]

(33)

with \( \Gamma_1(x) = x + \Gamma_2(x) \) and \( \Gamma_2(x)(t) = \sup_{0 \leq s \leq t} (-x(s))^+ \).

Recall the fluid-scaled makespan RV \( \bar{W}_n := n^{-1}W_n = n^{-1} \int_0^\infty (Q_n(t) - 1)^+ dt \) and the overage time \( O_n = (\tau_n - H)^+ \), where \( \tau_n = \inf \{ t > 0 : S_n(B_n(t)) \geq \Xi (N_n) \} \). From (31), (32) and (33), by formally removing the error terms, we derive a fluid model as follows. Let \( \mathcal{L} = \{ \lambda \in D^+ [0, \infty) : \lambda(t) = \alpha \text{ for } t \geq H \} \). Given \( \lambda \in \mathcal{L} \), let \( a = p\lambda \) and \( q = \Gamma_1(a - \mu e) = a - \mu e + \eta \), where \( \eta(t) := \Gamma_2(a - \mu e)(t) \) is the correction term (or Skorokhod regulator term). These are fluid models for the arrival process and queue length, respectively. Let also \( \bar{B}(t) := t - \mu^{-1}\eta(t) \) stand for cumulative busyness, and let \( \tau = \inf \{ t > 0 : \mu B(t) \geq a(H) \} \), \( \bar{W} = \mu^{-1} \int_0^\infty q(t) da(t) \) and \( \bar{O} = (\tau - H)^+ \) denote the fluid models for the termination time, wait and overage time, respectively. A fluid optimization problem (FOP) is formulated by letting

\[
\bar{J}(t) = c_w \bar{W} + c_o \bar{O},
\]

(34)
and

\[ \bar{V} := \inf_{\lambda \in \mathcal{L}} \bar{J}(\lambda). \quad (35) \]

In §3.2 below we show that there exists a \( \lambda^* \in \mathcal{L} \) that attains the minimum in (35). In §3.3 we show that the FOP value \( \bar{V} \) is an asymptotic lower bound on the fluid scale cost \( J_n(\{T_i\}) \) under an arbitrary sequence of schedules. In §3.4 we construct a bespoke sequence of finite population schedules that asymptotically achieves \( \bar{V} \), thus proving asymptotic optimality in fluid scale.

### 3.2 Fluid Optimal Schedule

Under our overload assumption (18), it is straightforward to see that our fluid model satisfies, for any \( \lambda \in \mathcal{L}, 0 < \tau - H = \mu^{-1}q(H) \). An optimal control should minimize the tradeoff between the fluid overage time and fluid makespan. The main result of this section in Proposition 1 identifies such an optimal control.

**Proposition 1** A fluid optimal control \( \lambda^* \in \mathcal{L} \) is given by

\[
\lambda^*(t) = \begin{cases} 
  p^{-1} \mu t & t \in [0, H) \\
  \alpha & t \geq H,
\end{cases}
\]

(36)

The proof is fairly straightforward and is a consequence of the following lemma that, loosely speaking, argues that it is optimal for the server to be busy at all times until all work has been completed.

**Lemma 1** For any control \( l \in \mathcal{L} \) with the corresponding correction term \( \eta(t) \geq 0 \), there exists a control \( \tilde{\lambda} \in \mathcal{L} \) such that the corresponding \( \bar{\eta}(t) = 0 \) for all \( t \in [0, \bar{\tau}] \), where \( \bar{\tau} = \inf\{t > 0 : \mu t \geq p\tilde{\lambda}(H)\} \), and \( \bar{J}(l) \geq \bar{J}(\tilde{\lambda}) \).

This result implies that the cost associated with any control where the correction term is non-zero in \([0, H]\) can be improved by choosing a control where the correction term is zero. Thus, if an optimal control exists, there exists one such control \( l \) that satisfies \( p(l(t_2) - l(t_1)) \geq \mu(t_2 - t_1) \), where \( 0 \leq t_1 \leq t_2 \leq H \). We now prove Proposition 1.

**Proof of Proposition 1** Following Lemma 1 we will assume that \( l \in \mathcal{L} \) is such that the correction term \( \eta \) is zero in \([0, H]\). Let \( \bar{c}_w = pc_w(\alpha \mu)^{-1} \) and \( \bar{c}_o = c_o(\mu)^{-1} \). Integrating the cost function \( \bar{J}(\lambda) \) by parts and using the fact that \( \lambda(H) = 1 \) and \( q(0-) = 0 \),

\[
\bar{J}(\lambda) = \bar{c}_w \left[ q(t)\lambda(t)\right]_0^H - \int_0^H \lambda(t)dq(t) + \bar{c}_o q(H)
\]

\[
= \bar{c}_w q(H) - \int_0^H \lambda(t)(pd\lambda(t) - \mu dt) + \bar{c}_o q(H)
\]

\[
= -\bar{c}_w \frac{\alpha^2 p}{2} + \bar{c}_w \mu \int_0^H \lambda(t)dt + (\bar{c}_w + \bar{c}_o)(p\alpha - \mu H).
\]

The only term that can be controlled is the second one, which is optimized by

\[
\lambda(t) = \begin{cases} 
  p^{-1} \mu t, & t \in [0, H), \\
  \alpha, & t \geq H,
\end{cases}
\]
since \( p(l(t_2) - l(t_1)) \geq \mu(t_2 - t_1) \) by the discussion following Lemma 1.

\[ \nabla \]

**Proof of Lemma 1.** Recall that fluid cost under \( l \) is

\[
\bar{J}(\lambda) = c_w p \mu^{-1} \int_0^H q(t) d\lambda(t) + c_o (\tau - H),
\]

where we have made use of fact that \( a = p \lambda \) and \( da(t) = 0 \) for all \( t > H \). Now, let \( \tilde{l} := l + p^{-1} \eta \) on \([0, H)\) and \( \tilde{l}(H) := \alpha \), so that \( \tilde{l} \in \mathcal{L} \). Observe that the queue length under \( \tilde{l} \) is

\[
\tilde{q}(t) = \begin{cases} 
q(t) & \text{if } t \in [0, H) \\
\alpha - \mu t & \text{if } t \in [H, \tilde{\tau}], \\
0 & \forall \ t > \tilde{\tau}.
\end{cases}
\]

Notice that \( \tilde{q}(H) \leq q(H) = \alpha - \mu H + \eta(H) \), implying that \( \tilde{\tau} \leq \tau \). The associated fluid cost is

\[
\bar{J}(\tilde{l}) = c_w p \mu^{-1} \int_0^H q(t) d\tilde{l}(t) + c_o (\tilde{\tau} - H).
\]

Since \( q(t) d\eta(t) = 0 \), it follows that

\[
\bar{J}(\tilde{l}) = c_w p \mu^{-1} \int_0^H q(t) d\tilde{l}(t) + c_o (\tilde{\tau} - H) \leq \bar{J}(l).
\]

Some remarks on Proposition 1 are warranted. First, and most importantly, under (18) the optimal schedule ensures that the queue length is zero in \([0, H)\) and positive in \([H, \tau]\) and zero for \( t \geq \tau \). This is an intuitively satisfying result in the sense that, given the system operator’s goal of minimizing the makespan while simultaneously minimizing the average time, it would make most sense to fully utilize the available capacity but not overload the system. Thus, the optimal schedule matches the arrival ‘rate’ with the effective service rate \( p^{-1} \mu \) in the interval \([0, H)\), and schedules the remainder (of \( \alpha - p^{-1} \mu H \) fluid units) at \( H \). In other words, the heavy-traffic condition emerges as a consequence of optimization. This result is in stark contrast to most queueing control problems where the heavy-traffic condition is assumed at the outset. Notice too that the fluid optimal solution parallels the sample path-wise solution in the complete information problem. In the absence of stochastic variation in the traffic and service, it is clearly possible to optimally arrange the traffic such that there is no waiting for any of the jobs who do turn up, and schedule the remainder at the end of the horizon.

### 3.3 Lower bound on the fluid scale cost

Recall that the fluid scaled makespan \( \bar{W}_n \) is defined as \( \bar{W}_n = n^{-1} \int_0^\infty (Q_n(s) - 1)^+ ds \). Now, fix \( 0 < K < \infty \) (to be determined later) and note that

\[
\bar{W}_n \geq n^{-1} \int_0^K (Q_n(s) - 1)^+ ds \\
\geq \int_0^K \bar{Q}_n(s) ds - Kn^{-1}.
\]
By (33), there exists a sequence of processes \( \{ \varepsilon_n \} \) that converges to the zero process in probability as \( n \to \infty \), such that
\[
\bar{Q}_n = \Gamma_1(p\bar{E}_n - \mu e + \varepsilon_n).
\]
By the Lipschitz continuity of the Skorokhod regulator map it follows that
\[
\bar{Q}_n \geq \Gamma_1(p\bar{E}_n - M) + \varepsilon_n,
\]
where \( M = \mu e \). Substituting this into (37) we observe that
\[
\bar{W}_n \geq \int_0^K \Gamma_1(p\bar{E}_n - M)(s)ds + \varepsilon_n - Kn^{-1},
\]
clearly implying that
\[
\bar{W}_n \geq \inf_{l \in \mathcal{D}[0,\infty]} \int_0^K \Gamma_1(pl - M)(t)dt + \varepsilon_n - Kn^{-1}.
\]
(38)

From the definition of \( \tau_n \) (13) it follows that
\[
\tau_n \geq \inf \{ t : \mu_B(t) + \varepsilon_n \geq \alpha p \},
\]
where we have used the fact that \( \bar{S}_n(B_n(t)) = \mu B_n(t) + \varepsilon_n \) and \( \bar{A}_n(H) = \alpha p + \varepsilon_n' \); note that we use \( \varepsilon_n \) to represent the difference between the two mean-zero error sequences. Since \( t \geq B_n(t) \) we have
\[
\tau_n \geq \inf \{ t : \mu t + \varepsilon_n \geq \alpha p \},
\]
implying that \( \tau_n \geq \alpha p \mu^{-1} + \varepsilon_n = \tau + \varepsilon_n \). It follows that
\[
(\tau_n - H)^+ \geq (\bar{\tau} - H + \varepsilon_n)^+.
\]
(39)

Let \( \bar{\tau} = p\alpha \mu^{-1} \) and consider
\[
\tilde{V} := c_w \inf_{\lambda \in \mathcal{L}} \left\{ \int_0^\infty \Gamma_1(p\lambda - M)(t)dt \right\} + c_o(\bar{\tau} - H)^+.
\]

As the next lemma shows \( \tilde{V} \) equals the FOP value, and can be achieved by the optimal schedule in Proposition[1].

Lemma 2
1. \( \tilde{V} = \bar{V} \).
2. The upper limit \( \infty \) in the integral can be replaced by any \( K \) sufficiently large.
3. The minimum is attained by \( l^* \) defined in (30).

Proof of Lemma 2 Consider \( \tilde{V} \) first and recall that for a fixed \( l \), \( \tau = \inf \{ t > 0 : \mu(t - I(t)) = \alpha p \} \). If \( \tau > \bar{\tau} \), it automatically follows that \( I(\bar{\tau}) > 0 \). This implies that the makespan cost \( c_w \int_0^\infty (pl(t) - \mu(t - I(t)))dt \) is not optimal. To see this, note that the makespan cost can be lower bounded by choosing \( l' \) such that \( l'(t) = \mu t \) for all \( t \in [0, \tau] \), and \( \tau = \bar{\tau} \) in this case. Thus, any optimal solution should be such that \( I(t) = 0 \) up to \( \tau = \bar{\tau} \), in which case we minimize
\[
\int_0^\tau q(t)dt = \int_0^\tau pl(t)dt - \int_0^\tau \mu dt,
\]
where only the first term on the right hand side is controlled. The minimizing schedule \( l \) that satisfies the constraint that \( l(t) = \alpha, \ t \geq H \) is

\[
l(t) = \begin{cases} p^{-1} \mu t & t \in [0, H) \\ \alpha & t \geq H. \end{cases}
\]

Now we will show that Lemma 2 together with (38) and (39) implies that the FOP value lower bounds the fluid-scaled cost.

**Theorem 1** The fluid-scaled cost of an arbitrary sequence of schedules, \( \{T_i\} \), is asymptotically lower bounded by the fluid optimal value \( \bar{V} \). That is,

\[
\liminf_{n \to \infty} J_n(\{T_i\}) \geq \bar{V}.
\]

**Proof of Theorem 1** Let \( j_n := c_w \bar{W}_n + c_o O_n \) represent the random cost incurred by following schedule \( \{T_i\} \). Since the constant \( K \) was arbitrary, we can set it to be greater than \( \bar{\tau} \). Lemma 2 together with (38) and (39) imply that,

\[
j_n \geq (\bar{V} + \varepsilon_n - Kn^{-1}) \lor 0.
\]

Observe that \( j_n \Rightarrow \bar{V} \) as \( n \to \infty \). Since \( j_n \geq 0 \), Fatou’s Lemma [10] implies that

\[
\liminf_{n \to \infty} \mathbb{E}[j_n] \geq \mathbb{E}[\liminf_{n \to \infty} j_n] = \bar{V}.
\]

\[
T_{i,n} = \min \left\{ \frac{P_i}{n \mu} + H \right\}, \ i = 1, \ldots, N_n, \ n \in \mathbb{N}.
\]
The number of jobs waiting in the queue at the end of the arrival horizon all n.

The scheduling function $E_n$ one-at-a-time at uniformly spaced intervals of length $p(n\mu)^{-1}$ up to time $H$, with the leftover $N_n - (1 + nH/\mu)$ customers who are scheduled to arrive at time $H$.

The main result of this section establishes the fact that the expected fluid-scaled cost $\bar{J}_n(T_{i,n}^f)$ converges to the fluid optimal value as well.

**Theorem 2** For each $n$, suppose that traffic schedule is $\{T_{i,n}^f\}$. Then

$$\limsup_{n \to \infty} \bar{J}_n(T_{i,n}^f) \leq \bar{V}. \quad (41)$$

**Lemma 3** The finite population schedule satisfies $E_n \to I^*$ uniformly on compacts as $n \to \infty$.

Now, let $(Q_n, I_n)$ represent the queue length and the idleness processes when traffic is scheduled per $E_n$. FLLN’s for the arrival and service processes, and Lemma 3 together imply the following result:

**Lemma 4** (i) The fluid-scaled queue length and idleness processes satisfy an FLLN: $(\bar{Q}_n, \bar{I}_n) \Rightarrow (q^*, I^*)$ as $n \to \infty$ where

$$q^*(t) = \begin{cases} 0 & t \in [0, H) \\ \alpha \rho - \mu t & t \in [H, \bar{\tau}] \\ 0 & t > \bar{\tau}, \end{cases}$$

and

$$I^*(t) = \begin{cases} 0 & t \in [0, \bar{\tau}] \\ \bar{t} & t > \bar{\tau}. \end{cases}$$

(ii) The fluid-scaled makespan and overage time RVs satisfy: $(\bar{W}_n, O_n) \Rightarrow (\bar{W}^*, \bar{O}^*)$ as $n \to \infty$, where $\bar{W}^* = \mu^{-1} \int_0^\infty q^*(t) dI^*(t)$ and $\bar{O}^* = (\bar{\tau} - H)$.

**Proof of Theorem 2** Let $J^R_n(T_{i,n}^f) = c_0 \bar{W}_n + c_0 O_n$ be the random cost. We start by noting that the convergence result in Lemma 3 implies that the random cost $J^R_n(T_{i,n}^f) \to \bar{J}(I^*)$ weakly converges to $\bar{V}$ as $n \to \infty$. implies that $J_n(T_{i,n}^f) = \mathbb{E}[J^R_n(T_{i,n}^f)]$ will converge to $\bar{V}$ provided that $J^R_n(T_{i,n}^f)$ is uniformly integrable. The remainder of this proof is dedicated to proving this claim.

We prove that $J^R_n(T_{i,n}^f)$ is uniformly integrable by showing that $\mathbb{E}|J^R_n(T_{i,n}^f)|^2 \leq C < \infty$ for all $n \in \mathbb{N}$. Consider the sequence $\{O_n\}$ first. Note that it suffices to consider the case where $\tau_n > H$. The number of jobs waiting in the queue at the end of the arrival horizon $H$ is $N_n - D_n(H) > 0$, where $D_n(H)$ is the number of departures in $[0, H]$. Since there are no more arrivals after time $H$ it can be seen that

$$\tau_n - H \leq \sum_{i=D_n(H)+1}^{N_n} \nu_i^n \leq \sum_{i=1}^{N_n} \nu_i^n. \quad (42)$$

Now, let $\Upsilon(m) := \sum_{i=1}^m \nu_i$ and $\Upsilon_n(m) := \sum_{i=1}^m \nu_i^n$. Minkowski’s inequality implies that

$$\left(\mathbb{E}|\Upsilon(N_n)|^2\right)^{1/2} \leq N_n \left(\mathbb{E}|\Upsilon(1)|^2\right)^{1/2}. \quad (43)$$
where the last inequality follows from the fact that \( N_n/n \leq \alpha \) by definition. Equation (42) and this bound imply that
\[
\mathbb{E}[(\tau_n - H)^+]^2 \leq \mathbb{E}|\tau_n - H|^2 \leq \alpha \mathbb{E}|V(1)|^2 < \infty,
\]
where the finiteness of the second moment is by assumption. Since the bound is independent of \( n \), it follows that \( O_n = (\tau_n - H)^+ \) are uniformly integrable.

Now consider the fluid-scaled makespan. Using the fact that the queue drains out and remains empty after \( \tau_n \) it follows that
\[
\bar{W}_n = n^{-1} \int_0^H Q_n(t)dt + n^{-1} \int_{H \wedge \tau_n}^H Q_n(t)dt.
\]
Note that the first term on the right hand side of the inequality is bounded above by \( n^{-1} N_n H \leq \alpha H \). Thus, it suffices to consider the second term when \( \tau_n > H \). As there are \( N_n - D_n(H) \) jobs waiting for service at the end of the horizon, it follows that
\[
n^{-1} \int_{H \wedge \tau_n}^H Q_n(t)dt \leq n^{-1} \left\{ (N_n - D_n(H)) \nu_{D_n(H)+1}^n + (N_n - D_n(H) - 1) \nu_{D_n(H)+2}^n + \cdots + \nu_{N_n}^n \right\}
\]
\[
= \frac{1}{n} \sum_{i=1}^{N_n-D_n(H)} (N_n - D_n(H) + 1 - i) \nu_{D_n(H)+i}^n
\]
\[
= \frac{N_n - D_n(H)}{n} \sum_{i=1}^{N_n-D_n(H)} \nu_{D_n(H)+i}^n - \frac{1}{n} \sum_{i=1}^{N_n-D_n(H)} (i-1) \nu_{D_n(H)+i}^n
\]
\[
\leq \frac{N_n}{n} \sum_{i=1}^{N_n} \nu_i^n,
\]
where the last inequality follows from the fact that \( n^{-1} \sum_{i=1}^{N_n-D_n(H)} (i-1) \nu_{D_n(H)+i}^n \geq 0 \) and \( D_n(H) \geq 0 \) for all \( n \geq 1 \). Using the bound in (43) we have
\[
n^{-1} \left( \mathbb{E} \left( \int_{H \wedge \tau_n}^H Q_n(t)dt \right)^2 \right)^{1/2} \leq \alpha \left( \mathbb{E}|\mathcal{Y}(1)|^2 \right)^{1/2}.
\]
Thus, it follows that \( \mathbb{E}|\bar{W}_n|^2 \) is uniformly bounded for all \( n \in \mathbb{N} \), implying that \( \{\bar{W}_n\} \) is uniformly integrable. Finally, since \( \{J_n^f \{T_{i,n}^f\}, \ n \geq 1 \} \) is a sequence of RVs that are each linear combinations of uniformly integrable RVs, it is uniformly integrable as well.

Thus, Theorem 2 shows that the family of finite population schedules \( \{E_n^f\} \) is asymptotically optimal in the sense that the FOP value can be achieved in the large population limit.

**Proof of Lemma 3.** Fix \( t \in [0, H) \) and \( n \geq 1 \). By definition it follows that
\[
\left| \frac{E_n^f(t)}{n} - l^*(t) \right| \leq \frac{1}{n} + \frac{1}{n} \left( \frac{nt}{p} - \left\lfloor \frac{nt}{p} \right\rfloor \right) \leq \frac{2}{n}.
\]
On the other hand, fix \( t \geq H \) and observe that
\[
\left| \frac{E^A_n(t)}{n} - \alpha \right| \leq \left| \frac{N_n}{n} - \alpha \right| \leq \frac{2}{n}.
\] (44)

These two bounds are independent of \( t \), proving the lemma. \( \square \)

**Proof of Lemma 4** Part (i) follows by using the FLLN’s alluded to in (30) and (32), and Lemma 2 and applying the continuous mapping theorem to the tuple \((\bar{Q}_n, \bar{I}_n)\) (see (33)).

For part (ii), observe that by definition the fluid-scaled makespan also satisfies
\[
\bar{W}_n = n^{-1} \int_0^\infty W_n(t) dA_n(t),
\]
where \( W_n(t) = n^{-1} \sum_{i=1}^{|nt|} \nu_i - t + B_n(t) \) is the workload process. Let \( w^* := \mu^{-1} q^* \), then,
\[
\left| \int_0^\infty W_n(t) d\frac{A_n(t)}{n} - \int_0^\infty w^*(t) da(t) \right|
\leq \left| \int_0^\infty W_n(t) d\left( \frac{A_n(t)}{n} - a(t) \right) \right| + \left| \int_0^\infty (W_n(t) - w^*(t)) da(t) \right|
\leq \int_0^\infty W_n(t) |\gamma_n(dt)| + \int_0^\infty |W_n(t) - w^*(t)| da(t),
\]
where \( \gamma_n := n^{-1} A_n - a \) is a signed measure. Consider the second integral above and observe that
\[
\int_0^\infty |W_n(t) - w^*(t)| da(t) \leq \sup_{0 \leq t \leq \tau_n + \bar{r}} |W_n(t) - w^*(t)|,
\]
where \( \tau_n \Rightarrow \bar{r} \) as \( n \to \infty \). Now, [15, Proposition 3] implies that \( W_n \Rightarrow w^* \). Consequently, it follows that
\[
\int_0^\infty |W_n(t) - w^*(t)| da(t) \Rightarrow 0 \text{ as } n \to \infty.
\]

On the other hand, by the Jordan decomposition theorem [17, pp 346] it follows that there exist positive, finite, measures \( \gamma_n^+ \) and \( \gamma_n^- \) such that \( \gamma_n = \gamma_n^+ - \gamma_n^- \), \( \gamma_n^+(0, \infty) < \infty \) and \( \gamma_n^-((0, \infty)) < \infty \). Furthermore, the (total) variation of the signed measure is \( |\gamma_n| = \gamma_n^+ + \gamma_n^- \). From the FLLN alluded to in (30) it follows that \( |\gamma_n| \Rightarrow 0 \) as \( n \to \infty \). Then, by [5, Corollary 8.4.8] it follows that
\[
\gamma_n^+ \Rightarrow 0 \text{ and } \gamma_n^- \Rightarrow 0 \text{ as } n \to \infty.
\] (45)

Now, let \( K \in (0, \infty) \) be a large positive constant, so that \( W_n^K(t) := n^{-1} \sum_{i=1}^{|nt|} \nu_i \land K - t + B_n(t) \leq n^{-1} \sum_{i=1}^{|nt|} \nu_i \land K \leq K \). Consider the integral,
\[
\int_0^\infty W_n^K |\gamma_n(dt)| \leq K \int_0^\infty |\gamma_n(dt)|
= K \int_0^\infty (\gamma_n^+(dt) + \gamma_n^-(dt)) \Rightarrow 0 \text{ as } n \to \infty,
\]
where the convergence follows from (45). Note too that this convergence is true for any \( 0 < K < \infty \), implying that
\[
\int_0^\infty W_n |\gamma_n(dt)| \Rightarrow 0 \text{ as } n \to \infty.
\] \( \square \)
3.5 The stochasticity gap at the fluid scale

The first-order deterministic FOP is solved by scheduling traffic to match the available capacity. In addition, the previous two sections have shown that the fluid scale cost is bounded by the FOP value and proposed an asymptotically optimal schedule for the LPOP. At the same time, for the complete information (CI) problem, we identified, in [25], that a $\Sigma_n$-measurable schedule [29] that optimizes this problem; this schedule allocates appointments such that there are no waiting customers during $[0,H)$ and the server is never idle. Clearly, for the LPOP, there is a cost to be paid for scheduling traffic without a priori knowledge of the randomness. The parallels between the CI and FOP optimal schedule and Theorem 1 suggest that there may be a gap between the LPOP value ($V_n^{CI}$) and the value of the CI problem ($V_n^{CI}$). We quantify this stochasticity gap by showing that $\gamma_n := V_n - V_n^{CI} \geq 0$ decreases to zero as $n \to \infty$. Recall that $\bar{V} = c_w \int_H^\bar{\tau} x(t)dt + c_o(\bar{\tau} - H)$ is the value of the FOP. The following is the main result of this section.

**Proposition 2** The SG in the fluid limit is zero. That is, $\gamma_n \to 0$ as $n \to \infty$.

The proof of Proposition 2 follows as a consequence of the following lemmas.

**Lemma 5** The optimal overage time in the CI problem satisfies:

$$\mathbb{E}[(\tau_n^* - H)^+] \to (\bar{\tau} - H) \text{ as } n \to \infty,$$

where $\bar{\tau} = p(\alpha \mu)^{-1}$.

Now, let $X_n(t) := n^{-1}(\Xi(N_n) - S_n(t) - 1)^+$ and $x(t) = (\alpha p - \mu t)$ for all $t \geq 0$. We prove that the expectation of the integral $\int_H^{H \vee \tau_n^*} X_n(t)dt$ converges as $n \to \infty$.

**Lemma 6** The optimal expected makespan of the CI problem satisfies

$$\mathbb{E}\left[\int_H^{H \vee \tau_n^*} X_n(t)dt\right] \to \int_H^{\bar{\tau}} x(t)dt \text{ as } n \to \infty.$$

**Proof of Proposition 2** Note that $\gamma_n = V_n - V_n^{CI} = (V_n - \bar{V}) + (\bar{V} - V_n^{CI})$. Then, Lemma 5 and Lemma 6 imply that $\bar{V} - V_n^{CI} \to 0$ as $n \to \infty$. Then, $\limsup_{n \to \infty} (V_n - \bar{V}) \leq \limsup_{n \to \infty} (J_n(\{T_i^{J_n}\}) - \bar{V}) \leq 0$. On the other hand, Theorem 1 implies that $\inf_{n \to \infty} (V_n - \bar{V}) \geq 0$. Thus, $(V_n - \bar{V}) \to 0$ as $n \to \infty$.

**Proof of Lemma 5** By definition, $\tau_n^* := \Upsilon_n(\Xi(N_n))$, where recall that $\Upsilon_n(m) := \sum_{i=1}^m \nu_i^*$. It is straightforward to deduce that $(\tau_n^* - H)^+ \to (\bar{\tau} - H)$ as $n \to \infty$ as a consequence of the LLN.

**Proof of Lemma 6** We first prove that the optimal makespan converges in probability to the limit on the right hand side. It suffices to assume that $\tau_n^* > H$, since we know from the proof...

20
of Lemma [3] that \( \tau_n^* \Rightarrow \bar{\tau} \) as \( n \rightarrow \infty \) and that \( \bar{\tau} > H \) (by the overload assumption [15]). Thus, consider
\[
\left| \int_H^{\tau_n^*} x_n(t) dt - \int_H^\tau x(t) dt \right| \leq \left| \int_H^{\tau_n^*} x_n(t) dt - \int_H^\tau x_n(t) dt \right| + \left| \int_H^\tau x_n(t) dt - \int_H^\tau x(t) dt \right|. \tag{48}
\]
Consider the first term on the RHS above, and observe that
\[
\left| \int_H^{\tau_n^*} x_n(t) dt - \int_H^\tau x_n(t) dt \right| = \left| \int_H^{\tau_n^*} x_n(t) dt 1_{\{\tau_n^* \leq \bar{\tau}\}} + \int_H^{\tau_n^*} x_n(t) dt 1_{\{\tau_n^* > \bar{\tau}\}} \right| \leq \alpha |\tau_n^* - \bar{\tau}|,
\]
where the last inequality follows from the fact that \( x_n(t) \leq \alpha \) for all \( t \in [0, \infty) \). Therefore, it follows that \( \int_H^{\tau_n^*} x_n(t) dt - \int_H^\tau x_n(t) dt \Rightarrow 0 \) as \( n \rightarrow \infty \). Next, consider the second term on the RHS. Using the facts that \( x_n(t) \Rightarrow x(t) \) as \( n \rightarrow \infty \) pointwise and \( |x_n(t) - x(t)| \leq \alpha \) for all \( t \in [0, \infty) \), the bounded convergence theorem implies that \( \int_H^\tau |x_n(t) - x(t)| dt \Rightarrow 0 \) as \( n \rightarrow \infty \). Thus, it follows that \( \int_H^{\tau_n^*} x_n(t) dt \Rightarrow \int_H^\tau x(t) dt \) as \( n \rightarrow \infty \). Finally, observe that
\[
\left| \int_H^{H + \tau_n^*} x_n(t) dt \right| \leq \alpha^2 |(\tau_n^* - H)^+|^2,
\]
and from the analysis in Lemma [5] it follows that \( \mathbb{E} \left| \int_H^{H + \tau_n^*} x_n(t) dt \right|^2 < \infty \). Therefore, the sequence of integrals are uniformly integrable, implying [17].

4 Large population optima: diffusion scale

Some of the results in this section require a strengthening of the second moment condition of the service time.

Assumption 1 The service times \( \nu_i \) possess a finite \( 3 + \varepsilon \) moment, that is, \( \mathbb{E}[\nu_i^{3+\varepsilon}] < \infty \) for some \( \varepsilon > 0 \).

4.1 Model equations and BOP derivation

As captured by the fact that the FOP is deterministic, the inherent stochasticity in the FPOP degenerates in fluid scale. A more realistic setting should capture the effect of the stochastic variation introduced by the no-shows and the random service times. In this section we consider the scheduling problem at diffusion scale that incorporates second-order effects.

Our first goal in this subsection is to write down equations for the various quantities of interest related to the diffusion scale problem, and then use these equations to propose a Brownian optimization problem (BOP).

By the fluid scale analysis, the rescaled asymptotically optimal schedule \( E^f_n(t) \) converges to \( \lambda^*(t) = (p^{-1} \mu t) \land \alpha \). Under our assumption (15), \( p^{-1} \mu H < \alpha \), and so the function \( \lambda^* \) has a jump of size \( \lambda^H := \alpha - p^{-1} \mu H \) at \( H \). In general, we shall denote with a superscript \( H \) quantities that correspond to the allocation at the singular time point \( H \).

Denote
\[
\hat{E}_n(t) = \frac{E_n(t) - np^{-1} \mu t}{\sqrt{n}}, \quad t \in [0, H).
\]
Recall that $E_n(H) = N_n = \lfloor \alpha n \rfloor$. If we let $E_n^H = E_n(H) - E_n(H^-)$ then

$$
\hat{E}_n^H := \frac{E_n^H - n\lambda^H}{\sqrt{n}} = \frac{N_n - E_n(H^-) - n\alpha + np^{-1}\mu H}{\sqrt{n}} = -\hat{E}_n(H^-) + \frac{[n\alpha] - n\alpha}{\sqrt{n}}.
$$

Next, recall $\Xi(k) = \sum_{i=1}^k \xi_i, k \in \mathbb{Z}_+$. Let

$$
\hat{\Xi}_n(t) = \frac{\sum_{i=1}^{\lfloor nt \rfloor} (\xi_i - p)}{\sqrt{n}} = \frac{\Xi([nt]) - p\lfloor nt \rfloor}{\sqrt{n}}, \quad t \in \mathbb{R}_+.
$$

(49)

Now, $A_n(t) = \Xi \circ E_n(t)$ by (11). Let us consider this process on $[0, H)$ separately from its jump at $H$. For $t \in [0, H)$, use the above to write

$$
\hat{A}_n(t) := \frac{A_n(t) - n\mu t}{\sqrt{n}}
= \frac{\Xi(E_n(t)) - pE_n(t)}{\sqrt{n}} + pE_n(t) - np^{-1}\mu t
= \frac{\Xi([nE_n(t)]) - p\lfloor nE_n(t) \rfloor}{\sqrt{n}} + pE_n(t) - np^{-1}\mu t
= \hat{\Xi}_n(E_n(t)) + p\hat{E}_n(t), \quad t \in [0, H).
$$

(50)

The number of show ups at the time $H$ is $A_n^H := A_n(H) - A_n(H^-) = \Xi(N_n) - \Xi(E_n(H^-))$. Hence

$$
\hat{A}_n^H := \frac{A_n^H - np\lambda^H}{\sqrt{n}}
= \frac{\Xi(N_n) - n\alpha}{\sqrt{n}} - \frac{\Xi(E_n(H^-)) - pE_n(H^-)}{\sqrt{n}} - pE_n(H^-) - np^{-1}\mu H
= \hat{\Xi}_n(\alpha) - \hat{\Xi}_n(E_n(H^-)) - p\hat{E}_n(H^-).
$$

(51)

Next we let

$$
\hat{S}_n(t) = \frac{S_n(t) - n\mu t}{\sqrt{n}}, \quad t \geq 0.
$$

We define the diffusion scale queue length, for $t \in [0, H)$ only, as

$$
\hat{Q}_n(t) = \frac{Q_n(t)}{\sqrt{n}}, \quad t \in [0, H).
$$

It is possible to consider the diffusion scale queue length for $t \geq H$ by first centering about $q^*(t)$ (as defined in Lemma 3) and then rescaling, but to avoid confusion, we do not extend the process $\hat{Q}_n$ beyond the interval $[0, H)$. We denote $q_n = n^{-1/2}(Q_n(H) - q^*(H))$.

By (2), letting $I_n(t) = t - B_n(t)$ denote the cumulative idleness process,

$$
\hat{Q}_n(t) = n^{-1/2}(A_n(t) - S_n \circ B_n(t))
= \hat{A}_n(t) - \hat{S}_n(B_n(t)) + n^{1/2}\mu I_n(t)
= \hat{\Xi}_n(E_n(t)) + p\hat{E}_n(t) - \hat{S}_n(B_n(t)) + n^{1/2}\mu I_n(t), \quad t \in [0, H),
$$

(52)

$$
= \Gamma_1[p\hat{E}_n + X_n](t), \quad t \in [0, H),
$$

(53)
where (50) is used, and one denotes

\[ X_n(t) = \hat{\zeta}_n(\hat{E}_n(t)) - \hat{S}_n(B_n(t)). \]

The queue length dynamics for the BOP will later be derived from the above relation.

As for \( q_n \), we can write it, using (51) and (52), as

\[ q_n = \hat{Q}_n(H-) + \hat{A}_n^H \]

\[ = -\hat{S}_n(B_n(H-)) + \hat{\zeta}_n(\alpha) + n^{1/2} \mu I_n(H-) \]

\[ = \Gamma_1 [p\hat{E}_n + X_n](H-) + \hat{\zeta}_n(\alpha) - \hat{\zeta}_n(\hat{E}_n(H-)) - p\hat{E}_n(H-). \] (55)

Next we develop equations for the two ingredients of the cost, namely the overtime \([\tau_n - H]^+\) and the makespan, suitably normalized at the diffusion scale.

For \( t \geq H \), (2) is still valid, but \( A_n(t) \) is simply given by \( A_n(H) \) since there are no arrivals after time \( H \). Moreover, the server is busy continuously on \([H, \tau_n)\), on the event \( \tau_n > H \). Hence \( B_n(t) = B_n(H) + t - H \) for \( t \in [H, \tau_n) \). Clearly, \( Q_n(H) = Q_n(H-) + A_n^H \). For \( t \in [H, \tau_n] \), the queue length is given by

\[ Q_n(t) = Q_n(H) - D_n(t) + D_n(H) \]

\[ = Q_n(H) - S_n(B_n(t)) + S_n(B_n(H)) \]

\[ = np\lambda^H + \left[ Q_n(H-) + A_n^H - np\lambda^H \right] \]

\[ - n\mu(t - H) - [S_n(B_n(t)) - n\mu(B_n(t))] \]

\[ + [S_n(B_n(H)) - n\mu B_n(H)]. \]

Dividing by \( \sqrt{n} \), for \( t \in [H, \tau_n] \),

\[ n^{-1/2}Q_n(t) = n^{1/2}p\lambda^H + q_n - n^{1/2}\mu(t - H) - \hat{S}_n(B_n(t)) + \hat{S}_n(B_n(H)). \] (56)

We have for \( \tau_n \) the equation \( Q_n(\tau_n) = 0 \) and for \( \bar{\tau} \), \( q^*(\bar{\tau}) = 0 \), where we recall that for \( t > H \),

\[ q^*(t) = (p\lambda^H - \mu(t - H)) \vee 0 = (p\alpha - \mu H - \mu(t - H)) \vee 0 = (p\alpha - \mu t) \vee 0. \] Hence \( p\lambda^H - \mu(\bar{\tau} - H) = 0 \).

Using these two relations in (56) gives

\[ 0 = n^{1/2}[\mu(\tau_n - \bar{\tau})] + q_n - \hat{S}_n(B_n(\tau_n)) + \hat{S}_n(B_n(H)). \]

If we set

\[ \hat{\tau}_n = n^{1/2}(\tau_n - \bar{\tau}), \] (57)

then

\[ \mu\hat{\tau}_n = q_n - \hat{S}_n(B_n(\tau_n)) + \hat{S}_n(B_n(H)). \] (58)

Equation (58) will be used to propose a formal limit of \( \hat{\tau}_n \), and later, to analyze rigorously the weak limit thereof.
Next, the FOP quantity for the makespan is \( \bar{W} = \int_H^\tau (p\lambda^H - \mu(t-H))dt \), where \( \bar{\tau} = H + p\mu^{-1}\lambda^H \).

Thus
\[
\hat{W}_n := n^{-1/2}(\hat{W}_n - \bar{W}) = n^{-1/2}W_n - n^{-1/2}(\bar{W}) = \hat{W}_n(1) + \hat{W}_n(2),
\]
with \( \hat{W}_n(1) := \int_{0}^{\tau_n} \hat{Q}_n(t)dt, \)
\[
\hat{W}_n(2) := n^{-1/2} \int_{\tau_n}^{\tau_n} Q_n(t)dt - n^{-1/2} \int_{\tau_n}^{\tau_n}(p\lambda^H - \mu(t-H))dt.
\]

On the event \( \tau_n < H \), the first term in the expression for \( \hat{W}_n(2) \) is zero, and we obtain \( \hat{W}_n(2) = -n^{-1/2} \bar{W} \). Next, consider the event \( \tau_n \geq H \). Then
\[
\hat{W}_n(2) = \int_{H}^{\tau_n} |n^{-1/2}Q_n(t) - n^{-1/2}(p\lambda^H - \mu(t-H))|dt + n^{-1/2} \int_{\tau_n}^{\tau_n}(p\lambda^H - \mu(t-H))dt.
\]

A use of \([56]\) and the computed value of \( \bar{\tau} \) gives
\[
\hat{W}_n(2) = \int_{H}^{\tau_n} [n^{-1/2}Q_n(t) - n^{-1/2}(p\lambda^H - \mu(t-H))]dt - \frac{\mu}{2}n^{-1/2}(\tau_n - \bar{\tau})^2.
\]

To derive the BOP, note first that the FCLT applies to the processes \( \hat{\Xi}_n \) and \( \hat{S}_n \). That is, let \( X^{(1)} \) and \( X^{(2)} \) be mutually independent 1-dimensional BMs with zero drift and diffusion coefficient \((p(1-p))^{1/2}\) and \(1^{1/2}C_S\), respectively. Then by the FCLT, \((\hat{\Xi}_n, \hat{S}_n) \Rightarrow (X^{(1)}, X^{(2)}) \) \([4] \S 17\).

We take formal limits in equation \([52]\). Denote by \( Q, U \) and \( L \) limits of the processes \( Q_n, p\hat{E}_n \) and \( n^{1/2}\mu\hat{I}_n \), respectively, on the time interval \([0, H] \). Denote \( \bar{\mu} = p^{-1}\mu \), and approximate \( E_n(t) \) as \( \bar{\mu}t \), and \( B_n(t) \) as \( t \in [0, H] \). Then, we expect the following relationship to hold in the limit
\[
Q(t) = U(t) + X^{(1)}(\bar{\mu}t) - X^{(2)}(t) + L(t), \quad t \in [0, H].
\]

Moreover,
\[
Q(t) \geq 0, \quad t \in [0, H], \quad \text{and} \quad \int_{[0, H]} Q(t)dtL(t) = 0.
\]

From \([51]\), letting \( A^H \) be a weak limit of \( \hat{A}_n^H \),
\[
A^H = X^{(1)}(\alpha) - X^{(2)}(\bar{\mu}H) - U(H-).
\]

To obtain an expression for \( \bar{\tau} \), a weak limit of \( \bar{\tau}_n \), use \([58]\) to write
\[
\bar{\tau} = \mu^{-1}(Q(H-) + A^H - X^{(2)}(\bar{\tau}) + X^{(2)}(H))
\]
\[
= \mu^{-1}(X^{(1)}(\alpha) - X^{(2)}(\bar{\tau}) + L(H-)).
\]

With \( \hat{W}, \hat{W}(1) \) and \( \hat{W}(2) \) representing limits of \( \hat{W}_n, \hat{W}_n(1) \) and \( \hat{W}_n(2) \), respectively, we have from \([59]\), \( \hat{W}(1) = \int_{H}^{\tau}(Q(t))dt \) (since \( \tau_n \) converges to \( \bar{\tau} = H \)), while by \([63]\),
\[
\hat{W}(2) = \int_{H}^{\tau}(Q(H-) + A^H - X^{(2)}(t) + X^{(2)}(H))dt = \int_{H}^{\tau}(X^{(1)}(1) - X^{(2)}(t) + L(H-))dt.
\]
The cost is thus given by
\[
\hat{J}(U) = c_w E[\hat{W}(1) + \hat{W}(2)] + c_o E[\hat{\tau}]
\]
\[
= c_w E \int_0^H Q(t) dt + c_w(\hat{\tau} - H)E[L(H-)] + c_o \mu^{-1} E[L(H-)]
\]
\[
= c_w E \int_0^H Q(t) dt + \tilde{c}_o E[L(H-)],
\]  
(66)
where \( \tilde{c}_o = c_w(\hat{\tau} - H) + c_o \mu^{-1} \). Finally, we can simplify (64) by considering \( X \), a BM with drift zero and diffusion coefficient \( \sigma = (\bar{\mu}p(1 - p) + \mu C_S^2)^{1/2} = \mu^{1/2}(1 - p + C_S^2)^{1/2} \) in place of the two BM terms, and write
\[
Q(t) = U(t) + X(t) + L(t), \quad t \in [0, H).
\]  
(67)
We thus let \( \mathcal{U} \) denote the collection of RCLL functions \( u : [0, H] \to \mathbb{R} \), and note that given \( u \in \mathcal{U} \) (67) and (65) uniquely define \( Q \) and \( L \) in terms of \( X \).

We can now state the BOP of interest, as a problem involving (65), (66) and (67), with value given by
\[
\hat{V} = \inf_{U \in \mathcal{U}} \hat{J}(U).
\]  
(68)

Remark. Instead of \( \mathcal{U} \) being functions defined on \( [0, H] \) we can work with functions on \( [0, H] \) and replace the term \( E[L(H-)] \) by \( E[L(H)] \) in (66). This will not change the value \( \hat{V} \), due to the fact that having a jump \( L(H) - L(H-) > 0 \) can only increase the cost \( \hat{J} \) as compared to having \( L(H) = L(H-) \) (the jump cannot be negative since \( L \) is non-decreasing). Throughout what follows we shall work with this slightly modified definition of \( \mathcal{U} \) and \( \hat{J}(U) \).

Remark. We can present the optimization problem in a way that the cost is more explicit, and moreover makes it easy to see that it is a convex optimization problem. The pair of equations (65) and (67) is related to the Skorohod Problem on the half line. Namely, \( Q = \Gamma_1[U + X] \). Thus
\[
Q(t) = U(t) + X(t) - \inf_{s \in [0, t]} [U(s) + X(s)] \wedge 0], \quad L(t) = Q(t) - U(t) - X(t).
\]  
(69)
We can therefore write \( \hat{J} \) as
\[
\hat{J}(U) = c_w E \int_0^H \Gamma_1[U + X](t) dt + \tilde{c}_o E[\Gamma_1[U + X](H) - U(H) - X(H)].
\]

4.2 Large time solution of the BOP

In this subsection we analyze the BOP at the large \( H \) limit. Note carefully that Assumption (18) puts a restriction on \( H \), namely \( p^{-1} \mu H < \alpha \). Thus \( H \) cannot be taken arbitrarily large without modifying \( (\mu, p, \alpha) \). In our treatment \( \mu \) and \( p \) remain fixed and \( \alpha \) and \( H \) grow so that the assumption remains valid. However, this issue is not significant in this subsection where we only work with the BOP itself, because the parameter \( \alpha \) does not show up in it. It does become relevant in later sections.

Recall that \( X \) is a \((0, \sigma)\)-BM, \( \mathcal{U}_H \) denotes the collection of RCLL functions \([0, H] \to \mathbb{R} \), and for \( U \in \mathcal{U}_H \) let \( L = L^U \) and \( Q = Q^U \) be defined as
\[
L_t = \sup_{s \in [0, t]} (-X(s) - U(s))^+, \quad Q(t) = X(t) + U(t) + L(t), \quad t \in [0, H].
\]  
25
Let also
\[
\hat{J}_H(U) = \frac{c_w}{H} \mathbb{E} \int_0^H Q(t) \, dt + \frac{\tilde{c}_o}{H} \mathbb{E}[Q(H) - U(H)], \quad U \in \mathcal{U}_H, \quad (70)
\]
\[
\hat{V}_H = \inf_{U \in \mathcal{U}_H} \hat{J}_H(U).
\]
Denote by $\mathcal{U}_H^{\text{lin}}$ the collection of linear functions $U(t) = \beta t$, $t \in [0, H]$ for some $\beta \in \mathbb{R}$. Note that the process $Q$ corresponding to such a control is a reflected BM with drift $\beta$ and diffusion coefficient $\sigma$.

For $\beta < 0$ let $m_{\text{RBM}(\beta)}(dx) = -\frac{2\beta}{\sigma^2} e^{\beta x/\sigma^2} dx$, $x \in [0, \infty)$. This probability measure on $[0, \infty)$ is the stationary distribution of RBM with drift $\beta < 0$ and diffusion coefficient $\sigma$.

Let
\[
V^* = \inf_{\beta < 0} \left[ c_w \int x m_{\text{RBM}(\beta)}(dx) - \tilde{c}_o \beta \right]. \quad (71)
\]
We next establish that for the large horizon BOP it is sufficient to consider control functions in $\mathcal{U}_H^{\text{lin}}$.

**Proposition 3** One has
\[
\lim_{H \to \infty} \hat{V}_H = \lim_{H \to \infty} \inf_{U \in \mathcal{U}_H^{\text{lin}}} \hat{J}_H(U) = V^* = \sigma \sqrt{2c_w \tilde{c}_o}. \quad (72)
\]
Moreover, $\beta^* = -\sigma \sqrt{c_w/(2\tilde{c}_o)}$ is optimal for both the expressions in (71) and (72), that is, with $U^*(t) = \beta^* t$, $\lim_{H \to \infty} \hat{J}_H(U^*) = V^*$ and $c_w \int x m_{\text{RBM}(\beta^*)}(dx) - \tilde{c}_o \beta^* = V^*$.

The proof is based on several lemmas. The first is concerned with large time behavior of RBM and computes $V^*$.

**Lemma 7** 1. For each $\beta \in \mathbb{R}$, let $Q^\beta_t$ be a $(\beta, \sigma)$-RBM starting at the origin. Then
\[
\lim_{t \to \infty} \inf_{\beta \in \mathbb{R}} [c_w \mathbb{E}[Q^\beta_t] - \tilde{c}_o \beta] = V^*
\]
2. The infimum in (71) is attained at $\beta^* = -\sigma \sqrt{c_w/(2\tilde{c}_o)}$ and $V^* = \sigma \sqrt{2c_w \tilde{c}_o}$.

The following lemma shows that one can focus on controls under which $\mathbb{E}[Q_H] \geq 2\epsilon H$ is sublinear in $H$.

**Lemma 8** For every $\epsilon > 0$ there exists $H_0$ such that for $H > H_0$ and $U$ for which $\mathbb{E}[Q^U_H] \geq \epsilon H$ one can find $\tilde{U}$ with $\mathbb{E}[Q^\tilde{U}_H] < \epsilon H$ and $\hat{J}_H(\tilde{U}) \leq \hat{J}_H(U) + e_1(H)$. Here, $e_1(H)$ does not depend on $U$ and converges to zero as $H \to \infty$.

The following lemma argues that one may focus on controls that are constant on an initial and terminal intervals. More precisely, given $z, k, H \in (0, \infty)$, $2z < H$, define the class of controls $\mathcal{U}^\#(z, k, H)$ as the collection of members $U \in \mathcal{U}_H$ which satisfy $U_t = k$ for $t \in [0, z)$ and $U_t = U_H$ for $t \in [H - z, H]$. 
Lemma 9 Given $z, k, H$ and $U \in U_H$, let $U^* \in U^* (z, k, H)$ be defined as

$$U^*_t = \begin{cases} k, & t \in [0, z), \\ U_t, & t \in [z, H - z), \\ U_H, & t \in [H - z, H). \end{cases}$$

Fix $\varepsilon > 0$, let $H_0 = H_0(\varepsilon)$ be as in Lemma 8 and consider $H > H_0$ and $U \in U_H$ for which $E_{Q_H} \leq \varepsilon H$. Then

$$\hat{J}_H(U^*) \leq \hat{J}_H(U) + e_2(z, k, H), \quad (74)$$

where

$$\limsup_{H \to \infty} e_2(z, k, H) \leq c_w E[r] + c_w \varepsilon z, \quad (75)$$

$$r = r(k, z, X) = \sup_{s \in [0, z)} (-k - X_s)^+. \quad \text{[Equation]}$$

The following lemma relates the large time behavior of $\hat{J}_H(U)$ for $U$ as in Lemma 9 to the expression $V^*$.

Lemma 10 One has

$$\liminf_{H \to \infty} \inf_{U \in U^* (z, k, H)} \hat{J}_H(U) \geq V^* - e_3(z), \quad \text{where} \quad e_3(z) \to 0 \text{ as } z \to \infty.$$

Proof of Proposition 3. Using Lemmas 8, 9 and 10 for any $\varepsilon > 0$, $z > 0$ and $k > 0$,

$$\liminf_{H \to \infty} \hat{V}_H \geq \liminf_{H \to \infty} \inf_{U \in U_H : E_{Q_H} \leq \varepsilon H} \hat{J}_H(U) \geq \liminf_{H \to \infty} \inf_{U \in U^* (z, k, H) : E_{Q_H} \leq \varepsilon H} \hat{J}_H(U) - \limsup_{H \to \infty} e_2(z, k, H) \geq V^* - \limsup_{H \to \infty} e_2(z, k, H) - e_3(z),$$

for $e_2$ and $e_3$ as in these lemmas. Thus

$$\liminf_{H \to \infty} \hat{V}_H \geq V^* - c_w E \left[ \sup_{s \in [0, z)} (-k - X_s)^+ \right] - c_w \varepsilon z - e_3(z).$$

We refer to the last three terms on the RHS above as the first, second and third error terms in the order at which they appear. We first take $\varepsilon \to 0$ so that the second error term vanishes. Then we take $k \to \infty$ to have the first error term vanish, as a direct consequence of $\sup_{s \in [0, z)} (-k - X_s)^+ \leq (-k + \|X\|_z)^+$ and $E[\|X\|_z] < \infty$. Finally we take $z \to \infty$ and the third term vanishes. We have thus shown that $\liminf_{H \to \infty} \hat{V}_H \geq V^*$. For a matching upper bound we simply select $U \in U_H^{\text{lin}}$ with $\beta = \beta^*$ and appeal to Lemma 7. We conclude that $\lim_{H \to \infty} \hat{V}_H = V^*$. \hfill \Box

Proof of Lemma 7. For each $t \geq 0$, The CDF of $Q_t^\beta$ is given by

$$P(Q_t^\beta \leq y) = \Phi\left(\frac{y - \beta t}{\sigma t^{1/2}}\right) - e^{2\beta y/\sigma^2} \Phi\left(-\frac{y - \beta t}{\sigma t^{1/2}}\right), \quad y \geq 0,$$
where $\Phi$ is the standard normal CDF ([13] page 15). For fixed $\beta < 0$, the limit distribution as $t \to \infty$ is exponential with mean $\sigma^2/(2|\beta|)$. Moreover, it can be directly checked that the CDF is monotone decreasing in $t$. Hence by monotone convergence, the expectation $\mathbb{E}[Q_t^\beta]$ converges, as $t \to \infty$, to $\sigma^2/(2|\beta|)$, provided $\beta < 0$. For $\beta \geq 0$, $P(Q_t^\beta \leq y) \to 0$ for all $y$, hence $\mathbb{E}[Q_t^\beta] \to \infty$.

Thus, denoting $F(t, \beta) = c_w \mathbb{E}[Q_t^\beta] - \tilde{c}_\sigma \beta$ and $F(\beta) = c_w \sigma^2/(2|\beta|) + \tilde{c}_\sigma |\beta|$ for $\beta < 0$, $F(\beta) = \infty$ for $\beta \geq 0$, we have the pointwise convergence $\lim_{t \to \infty} F(t, \beta) = F(\beta)$.

Our goal now is to show
\[ \lim_{t \to \infty} \inf_{\beta \in \mathbb{R}} F(t, \beta) = \inf_{\beta < 0} F(\beta). \] (76)

We achieve this in three steps. First we show that $\inf_{\beta \geq 0} F(t, \beta) \to \infty$ as $t \to \infty$. Then we argue that there exist $-\infty < a < -1 < b < 0$ such that, for all large $t$, $\inf_{\beta \in \mathbb{R}} F(t, \beta) = \inf_{\beta \in [a, b]} F(t, \beta)$. Then we are in a position to use Dini’s theorem to argue that the order of the $t$-limit and the $\beta$-ininfum can be interchanged. We shall use an additional monotonicity property. It can be readily checked by the above CDF formula that $\beta \to P(Q_t^\beta \leq y)$ is monotone decreasing (for each $t$ and $y$). Hence $\beta \to \mathbb{E}[Q_t^\beta]$ is monotone increasing (for each $t$).

For the first step alluded to above, the pointwise convergence $\mathbb{E}[Q_t^\beta] \to \infty$ as $t \to \infty$ can be used to deduce $\inf_{\beta \in [0, 1]} [c_w \mathbb{E}[Q_t^\beta] - \tilde{c}_\sigma \beta] \to \infty$ because for $\beta \in [0, 1]$ and all $t$, we have $c_w \mathbb{E}[Q_t^\beta] - \tilde{c}_\sigma \beta \to c_w \mathbb{E}[Q_t^0] - \tilde{c}_\sigma \to \infty$ as $t \to \infty$. To show $\inf_{\beta \in (1, \infty)} [c_w \mathbb{E}[Q_t^\beta] - \tilde{c}_\sigma \beta] \to \infty$ we argue as follows. By the formula for $Q_t^\beta$ we have the lower bound $Q_t^\beta \geq X_t + \beta t$. Hence for all $\beta > 1$, $c_w Q_t^\beta - \tilde{c}_\sigma \beta \geq c_w X_t + \beta (c_w t - \tilde{c}_\sigma)$. Hence for $t > \tilde{c}_\sigma/c_w$, $c_w Q_t^\beta - \tilde{c}_\sigma \beta \geq c_w X_t + (c_w t - \tilde{c}_\sigma)$. Taking expectation gives $\inf_{\beta \in (1, \infty)} [c_w \mathbb{E}[Q_t^\beta] - \tilde{c}_\sigma \beta] \geq c_w t - \tilde{c}_\sigma \to \infty$ as $t \to \infty$.

For the next step, fix $u > 0$ and let $-\infty < a < -1 < b < 0$ such that $\tilde{c}_\sigma |a| > u$, $\tilde{c}_\sigma |b| < 1$ and $F(b) > u$ (note that $F(0-) = \infty$). Then for any $\beta < a$, $F(t, \beta) \geq \tilde{c}_\sigma |\beta| > u$. Next, consider $\beta \in (b, 0)$. The pointwise convergence of $F(t, b)$ to $F(b)$ implies that for some $t_0$ and all $t \geq t_0$, $F(t, b) > u - 1$ and, since $\tilde{c}_\sigma |b| < 1$, $c_w \mathbb{E}[Q_t^b] > u - 2$. Using again the monotonicity in $\beta$, $F(t, \beta) \geq c_w \mathbb{E}[Q_t^\beta] > u - 2$ for $\beta \in (b, 0)$.

Since for fixed $\beta < 0$ the limit $\lim_{t \to \infty} F(t, \beta)$ is finite, and the constant $u$ is arbitrary, it follows that $a$ and $b$ as above can be found so that the infimum is achieved in $[a, b]$ for all large $t$.

Next, $F(t, \beta)$ is continuous in $\beta$ for $\beta$ in the compact interval $[a, b]$, and these functions converge pointwise as $t \to \infty$ to a continuous function $F(\beta)$. Hence by Dini’s theorem, the convergence is uniform in $\beta$. We conclude that, as $t \to \infty$, $\inf_{\beta \in [a, b]} F(t, \beta) \to \inf_{\beta \in [a, b]} F(\beta)$. This proves part 1 of the lemma.

It remains to solve the optimization problem ([71]), or equivalently the RHS of ([76]). As already stated, for $\beta < 0$, the first moment of $m_{\text{RBM}}(\beta)$ is given by $\sigma^2/(2|\beta|)$. We are therefore interested in minimizing
\[ c_w \frac{\sigma^2}{2|\beta|} + \tilde{c}_\sigma |\beta| \]
over $\beta \in (-\infty, 0)$. By a direct calculation, the minimum is attained at $\beta^* = -\sigma(c_w/2\tilde{c}_\sigma)^{1/2}$ and is given by $\sigma(2c_w \tilde{c}_\sigma)^{1/2}$. □

**Proof of Lemma** Fix $\varepsilon > 0$. Given any $H$ and any $U \in \mathcal{U}_H$ we have for $Q = Q^U$ the relation
\[ Q_t = U_t + X_t + \sup_{s \leq t} (-U_s - X_s)^+, \quad t \in [0, H]. \]
Define \( q = q^U \) as
\[
q_t = U_t + \sup_{s \leq t} (-U_s)^+, \quad t \in [0, H].
\]
Then
\[
\|Q - q\|_H \leq 2\|X\|_H. \tag{77}
\]
Consider \( U \) for which \( \mathbb{E}[Q_H] \geq \varepsilon H \). Then \( q_H \geq \varepsilon H - 2\mathbb{E}[\|X\|_H] \). Fix \( H_0 \) so large that for every \( H > H_0 \), \( 2\mathbb{E}[\|X\|_H] < \varepsilon H / 4 \), and consider in what follows only \( H > H_0 \). Then \( q_H > 3\varepsilon H / 4 \). Let \( \tilde{U} \) be defined as \( \tilde{U} = U \) on \([0, H]\) and \( \tilde{U}_H = U_H - q_H \) (here, \( q = q^U \)). Denote \( \tilde{Q} = Q^\tilde{U} \) and \( \tilde{q} = q^\tilde{U} \).

Clearly, on \([0, H]\), we have \( \tilde{q} = q \) and \( \tilde{Q} = Q \). As for the time \( H \), we have
\[
\tilde{q}_H = U_H - q_H + \sup_{s \leq H} (-U_s + q_H 1_{\{s = H\}})^+.
\]

As a result,
\[
\tilde{Q}_H = \tilde{q}_H + \tilde{Q}_H - \tilde{q}_H = \tilde{Q}_H - \tilde{q}_H \leq 2\|X\|_H.
\]
by (77). This shows \( \mathbb{E}[\tilde{Q}_H] \leq 2\mathbb{E}[\|X\|_H] < \varepsilon H / 4 \). Moreover, by (70),
\[
\tilde{J}_H(\tilde{U}) \leq \tilde{J}_H(U) + \frac{c_4}{H} 2\mathbb{E}[\|X\|_H] \leq \tilde{J}_H(U) + c_4 H^{-1/2},
\]
for a suitable constant \( c_4 \). This proves the lemma. \( \square \)

**Proof of Lemma 9** Denote \( Q = Q^U \) and \( Q^# = Q^U^# \). First, we provide lower estimates on \( Q - Q^# \) on each of the three intervals separately:

**The interval \([0, z]\).** Here we use the trivial lower bound \( Q_t \geq 0 \). As for \( Q^# \),
\[
Q^#_t = k + X_t + \sup_{s \leq t} (-k - X_s)^+ \leq 2k + 2\|X\|_z.
\]

**The interval \([z, H - z]\).** We have
\[
Q_t = U_t + X_t + \sup_{s \leq t} (-U_s - X_s)^+ \\
\geq U_t + X_t + \sup_{s \in [z, t]} (-U_s - X_s)^+ \\
\geq U_t + X_t + \max_{s \in [z, t]} \left( r, \sup_{s \in [z, t]} (-U_s - X_s)^+ \right) - r,
\]
where we have used the fact that \( a \geq a \vee b - b \) provided \( a \geq 0 \) and \( b \geq 0 \). Recalling that for \( t \in [z, H - z] \) \( U \) and \( U^# \) agree and that \( U^# = k \) on \([0, z]\), the expression above is equal to
\[
Q^#_t + X_t + \sup_{s \in [0, t]} (-U^#_s - X_s)^+ - r.
\]
It follows that
\[
Q_t \geq Q^#_t - r.
\]

**The interval \([H - z, H]\).** In fact, we will only need a lower estimate on \( Q_H - Q^#_H \). We have
\[
Q_H = U_H + X_H + \sup_{s \leq H} (-U_s - X_s)^+,
\]
\[ Q^+_H = U_H + X_H + \max \left( \sup_{s < H - z} (-U_s^+ - X_s)^+, \sup_{s \in [H - z, H]} (-U_H - X_s)^+ \right). \]

Hence
\[
Q_H \geq U_H + X_H + \sup_{s \in [z, H]} (-U_s - X_s)^+ \\
\geq U_H + X_H + \max \left( r, \sup_{s \in [z, H]} (-U_s - X_s)^+ \right) - r \\
\geq U_H + X_H + \max \left( r, \sup_{s \in [z, H - z]} (-U_s - X_s)^+, \sup_{s \in [H - z, H]} (-U_H - X_s)^+ \right) - r - \hat{r},
\]
where \( \hat{r} = \sup_{s \in [H - z, H]} |X_s - X_H| \). This shows
\[ Q_H \geq Q^+_H - r - \hat{r}. \]

Next,
\[
\hat{J}_H(U) = \frac{c_w}{H} \mathbb{E} \int_0^H Q_s ds + \frac{\bar{c}_o}{H} \mathbb{E}[Q_H - U_H] \\
\geq \frac{c_w}{H} \mathbb{E} \int_z^{H - z} Q_s ds + \frac{\bar{c}_o}{H} \mathbb{E}[Q_H - U_H] \\
\geq \frac{c_w}{H} \left( \mathbb{E} \int_z^{H - z} Q^+_s ds - (H - 2z)\mathbb{E}[r] \right) + \frac{\bar{c}_o}{H} \{ \mathbb{E}[Q^+_H - U^+_H] - \mathbb{E}[r + \hat{r}] \}.
\]

Also,
\[
\hat{J}_H(U^+) = \frac{c_w}{H} \mathbb{E} \int_0^H Q^+_s ds + \frac{\bar{c}_o}{H} \mathbb{E}[Q^+_H - U^+_H] \\
\leq \frac{c_w}{H} \left[ 2k + 2\mathbb{E}[\|X\|_z] + \mathbb{E} \int_z^{H - z} Q^+_s ds + z\mathbb{E}[Q_H + \hat{r}] \right] + \frac{\bar{c}_o}{H} \mathbb{E}[Q^+_H - U^+_H],
\]
where we used that for \( t \in [H - z, H] \) one has \( Q^+_t = X_t + U^+_t + L^+_t \leq X_t + U^+_t + L^+_H = X_t - X_H + Q^+_H \), whence \( Q^+_t \leq Q^+_H + \hat{r} \). Combine these two bounds to obtain
\[
\hat{J}_H(U^+) - \hat{J}_H(U) \leq \frac{c_w}{H} \left[ (H - 2z)\mathbb{E}[r] + 2k + 2\mathbb{E}[\|X\|_z] + z\mathbb{E}[Q^+_H + \hat{r}] \right] + \frac{\bar{c}_o}{H} \mathbb{E}[r + \hat{r}] \\
\leq \frac{c_w}{H} \left[ (H - 2z)\mathbb{E}[r] + 2k + 2\mathbb{E}[\|X\|_z] + z\mathbb{E}[Q_H + r + 2\hat{r}] \right] + \frac{\bar{c}_o}{H} \mathbb{E}[r + \hat{r}] \\
\leq \frac{c_w}{H} \left[ (H - 2z)\mathbb{E}[r] + 2k + 2\mathbb{E}[\|X\|_z] + z\varepsilon H + z\mathbb{E}[r + 2\hat{r}] \right] + \frac{\bar{c}_o}{H} \mathbb{E}[r + \hat{r}].
\]

Denote by \( e_2(z, k, H) \) the expression on the last line above. Note that while \( \hat{r} \) depends on \( H \), its expectation does not (and is finite). Thus \( e_2 \) satisfies (75).
Proof of Lemma 10. Fix $z, k, H$ and a control $U \in \mathcal{U}^\#(z, k, H)$. Then $Q_t = Q^U_t = X_t + U_t + \sup_{s \leq t}[-X_s - U_s]^+ \geq \sup_{s \leq t}[X_t - X_s + U_t - U_s]$. Hence, for $z + t \leq H$,

$$
\int_0^{z+t} Q_s ds \geq \int_z^{z+t} Q_s ds \\
\geq \int_z^{z+t} \sup_{\theta \in [0,z]} [X_s - X_{s-\theta} + U_s - U_{s-\theta}] ds \\
\geq \int_z^{z+t} \sup_{\theta \in [0,z]} [X_s - X_{s-\theta} + U_s - U_{s-\theta}] ds.
$$

For each $s \geq z$, the stochastic process $\{X_s - X_{s-\theta}\}_{\theta \in [0,z]}$ is equal in law to $\{X_z - X_{z-\theta}\}_{\theta \in [0,z]}$. As a result,

$$
\mathbb{E} \int_0^{z+t} Q_s ds \geq \mathbb{E} \int_z^{z+t} \sup_{\theta \in [0,z]} [X_s - X_{s-\theta} + U_s - U_{s-\theta}] ds.
$$

We now use the inequality

$$
\int_a^b \sup_{\theta} f(s, \theta) ds \geq \sup_{\theta} \int_a^b f(s, \theta) ds.
$$

This gives

$$
\frac{1}{t} \mathbb{E} \int_0^{z+t} Q_s ds \geq \frac{1}{t} \mathbb{E} \sup_{\theta \in [0,z]} \int_z^{z+t} [X_s - X_{s-\theta} + U_s - U_{s-\theta}] ds \\
= \mathbb{E} \sup_{\theta \in [0,z]} \left\{[X_z - X_{z-\theta}] + \frac{1}{t} \int_z^{z+t} [U_s - U_{s-\theta}] ds\right\}.
$$

We have

$$
\int_z^{z+t} [U_s - U_{s-\theta}] ds = \int_z^{z+t} U_s ds - \int_{z-\theta}^{z-\theta+t} U_s ds = \int_z^{z+t} U_s ds - \int_z^{z-\theta} U_s ds.
$$

Moreover, by the assumption on $U$, we have $U = k$ on $[0, z)$, $U = U_H$ on $[H - z, H]$. Thus with $t + z = H$,

$$
\frac{1}{H - z} \mathbb{E} \int_0^{H} Q_s ds \geq \mathbb{E} \sup_{\theta \in [0,z]} \left\{[X_z - X_{z-\theta}] + \theta \frac{1}{H - z} (U_H - k)\right\}.
$$

Thus

$$
\tilde{J}_H(U) = \frac{c_w}{H} \mathbb{E} \int_0^H Q_t dt + \frac{\tilde{c}_o}{H} \mathbb{E}[Q_H - U_H] \\
\geq c_w \mathbb{E} \sup_{\theta \in [0,z]} \left\{\frac{H - z}{H} [X_z - X_{z-\theta}] + \theta \left(\frac{U_H}{H} - \frac{k}{H}\right)\right\} - \tilde{c}_o \frac{U_H}{H} \\
\geq \inf_{\beta \in \mathbb{R}} \left\{c_w \mathbb{E} \sup_{\theta \in [0,z]} \left\{\frac{H - z}{H} [X_z - X_{z-\theta}] + \theta (\beta - \frac{k}{H})\right\} - \tilde{c}_o \beta\right\}.
$$
Denoting $\delta = z/H$,

$$
\hat{J}_H(U) \geq \inf_{\beta \in \mathbb{R}} \left\{ c_w \mathbb{E} \sup_{\theta \in [0, z]} \left\{ (1 - \delta) [X_z - X_{z-\theta}] + \theta \beta \right\} - \bar{c}_\delta \beta \right\} - k\delta
$$

$$
\geq \inf_{\beta \in \mathbb{R}} \left\{ c_w \mathbb{E} \sup_{\theta \in [0, z]} \left\{ [X_z - X_{z-\theta}] + \theta \beta \right\} - \bar{c}_\delta \beta \right\} - k\delta - 2\delta \mathbb{E} |X|.
$$

Send $H \to \infty$ (hence $\delta \to 0$) to obtain

$$
\liminf_{H \to \infty} \inf_{U \in U^\#(z, k, H)} \hat{J}_H(U) \geq \inf_{\beta \in \mathbb{R}} A(z, \beta),
$$

where

$$
A(z, \beta) = \left\{ c_w \mathbb{E} \sup_{\theta \in [0, z]} \left\{ [X_z - X_{z-\theta}] + \theta \beta \right\} - \bar{c}_\delta \beta \right\}.
$$

Now, if we let $Q_z = \sup_{\theta \in [0, z]} \{[X_z - X_{z-\theta}] + \theta \beta\}$, then $Q_z$ is a $(\beta, \sigma)$-RBM starting from zero. Hence by Lemma 7(1), $\lim_{z \to \infty} \inf_{\beta \in \mathbb{R}} A(z, \beta) = V^*$. This proves the lemma.

### 4.3 Lower bound on the diffusion scale cost

Recall from (70) the definitions of $\hat{J}_H$ and $\hat{V}_H$, the cost and value of the BOP. Also recall the diffusion scale cost $\hat{J}_{n,H}(\{T_i\})$ and value $\hat{V}_{n,H} = n^{1/2} [V_{n,H} - \hat{V}_H]$ where $V_{n,H}$ is defined in (7) and $\hat{V}_H$ is the FOP value defined in (35). This subsection is devoted to proving the following result.

**Theorem 3** Let Assumption [H] hold. Fix $H$. Then

$$
H^{-1} \liminf_{n \to \infty} \hat{V}_{n,H} \geq \hat{V}_H. \tag{78}
$$

Assumption [H] is in force throughout this subsection. (It is used in the proof of Lemma 12 below).

We say that a sequence $\{T_i^n\} \subset \mathcal{T}_n, n \in \mathbb{N}$ achieves the limit inferior in (78) if

$$
\lim_{n \to \infty} \hat{J}_{n,H}(\{T_i^n\}) = \liminf_{n \to \infty} \hat{V}_{n,H}. \tag{79}
$$

If the expression on the LHS of (78) is infinite then there is nothing to prove. Hence we may, and will, assume that for any such $\{T_i^n\}$, the sequence $\hat{J}_{n,H}(\{T_i^n\})$ of (79) is bounded. The following lemma provides various convergence results, based to a large extent on the boundedness of the sequence of costs.

**Lemma 11** There exists a sequence $\{T_i^n\} \subset \mathcal{T}_n, n \in \mathbb{N}$ that achieves the limit inferior in (78) and for which assertions (i)–(iv) below hold.

i. $\sup_n \mathbb{E}[(\tilde{\tau}_n^-)^2] \vee \mathbb{E}[\tilde{\tau}_n^+] < \infty$ (in particular, $\tilde{\tau}_n$ are tight and $\tau_n \Rightarrow \bar{\tau}$, as $n \to \infty$).

ii. $\sup_{t \in [0, \tau_n]} |B_n(t) - t| \Rightarrow 0$, as $n \to \infty$.

iii. $\sup_n \int_0^H (p\tilde{E}_n(t)) \, dt < \infty$ and $\sup_n \{\Gamma(p\tilde{E}_n)(H-) - p\tilde{E}_n(H-)\} < \infty$.

iv. $\sup_{t \in [0, H]} |\tilde{E}_n(t) - p^{-1} \mu t| \to 0$ and $|\tilde{E}_n^H - \lambda^H| \to 0$, as $n \to \infty$.
Fix a sequence \( \{T^n_i\} \) as in Lemma 11. Let all the processes and RVs such as \( W_n, Q_n, \tau_n, \) etc. denote those associated with the schedule \( \{T^n_i\} \), for each \( n \). Recall the diffusion scale expression \( \hat{W}_n \) from (59). Also recall \( \hat{W}_n = \hat{W}_n(1) + \hat{W}_n(2) \). Then by (23),

\[
\hat{J}_{n,H}(\{T^n_i\}) = \mathbb{E}[c_w \hat{W}_n(1) + c_w \hat{W}_n(2) + c_o \hat{\tau}_n].
\]

(80)

Recall that \((\hat{\Xi}_n, \hat{S}_n) \Rightarrow (X^{(1)}, X^{(2)})\), that these two BMs are mutually independent, and that, by its definition, \( X \) is equal in law to the sum \( X^{(1)}(\mu) + X^{(2)}(\cdot) \).

In the derivation of the BOP in §4.1, we took formal limits in the equations that describe the scaled processes, such as (52) for \( Q_n \), (58) for \( \tau_n \), etc. We are unable to turn this into a rigorous argument in a straightforward manner, because there is no apparent pre-compactness for the sequence of functions \( \{\hat{E}_n\} \). For example, in (52), there is no justification to replace the limit of the term \( p\hat{E}_n \) by some control \( U \). We therefore take a different route, where we are able to provide a lower bound in which the error term converges to zero as \( n \to \infty \) due only to the convergence of the stochastic processes and RVs involved (such as \( \tau_n, \hat{\Xi}_n \)), not relying on any convergence associated with \( \hat{E}_n \).

An outline of the argument is as follows. We appeal to Skorohod’s representation theorem and derive (in Lemma 12 below) a bound of the form

\[
\mathbb{E}[c_w \hat{W}_n(1) + c_w \hat{W}_n(2) + c_o \hat{\tau}_n] \geq H\hat{J}_H(p\hat{E}_n) - \mathbb{E}[\varepsilon_n],
\]

(81)

where \( \varepsilon_n \) is a sequence of RVs satisfying \( \mathbb{E}[\varepsilon_n] \to 0 \) as \( n \to \infty \). This estimate is based on the closeness of \((\hat{\Xi}_n, \hat{S}_n)\) to \((X^{(1)}, X^{(2)})\) but not on \( \hat{E}_n \) being close to any candidate limit. Now, for each \( n \), \( p\hat{E}_n \) is a member of \( \mathcal{U}_H \). Thus, using (80), it follows from the definition of \( \hat{V}_H \) that

\[
\hat{J}_{n,H}(\{T^n_i\}) \geq H\hat{V}_H - \mathbb{E}[\varepsilon_n].
\]

(82)

In view of the fact that \( \mathbb{E}[\varepsilon_n] \to 0 \), the result will follow.

Toward stating Lemma 12, note that the convergence \( \hat{\Xi}_n \Rightarrow X^{(1)} \) and the one stated in Lemma 11(iv) imply that \( \hat{\Xi}_n \circ \hat{E}_n \Rightarrow X^{(1)}(\mu) \) (recall that \( \mu = p^{-1}\mu \)). By Lemma 11(i), \( \tau_n \geq H \) with probability tending to 1, hence by Lemma 11(ii), \( \sup_{t \in [0,H]} |B_n(t) - t| \Rightarrow 0 \). Consequently, \( \hat{S}_n \circ B_n \Rightarrow X^{(2)} \), and so \( X_n \Rightarrow X \) in the uniform topology on \([0,H] \). Moreover, for \( t \in [H, \tau_n) \), (on the event \( \tau_n > H \)), \( B_n(t) = B_n(H) + (t - H) \) by the non-idling property. It follows that \( (\hat{S}_n \circ B_n)(\cdot \land \tau_n) \Rightarrow X^{(2)}(\cdot \land \hat{\tau}) \). We now appeal to Skorohod’s representation theorem, by which we may assume without loss of generality that a.s.,

\[
\tau_n \to \hat{\tau}, \quad \text{and} \quad (\hat{\Xi}_n, \hat{\Xi}_n \circ \hat{E}_n, (\hat{S}_n \circ B_n)(\cdot \land \tau_n)) \to (X^{(1)}, X^{(1)}(\mu), X^{(2)}(\cdot \land \hat{\tau})),
\]

(83)

uniformly on compacts. If we let \( X = X^{(1)}(\mu) - X^{(2)} \) then we also have \( X_n(\cdot \land \tau_n) \to X(\cdot \land \hat{\tau}) \) a.s.

**Lemma 12** The estimate (81) holds with a sequence of RVs \( \varepsilon_n \) for which \( \mathbb{E}[\varepsilon_n] \to 0 \) as \( n \to \infty \).

**Proof of Theorem 3** The estimate (81) holds by Lemma 12. Hence (82) is valid. Taking the limit inferior and using the convergence \( \mathbb{E}[\varepsilon_n] \to 0 \), stated in Lemma 12 establishes the result. □

We turn to the proofs of the lemmas. We shall use uniform second moment bounds as follows. For every \( t \),

\[
\sup_n \mathbb{E}[\|\hat{\Xi}_n\|^2] < \infty, \quad \sup_n \mathbb{E}[\|\hat{S}_n\|^2] < \infty,
\]

(84)
where the first assertion follows by Doob’s $L^2$ maximum inequality [9 §4.4], and the second is shown in [18 Theorem 4].

Recall that $c$ denotes a generic positive constant (non-random, independent of $n$), whose value may change from line to line. Moreover, $\{\Theta_n\}$ will denote a generic sequence of non-negative RVs that are uniformly square integrable, i.e., $\sup_n \mathbb{E}[\Theta_n^2] < \infty$. The value of the sequence $\{\Theta_n\}$ may also change from line to line.

Note that in view of (81), for every fixed $t$, one has $\|\hat{S}_n\|_t \leq \Theta_n$ and $\|\hat{E}_n\|_t \leq \Theta_n$. Moreover, $\|\hat{S}_n \circ B_n\|_t \leq \Theta_n$ due to the fact $0 \leq B_n(s) \leq s$ for all $s$.

**Proof of Lemma 11.** We will argue that assertions (i)–(iii) hold for any sequence $\{T^n_i\}$ that achieves the limit inferior in (78). Hence we fix such a sequence and denote it by $\{T^n_i\}$ (thus, (79) is valid for this sequence). On the other hand, the proof of part (iv) will require a certain construction; it will be achieved by modifying this fixed sequence in a suitable way.

It follows from (80) and the fact that the sequence of costs is bounded that

$$c_w \mathbb{E}[\hat{W}_n(1)] + c_w \mathbb{E}[\hat{W}_n(2)] + c_w \mathbb{E}[\hat{\tau}_n] \leq c. \quad (85)$$

We would like to deduce from (85) that each of the terms on the LHS is bounded above by a constant. Before we may do so we must provide a lower bound on each of these terms. The first term is non-negative by its definition.

Next we show that $\mathbb{E}[(\hat{\tau}_n^2)] \leq c$, equivalently $\hat{\tau}_n \leq \Theta_n$. By (52), using the boundedness of $\hat{E}_n(H^-)$ and $B_n(-)$, and the non-negativity of $I_n$, we have $\hat{Q}_n(H^-) \geq -\Theta_n + p\hat{E}_n(H^-)$. By (51), $A^H_n \geq -\Theta_n - p\hat{E}_n(H^-)$.

Thus

$$\hat{Q}_n(H) \geq -\Theta_n. \quad (86)$$

Consider the event $\hat{\tau}_n \leq 0$ and use (58). On this event, the expression $B_n(\tau_n)$ is bounded above by $\hat{\tau}$. Hence the term $\hat{S}_n(B_n(\tau_n))$ is bounded in absolute value by $\|\hat{S}_n\|_{\hat{\tau}}$. Using this and the LB (86) in (58) gives $\hat{\tau}_n 1_{\hat{\tau}_n \leq 0} \geq -\Theta_n$. This gives

$$\mathbb{E}[(\hat{\tau}_n^2)] \leq c, \quad n \in \mathbb{N}. \quad (87)$$

A lower bound on $\mathbb{E}[\hat{W}_n(2)]$ is achieved by considering the three expressions

$$l_n' = \mathbb{E}[\hat{W}_n(2)1_{\{\tau_n < H\}}], \quad l_n'' = \mathbb{E}[\hat{W}_n(2)1_{\{\tau_n \geq \hat{\tau}\}}], \quad \mathbb{E}[\hat{W}_n(2)1_{\{\tau_n \geq \hat{\tau}\}}].$$

For $l_n'$, we use the lower bound $-cn^{1/2}$ on $\hat{W}_n(2)$, and (87) by which $\mathbb{P}(\tau_n < H) = \mathbb{P}((\tau_n - \hat{\tau})^- > (\hat{\tau} - H)) = \mathbb{P}(\hat{\tau}_n^- > n^{1/2}(\hat{\tau} - H)) \leq cn^{-1}$. This shows $l_n' \geq -cn^{-1/2}$.

For $l_n''$, on the event $\tau_n \in [H, \hat{\tau}]$, we use (63). By this equation, we have

$$\hat{W}_n(2)1_{\{\tau_n \in [H, \hat{\tau}]\}} \geq -\Theta_n - \frac{\mu}{2}n^{-1/2}(\hat{\tau}_n^-)^2.$$ 

This shows $l_n'' \geq -c$.

As for $l_n'''$, it follows from (61) by a calculation similar to that leading to (63) that, on $\{\tau_n > \hat{\tau}\}$,

$$\hat{W}_n(2) = \int_H^{\hat{\tau}} [q_n - \hat{S}_n(B_n(H) + t - H) + S_n(B_n(H))]dt + n^{1/2} \int_{\hat{\tau}}^{\tau_n} Q_n(t)dt.$$

The last term is non-negative on the indicated event, hence

$$\hat{W}_n(2)1_{\{\tau_n > \hat{\tau}\}} \geq -\Theta_n.$$
Thus \( l_n'' \geq -c \). We conclude that \( \mathbb{E}[\tilde{W}_n(2)] \geq -c \).

In view of these lower bounds, (88) now implies

\[
(a) \quad \mathbb{E}[\tilde{W}_n(1)] \leq c, \quad \quad (b) \quad \mathbb{E}[\tilde{W}_n(2)] \leq c, \quad \quad (c) \quad \mathbb{E}[\tau_n^+] \leq c.
\]

The bounds (87) and (88)(c) prove part (i) of the lemma.

Next, the tightness of \( \tilde{\tau}_n \), used in (88), implies the tightness of \( q_n \). By (54), this implies the tightness of \( n^{1/2}I_n(H-) \). Since \( I_n(H-) = I_n(H) = H - B_n(H) \), we obtain \( B_n(H) \Rightarrow H \). By the property \( |B_n(t) - B_n(s)| \leq |t - s| \), this implies \( \sup_{t \in [0,H]} |B_n(t) - t| \Rightarrow 0 \), and since for \( t \in [H, \tau_n] \) we have \( B_n(t) - B_n(H) = t - H \), the result stated in part (ii) of the lemma follows.

The bound (88)(a) clearly implies the tightness of \( \tilde{W}_n(1) \). By the expression (60) for \( \tilde{W}_n(1) \) and the convergence \( \tau_n \Rightarrow \tau \), this gives the tightness of \( \int_0^H \hat{Q}_n(t)dt \). Using (53) and the Lipschitz property of \( \Gamma_1 \) (with constant 2),

\[
\int_0^H \Gamma_1[pE_n](t)dt \leq \int_0^H [pE_n + X_n](t)dt + 2H\|X_n\|_H = \int_0^H \hat{Q}_n(t)dt + 2H\|X_n\|_H,
\]

hence the tightness of the RHS implies that of the LHS. However, the expression on the LHS is deterministic, thus it is, simply, bounded. This gives the first assertion in part (iii).

The aforementioned tightness of the RVs \( n^{1/2}I_n(H-) \), along with the equality between the two expressions (55) and (56), implies the tightness of the RVs \( \Gamma_1[p\hat{E}_n(H-)] - p\hat{E}_n(H-) \) (in view of the tightness of the terms involving \( \hat{\Sigma}_n \) and \( \hat{S}_n \) in these expressions). Arguing as above by the Lipschitz continuity of \( \Gamma_1 \) establishes the second assertion in part (iii).

Finally we prove part (iv). Given \( \varepsilon > 0 \), we first show that \( \sup_{t \in [0,H-\varepsilon]} (\hat{E}_n(t) - p^{-1}\mu t) \leq \varepsilon \) provided \( n \) is sufficiently large. Recall that \( \hat{E}_n(t) \) is non-decreasing. Thus if the inequality \( \sup_{t \in [0,H-\varepsilon]} (\hat{E}_n(t) - p^{-1}\mu t) > \varepsilon \) is valid for some \( n \) then there exists \( t = t_n \in [0,H-\varepsilon] \) such that for all \( s \in [t,t+\varepsilon_0 \wedge \varepsilon] \), where \( \varepsilon_0 = \varepsilon p^{-1}/2 \), \( \hat{E}_n(s) - p^{-1}\mu s > \varepsilon - p^{-1}\mu(s-t) > \frac{\varepsilon}{2} \). Hence by the definition of \( \hat{E}_n \), \( \hat{E}_n(s) \geq \sqrt{n}E \) for the same set of times \( s \). By the definition of \( \Gamma \), we have \( \Gamma[p\hat{E}^n](s) \geq p\hat{E}_n(s) \), for each \( s \) in the interval alluded to above. Hence \( \int_0^H \Gamma(p\hat{E}^n)ds \geq c_\varepsilon \sqrt{n} \), where \( c_\varepsilon > 0 \) depends on \( \varepsilon \) but not on \( n \). By part (iii), this can occur for only finitely many \( n \). Hence the claim.

Next, given \( \varepsilon > 0 \), assume that the inequality \( \hat{E}_n(t) - p^{-1}\mu t > 3\varepsilon p^{-1}\mu \) is valid for some \( n \) and \( t = t_n \in [H-\varepsilon, H] \). Then \( E_n(t) > p^{-1}\mu(t + 3\varepsilon)n \geq p^{-1}\mu(H + 2\varepsilon)n \). Construct from \( E_n \) another schedule \( E_n(1)(s) = E_n(s) \wedge p^{-1}\mu(H + 2\varepsilon)n \), for \( s \in [0,H] \). Then the schedules agree on \( s \in [0,t] \). Moreover, the new schedule satisfies the constraint \( E_n(s) - p^{-1}\mu t < \varepsilon \varepsilon \) for all times \( t \). The resulting queue length can only be decreased by this modification. Moreover, the effect of the modification on the average time is negligible at the scaling limit, as follows by the following argument which shows that under both schedules no idle time is accumulated during \( [t,H] \), with high probability. This owes to the fact that for \( s \in [t,H] \),

\[
\hat{E}^{(1)}(s) = p^{-1}\mu(H + 2\varepsilon)
\]
hence according to (33), with the error term ε_n as in that equation,

\[
Q_n(s) = p\hat{E}_n(s) - \mu s + \varepsilon_n(s) + \sup_{u \leq s}( -p\hat{E}_n(u) + \mu u - \varepsilon_n(u))^+ \\
\geq \mu(H + 2\varepsilon) - \mu s + \varepsilon_n(s) + \sup_{u \leq s}( -p\hat{E}_n(u) + \mu u - \varepsilon_n(u))^+ \\
\geq 2\mu \varepsilon - \|\varepsilon_n\|_H.
\]

This shows that for any \( \varepsilon > 0 \) one can construct \( E_n \) for which \( \sup_{t \in [0, H]}(\hat{E}_n(t) - p^{-1}\mu t) < \varepsilon \), while (79) and assertions (i)–(iii) of the lemma hold. A diagonal argument may now be used to take \( \varepsilon = \varepsilon(n) \downarrow 0 \).

Next, a similar use of the formula (33) now for the term \( \mu I_n \) shows that if

\[
\inf_{t \in [0, H]}(\hat{E}_n(t) - p^{-1}\mu t) \leq -\varepsilon
\]

then one has \( I_n(H) \geq c\varepsilon \) with high probability. In this case, the cost associated with the scaled average time \( \tilde{\tau}_n \) grows without bound as \( n \to \infty \).

Finally, the second assertion of part (iv) follows from the first one by using the constraint \( \hat{E}_n(H) = N_n \).

Proof of Lemma 12. We first estimate \( \hat{W}_n(1) \) from below. By (52), for \( t \in [0, H) \), \( \hat{Q}_n(t) \) is given by \( p\hat{E}_n(t) + X_n(t) + n^{1/2}\mu I_n(t) \), where we recall that

\[
X_n(t) = \hat{\Xi}_n(\hat{E}_n(t)) - \hat{S}_n(B_n(t)).
\]

We use (53) and the fact that \( \Gamma_1 \) is Lipschitz with constant 2 in the supremum norm to write

\[
\hat{W}_n(1) = \int_0^{H \land \tau_n} \hat{Q}_n(t)dt \\
= \int_0^{H \land \tau_n} \{ \Gamma_1[p\hat{E}_n + X_n](t) - \Gamma_1[p\hat{E}_n + X](t) \}dt + \int_0^{H \land \tau_n} \Gamma_1[p\hat{E}_n + X](t)dt \\
\geq \int_0^H \Gamma_1[p\hat{E}_n + X](t)dt - \varepsilon_0^n,
\]

where

\[
\varepsilon_0^n = 2(H \land \tau_n)\|X_n - X\|_{H \land \tau_n} + \int_{H \land \tau_n} \Gamma_1[p\hat{E}_n + X](t)dt.
\]

The term \( q_n \) (see (53)) appears both in the expression for \( \hat{W}_n(2) \) and \( \tau_n \). We have

\[
q_n = \Gamma_1[p\hat{E}_n + X_n](H-) + \hat{\Xi}_n(\alpha) - \hat{\Xi}_n(\hat{E}_n(H-)) - p\hat{E}_n(H-) \\
\geq A_n - \varepsilon_1^n,
\]

where

\[
A_n = \Gamma_1[p\hat{E}_n + X](H-) - p\hat{E}_n(H-) + X^{(1)}(\alpha) - X^{(1)}(\mu H),
\]

\[
\varepsilon_1^n = 2\|X_n - X\|_H + |\hat{\Xi}_n(\alpha) - X^{(1)}(\alpha)| + |\hat{\Xi}_n(\hat{E}_n(H-)) - X^{(1)}(\mu H)|.
\]
Recall that on the event $\tau_n < H$, $\hat{W}_n(2) = -n^{1/2}\hat{W}$. On the event $\tau_n \geq H$, we have the expression (63). We obtain (in both cases),

$$\hat{W}_n(2) \geq (\tau_n - H)^+ (\hat{Q}_n(H^-) + \hat{A}_n) - \int_H^{H+\tau_n} (X(2)(t \wedge \bar{\tau}) - X(2)(H)) dt - \varepsilon_n^2 - \varepsilon_n^3 - \varepsilon_n^4,$$

where

$$\varepsilon_n^2 = 2\|\hat{S}_n \circ B_n (\cdot \wedge \tau_n) - X(2)(\cdot \wedge \bar{\tau})\|_{\tau_n},$$

$$\varepsilon_n^3 = \frac{H}{2} n^{1/2} (\tau_n - \bar{\tau})^2,$$

$$\varepsilon_n^4 = n^{1/2} \hat{W} 1_{(\tau_n < H)}.$$ 

Hence

$$\hat{W}_n(2) \geq (\bar{\tau} - H) \Lambda_n - \int_H^{\bar{\tau}} (X(2)(t \wedge \bar{\tau}) - X(2)(H)) dt - \varepsilon_n^2 - \varepsilon_n^3 - \varepsilon_n^4 - \varepsilon_n^5,$$

where

$$\varepsilon_n^5 = |\tau_n - \bar{\tau}|(\hat{Q}_n(H^-) + \hat{A}_n) + \bar{\tau} \varepsilon_n^1 + 2|\tau_n - \bar{\tau}| \|X(2)\|_{\bar{\tau}}.$$

As for $\hat{\tau}_n$, using (58),

$$\hat{\tau}_n \geq \mu^{-1} \left[ \Lambda_n - X(2)(\bar{\tau}) + X(2)(H) - \varepsilon_n^1 - \varepsilon_n^2 \right].$$

We now combine the lower bounds obtained above on $\hat{W}_n(1)$, $\hat{W}_n(2)$ and $\hat{\tau}_n$ and compare to the expression (66) with $p \hat{E}_n$ substituted for $U$. The term $L(H^-)$ appearing in (66) is related to $\Lambda_n$ via

$$E[L(H^-)] = E[1_{(\hat{\tau}_n < H)}] = E[1_{(\hat{\tau}_n < H)}] = E[\Lambda_n].$$

We have thus shown that (64) holds with

$$\varepsilon_n = c_5 (\varepsilon_n^0 + \cdots + \varepsilon_n^5),$$

where $c_5$ is a constant.

It now remains to show that each of the terms $E[\varepsilon_n^i]$, $i = 0, 1, \ldots, 5$ converges to zero.

The first term in $\varepsilon_n^0$ converges to zero a.s. by (63). It follows from (64) that this term is uniformly integrable. Hence its expectation also converges to zero. As for the second term in $\varepsilon_n^0$, using the Lipschitz property of $\Gamma_1$, this term is bounded by

$$1_{\{\tau_n < H\}} \left\{ \int_0^H \Gamma_1[p \hat{E}_n(t)] dt + 2H \|X\|_H \right\} \leq 1_{\{\tau_n < H\}} \left\{ c + 2H \|X\|_H \right\},$$

where we used Lemma (11) and $c$ is a suitable constant. The indicator function converges to zero a.s., by (63), while the expectation of $\|X\|_H$ is finite. Hence by dominated convergence, $E[\varepsilon_n^0] \to 0$.

The a.s. convergence of $\varepsilon_n^1$ and $\varepsilon_n^2$ to zero follows from (63) whereas their uniform integrability follows from (64). Thus $E[\varepsilon_n^1] \to 0$ and $E[\varepsilon_n^2] \to 0$.

Next, by (57), $n^{1/2}(\tau_n - \bar{\tau})^2 = n^{-1/2} \varepsilon_n^3$. Thus to show that $E[\varepsilon_n^3] \to 0$ it suffices to improve the estimate from Lemma (11) to show that $E[\varepsilon_n^2]$ is bounded.

To this end, recall the expression (58). Since we already established the boundedness of the second moment of $q_n$, it suffices to show that also the second and third terms in (58) have bounded
second moments. Since $B_n(H) \leq H$, the second moment of the last term in (58) is bounded by $\mathbb{E}\|\hat{S}_n\|_H^2$; hence (84) gives a uniform bound. It remains to show that
\[
\sup_n \mathbb{E}[\hat{S}_n(B_n(\tau_n))^2] < \infty.
\] (90)

Here we shall use the $3+\varepsilon$ moment assumption. First, note that $B_n(\tau_n)$ is the total time the server works on jobs, thus is equal to the total arriving work. A bound on this is given by $\sum_{i=1}^{N_n} \nu_{i,n} = n^{-1} \sum_{i=1}^{N_n} \nu_i$. Denoting $w_n = \sum_{i=1}^{N_n} \nu_i$, we have
\[
\mathbb{E}[\hat{S}_n(B_n(\tau_n))^2] = \mathbb{E}[1_{\{n^{-1}w_n < 1\}} \hat{S}_n(B_n(\tau_n))^2] + \sum_{k=0}^{\infty} \mathbb{E}[1_{\{n^{-1}w_n \in [2^k, 2^{k+1})\}} \hat{S}_n(B_n(\tau_n))^2]
\]
\[
\leq \mathbb{E}[1_{\{n^{-1}w_n < 1\}} \|\hat{S}_n\|_{n^{-1}w_n}^2] + \sum_{k=0}^{\infty} \mathbb{E}[1_{\{n^{-1}w_n \in [2^k, 2^{k+1})\}} \|\hat{S}_n\|_{n^{-1}w_n}^2]
\]
\[
\leq \mathbb{E}[\|\hat{S}_n\|^2] + \sum_{k=0}^{\infty} \mathbb{E}[1_{\{n^{-1}w_n \in [2^k, 2^{k+1})\}} \|\hat{S}_n\|_{n^{-1}w_n}^{2q}]
\]
\[
\leq c + \sum_{k=0}^{\infty} \mathbb{P}(w_n \geq n2^k)^{1/p} \mathbb{E}[\|\hat{S}_n\|_{2^k+1}^{2q}]^{1/q},
\]
where (84) is used for the first term, and for the sum, Hölder’s inequality is used, where $p^{-1} + q^{-1} = 1$. Fix $\beta \in (3, 3+\varepsilon)$. Then by Minkowski’s inequality we have $\mathbb{E}[w_n^\beta] \leq cn^\beta \mathbb{E}[\nu_i^\beta]$. Hence $\mathbb{P}(w_n \geq n2^k) \leq c2^{-\beta k}$, where $c$ is finite and does not depend on $n$ or $k$. Next we appeal again to [JS, Theorem 4], which states that $\mathbb{E}[\|\hat{S}_n\|_t^{\beta}] \leq c(t^{1/2} + 1)$ (under the hypothesis that the $\beta$-th moment of $\nu_1$ is finite and $\beta \geq 2$) where $c$ does not depend on $t$ or $n$. We use this estimate with $t = 2^{k+1}$, and $q = \beta/2$ (accordingly, $p$ is determined). This gives
\[
\mathbb{E}[\hat{S}_n(B_n(\tau_n))^2] \leq c + \sum_{k=0}^{\infty} 2^{-\beta k/p}(2^{k+1} + 1).
\]

Now, $p = (1 - 2/\beta)^{-1}$, and since $\beta > 3$, we have $p < 3$. In particular, $\beta > p$. Therefore the above sum is finite. This proves (90), hence follows the estimate on $\mathbb{E}[\varepsilon_n^4]$. To show that $\mathbb{E}[\varepsilon_n^4] \to 0$ amounts to showing that $n^{1/2} \mathbb{P}(\tau_n < H) \to 0$. Now, $\tau_n \to \bar{\tau} > H$, and we have just shown that $\sup_n \mathbb{E}[\hat{S}_n^2] < \infty$. Hence, for $c = \bar{\tau} - H$,
\[
n^{1/2} \mathbb{P}(\tau_n < H) \leq n^{1/2} \mathbb{P}(n^{-1/2}|\tau_n| > c) \leq cn^{-1/2},
\]
for some constant $\tilde{c}$. This shows $\mathbb{E}[\varepsilon_n^4] \to 0$.

Finally, for a bound on $\varepsilon_n^5$ we use Cauchy-Schwartz to write
\[
\mathbb{E}[\varepsilon_n^5] \leq \mathbb{E}[(\tau_n - \bar{\tau})^2]\mathbb{E}[\varepsilon_n^2]^{1/2} + \bar{\tau}\mathbb{E}[\varepsilon_n^4] + c\mathbb{E}[(\tau_n - \bar{\tau})^2]^{1/2}.
\]
We have already shown that $q_n$ are uniformly square integrable. Hence the convergence of the first and last terms above to zero follows from the boundedness of $\mathbb{E}[\varepsilon_n^2]$. The second term has already been argued to converge to zero.

This concludes the proof that $\mathbb{E}[\varepsilon_n^i] \to 0$ for $i = 0, 1, \ldots, 5$ and completes the proof of the lemma.

\[\square\]
4.4 Upper bound on the diffusion scale cost

In this section we propose a sequence of schedules (indexed by \( n \)) whose diffusion scaled cost converges to the cost we obtained as a solution to the BOP. This establishes that the BOP cost is an asymptotic upper bound for diffusion scaled cost which, together with the lower bound, establishes the asymptotic optimality of our proposed schedule.

Let \( \beta^* \) be the optimal drift associated with the problem defined in Proposition 3, namely, \( \beta^* \) is such that the control \( U(t) = \beta^* t \) is optimal for the problem \( \lim_{H \to \infty} \inf_{U(t) \in [0, H]} J_H(U) \). Note that \( \beta^* < 0 \). Let \( n > (\beta^*/\mu)^2 \), and for \( t \in [0, H] \) define

\[
E^d_n(t) = \begin{cases} \frac{\mu t}{\sqrt{n}} \left( \mu + \frac{\beta^*}{\sqrt{n}} \right) & t < H, \\ N_n & t = H. \end{cases}
\]

(91)

To see that \( E^d_n(t) \) is an admissible schedule we need to verify that \( E^d_n(t) \geq 0 \) and that it is non-decreasing in \( t \). Both of these requirements follow from the condition that \( n > (\beta^*/\mu)^2 \) and from our assumption that \( p^{-1} \mu H < \alpha \) in [18]. The latter is used to verify that the jump of \( E^d_n(t) \) at \( t = H \) is non-negative.

Next, consider the diffusion-scaled schedule \( \hat{E}^d_n := \sqrt{n} (n^{-1} E^d_n - lt^*) \); recall that \( l^* \) is the fluid optimal schedule, defined in [31]. A straightforward computation shows that, as \( n \to \infty \)

\[
\hat{E}^d_n(t) \to \hat{u}(t) := \begin{cases} \beta^* t & t \in [0, H) \\ 0 & t \geq H. \end{cases}
\]

(92)

Furthermore, it can also be easily shown that the convergence is uniformly on compact sets of the time index. It follows that as \( H \to \infty \), \( \hat{u} \) converges to the drift of the stationary optimal RBM associated with the problem \( \lim_{H \to \infty} \inf_{U(t) \in [0, \infty]} J_H(U) \). The main result of this section proves that this sequence of schedules asymptotically achieves the large time horizon value of the BOP, determined in Proposition 3.

**Theorem 4** The sequence of schedules \( \{T^d_{i,n}, n \geq 1\} \) corresponding to the scheduling functions \( \{E^d_n, n \geq 1\} \) of (91), satisfies

\[
\lim_{H \to \infty} \lim_{n \to \infty} H^{-1} \hat{J}_{n,H}(\{T^d_{i,n}\}) = \lim_{H \to \infty} \hat{V}_H.
\]

**Proof.** Recall the diffusion-scaled cost in [80]:

\[
\hat{J}_{n,H}(\{T^d_{i,n}\}) = \mathbb{E}[\sum_{\tau_n} \hat{W}_n(1) + c_w \hat{W}_n(2) + c_o \tau_n],
\]

where \( \hat{W}_n(1) \), \( \hat{W}_n(2) \) and \( \tau_n \) are defined in [31], [31] and [31] (respectively). Applying Skorokhod’s representation theorem as in [33] we have that a.s.,

\[
\tau_n \to \bar{\tau}, \quad \text{and} \quad (\hat{X}_n, \hat{S}_n \circ \hat{E}_n^d, (\hat{S}_n \circ B_n)(\cdot \wedge \tau_n)) \to (X^{(1)}, X^{(1)}(\hat{\mu}), X^{(2)}(\cdot \wedge \bar{\tau})) \text{ as } n \to \infty.
\]

As before, let \( X := X^{(1)}(\hat{\mu}) - X^{(2)} \), so that \( X_n(\cdot \wedge \tau_n) \to X(\cdot \wedge \bar{\tau}) \) a.s.

Consider \( \hat{W}_n(1) \) first. From [18], [53] and [52], and the fact that \( B_n(t) \in o(n^{-1/2}) \) a.s. for all \( t \in [0, H] \), it follows that \( \hat{W}_n(1) = \int_0^H Q_n(t)dt - n^{-1/2} B_n(\tau_n) \) satisfies:

\[
\hat{W}_n(1) \to \int_0^H (\hat{p}u + X)(t)dt \text{ a.s. as } n \to \infty.
\]

(93)
Next, recall from (63) that on the event \( \{ \tau_n \geq H \} \)
\[
\hat{W}_n(2) = \int_H^{\tau_n} \left[ q_n - \hat{S}_n(B_n(t)) + \hat{S}_n(B_n(H)) \right] dt - \frac{\mu}{2} \sqrt{n}(\tau_n - \hat{\tau})^2,
\]
where \( q_n = \hat{Q}_n(H) + \hat{A}^H_n \) and \( \hat{A}^H_n = \hat{\Xi}_n(\alpha) - \hat{\Xi}_n(\hat{E}^d_n(H)) - p\hat{E}^d_n(H) \). Again, using (63) and (62) it can be easily seen that
\[
q_n \to \Gamma_1(p\hat{u} + X(H)) + X^{(1)}(\alpha) - X^{(1)}(\hat{\mu}H) - p\hat{u}(H) = \hat{q} \text{ a.s. as } n \to \infty.
\]
It follows from (58), (83) and (94) that
\[
\hat{\tau}_n \to \frac{1}{\mu} (\hat{q} - X^{(2)}(\hat{\tau}) + X^{(2)}(H)) = \hat{\tau} \text{ a.s. as } n \to \infty.
\]
Now, from the proof of Lemma 4(ii), when traffic is scheduled per \( E^d_n \) we have \( \tau_n \to \hat{\tau} \text{ a.s. as } n \to \infty \). Furthermore, since \( \hat{\tau} > H \), it follows from (63), (94) and (95) that
\[
\hat{W}_n(2) = \int_H^{\tau_n} \left[ \hat{q} - X^{(2)}(t) + X^{(2)}(H) \right] dt \text{ a.s. as } n \to \infty,
\]
where we have used the fact that \( \sqrt{n}(\tau_n - \hat{\tau})^2 = (\tau_n - \hat{\tau})\hat{\tau}_n \to 0 \text{ a.s. as } n \to \infty \).

At this point, we have shown that, as \( n \to \infty \), a.s.
\[
c_w\hat{W}_n(1) + c_w\hat{W}_n(2) + c_o\hat{\tau}_n \to c_w\hat{W}_n(1) + c_w\hat{W}_n(2) + c_o\hat{\tau}_n
\]
In order to prove convergence in \( L^1 \), following the analysis in (13) we will prove that the second moments of \( \hat{W}_n(1) \), \( \hat{W}_n(2) \) and \( \hat{\tau}_n \) are bounded. This, however, follows directly from (64) and the analysis in the proof of Lemma 4 and will not be repeated here. Therefore, we have that
\[
\hat{J}_{n,H}(\{T^d_{i,n}\}) = c_w\hat{W}_n(1) + c_w\hat{W}_n(2) + c_o\hat{\tau}_n
\]
is uniformly integrable, implying that \( \lim_{n \to \infty} \hat{J}_{n,H}(\{T^d_{i,n}\}) = J_H(\hat{u}) \), where
\[
J_H(\hat{u}) = \frac{c_w}{H} \mathbb{E} \left[ \int_0^{H} \Gamma_1(p\hat{u} + X)(t) \right] dt + \frac{c_o}{H} \mathbb{E} \left[ \int_{H}^{\hat{\tau}} \left( X^{(2)}(t) - X^{(2)}(H) + Q(H) + \hat{A}^H_n \right) dt \right] + \frac{c_o}{H} \mathbb{E} \left[ \hat{\tau} \right].
\]
Using the fact that \( X^{(1)} \) and \( X^{(2)} \) are Brownian motion processes and the definition of \( \hat{\tau} \) in (95), \( \hat{J}_H(\hat{u}) \) simplifies to
\[
\hat{J}_H(\hat{u}) = \frac{c_w}{H} \mathbb{E} \left[ \int_0^{H} \Gamma_1(p\hat{u} + X)(t) \right] dt + \frac{c_o}{H} \mathbb{E} \left[ \Gamma_1(p\hat{u} + X(H) - p\hat{u}(H)) \right],
\]
where \( \hat{c}_o = c_o + c_w(\hat{\tau} - H) \). Now, using the fact that \( \hat{u} \) converges to the drift function \( \beta^*e \) as \( H \to \infty \), it follows that \( \lim_{H \to \infty} J_H(\hat{u}) = \lim_{H \to \infty} \hat{V}_H \), thus completing the proof. \( \square \)
4.5 The stochasticity gap at the diffusion scale

Continuing our investigation of quantifying the effect of the stochasticity on the scheduling problem, we now consider the asymptotic SG in the diffusion scale. We study the limit of \( \hat{\gamma}_{n,H} = \sqrt{n}(V_{n,H} - V^C_{n,H}) \geq 0 \) as \( n \to \infty \) and then \( H \to \infty \). We first show that the value of the CI problem in the diffusion scale is asymptotically null.

**Lemma 13** Fix \( H > 0 \). We have \( \hat{\gamma}^{CI}_{n,H} = \sqrt{n}(V^{CI}_{n,H} - \bar{V}_H) \to 0 \) as \( n \to \infty \).

We delay the proof of the lemma to after the main result of this section.

**Proposition 4** Let Assumption 4 hold. Then the large horizon SG is positive. More precisely, \( \lim_{H \to \infty} \liminf_{n \to \infty} \hat{\gamma}_{n,H} = \lim_{H \to \infty} \hat{V}^* =: \hat{V}^* \).

**Proof.** First note that \( \hat{\gamma}_{n,H} = \sqrt{n}(V_{n,H} - \bar{V}_H) - \sqrt{n}(V^{CI}_{n,H} - \bar{V}_H) \), where \( \bar{V}_H \) is the FOP value from (35). Also recall the definition \( \hat{V}_{n,H} := \sqrt{n}(V_{n,H} - \bar{V}_H) \). Then, Theorem 3 and Lemma 13 imply that

\[
\lim_{H \to \infty} \liminf_{n \to \infty} \hat{\gamma}_{n,H} \geq \hat{V}^*.
\] (98)

On the other hand, Theorem 4 and Lemma 13 together imply that

\[
\lim_{H \to \infty} \limsup_{n \to \infty} \hat{\gamma}_{n,H} \leq \hat{V}^*,
\] (99)

completing the proof. \( \square \)

**Proof of Lemma 13.** Straightforward algebraic manipulation of (29) shows that

\[
\hat{\gamma}^{CI}_{n,H} = E\left[ \frac{c_w}{H} \sqrt{n} \left( \frac{1}{n} \int_{H}^{nT_n} \left( \Xi(N_n) - S_n(t) - 1 \right) dt - \int_{H}^{\tau^*} (\alpha p - \mu t) dt \right) \right] + \frac{c_o}{H} \sqrt{n} \left( (\tau_n^* - H)^+ - (\bar{\tau} - H) \right),
\]

where we have used the fact that \( \bar{V}_H = H^{-1}c_w \int_{H}^{\tau^*} (\alpha p - \mu t) dt + H^{-1}c_o(\bar{\tau} - H) \).

In the proof of Lemma 3 it was shown that \( \tau_n^* \to \bar{\tau} \) a.s. as \( n \to \infty \). Let \( x \in \mathbb{R} \) and consider the event \( \{ \sqrt{n}(\tau_n^* - \bar{\tau}) > x \} \), or equivalently \( \{ \tau_n^* > n^{-1/2}x + \bar{\tau} \} \). Recall that \( \tau_n^* := \inf\{ t > 0 : S_n(t) \geq \Xi(N_n) \} \), so that

\[
\{ \tau_n^* > n^{-1/2}x + \bar{\tau} \} = \left\{ S_n \left( n^{-1/2}x + \bar{\tau} \right) < \Xi(N_n) \right\}
\]

\[
= \left\{ \hat{S}_n(\alpha) - \hat{S}_n(n^{-1/2}x + \bar{\tau}) > x\mu \right\},
\] (100)

where the last equality follows by simple algebraic manipulations and recognizing that \( \bar{\tau} = \mu^{-1}\alpha p \).

Now, consider

\[
\hat{\Xi}_n(\alpha) - \hat{S}_n(n^{-1/2}x + \bar{\tau}) = \left( \hat{\Xi}_n(\alpha) - \hat{S}_n(\bar{\tau}) \right) + \left( \hat{S}_n(\bar{\tau}) - \hat{S}_n(n^{-1/2}x + \bar{\tau}) \right)
\]
Recall that \((\hat{\Xi}_n, \hat{S}_n) \Rightarrow (X^{(1)}, X^{(2)})\) as \(n \to \infty\). Therefore, it follows that \(\hat{\Xi}_n(\alpha) - \hat{S}_n(\bar{\tau}) \Rightarrow X^{(1)}(\alpha) - X^{(2)}(\bar{\tau})\) as \(n \to \infty\). On the other hand since \(n^{-1/2}x + \bar{\tau} \to \bar{\tau}\) as \(n \to \infty\), we have \(\hat{S}_n(\bar{\tau}) - \hat{S}_n(n^{-1/2}x + \bar{\tau}) \Rightarrow 0\) as \(n \to \infty\). Therefore,

\[
\hat{\Xi}_n(\alpha) - \hat{S}_n(n^{-1/2}x + \bar{\tau}) \Rightarrow X^{(1)}(\alpha) - X^{(2)}(\bar{\tau}).
\]  

(101)

Displays (100) and (101) together imply, as \(n \to \infty\),

\[
\hat{\tau}_n^* \Rightarrow \frac{1}{\mu} \left( X^{(1)}(\alpha) - X^{(2)}(\bar{\tau}) \right).
\]  

(102)

Now, consider \(\hat{\tau}_n^* = \sqrt{n}(\tau_n^* - H)^+ - (\bar{\tau} - H)\). For each \(n \geq 1\), we write \(\hat{\tau}_n^* = \hat{\tau}_n^* 1_{\{\tau_n^* > H\}} + \hat{\tau}_n^* 1_{\{\tau_n^* \leq H\}}\). The first term on the right hand side is simply \(\hat{\tau}_n^* 1_{\{\tau_n^* > H\}}\). Since \(\tau_n^* \Rightarrow \bar{\tau} > H\) as \(n \to \infty\), it follows for large enough \(n\) that \(\tau_n^* > H\), implying that \(\hat{\tau}_n^* \Rightarrow \frac{1}{\mu} \left( X^{(1)}(\alpha) - X^{(2)}(\bar{\tau}) \right)\).

Following (84), it is straightforward to deduce that \(\hat{\tau}_n^*\) is uniformly integrable, implying that

\[
\mathbb{E}[\hat{\tau}_n^*] \to \mathbb{E}\left[\frac{1}{\mu} \left( X^{(1)}(\alpha) - X^{(2)}(\bar{\tau}) \right)\right] = 0\text{ as } n \to \infty.
\]  

(103)

Next, the first term in the definition of \(\hat{\tau}_{n,H}^*\) can be written as

\[
\sqrt{n} \left( \frac{1}{n} \int_{H}^{\tau_n^*} (\Xi(N_n) - S_n(t)) dt - \int_{H}^{\bar{\tau}} (\alpha p - \mu t) dt \right)
\]

\[
= \sqrt{n} \left( \frac{1}{n} \int_{H}^{\tau_n^*} (\Xi(N_n) - S_n(t)) dt - \frac{1}{n} (\tau_n^* - H) - \int_{H}^{\bar{\tau}} (\alpha p - \mu t) dt \right) 1_{\{\tau_n^* > H\}}
\]

\[
+ \sqrt{n} \left( - \int_{H}^{\bar{\tau}} (\alpha p - \mu t) dt \right) 1_{\{\tau_n^* \leq H\}}.
\]

Consider the first term on the right hand side, under the event \(\{\tau_n^* > H\}\),

\[
\sqrt{n} \left( \frac{1}{n} \int_{H}^{\tau_n^*} (\Xi(N_n) - S_n(t)) dt - \int_{H}^{\bar{\tau}} (\alpha p - \mu t) dt \right) - \frac{1}{\sqrt{n}} (\tau_n^* - H),
\]

and focus on the term under the integral first:

\[
\sqrt{n} \left( \frac{1}{n} \int_{H}^{\bar{\tau}} (\Xi(N_n) - S_n(t)) dt - \int_{H}^{\bar{\tau}} (\alpha p - \mu t) dt \right) + \frac{1}{\sqrt{n}} \int_{\bar{\tau}}^{\tau_n^*} (\Xi(N_n) - S_n(t)) dt.
\]  

(104)

Note that the breaking up the integral is justified since \(S_n(t)\) is well-defined for all \(t \geq 0\). Consider the latter integral:

\[
\frac{1}{\sqrt{n}} \int_{\bar{\tau}}^{\tau_n^*} (\Xi(N_n) - S_n(t)) dt = \int_{\bar{\tau}}^{\tau_n^*} (\hat{\Xi}_n(\alpha) - \hat{S}_n(t)) dt + \sqrt{n} \int_{\bar{\tau}}^{\tau_n^*} (\alpha p - \mu t) dt.
\]

It follows that the right hand side equals

\[
\int_{\bar{\tau}}^{\tau_n^*} (\hat{\Xi}_n(\alpha) - \hat{S}_n(t)) dt + \alpha p \hat{\tau}_n^* - \frac{\mu}{2} \hat{\tau}_n^* (\tau_n^* + \bar{\tau}),
\]
and as \( n \to \infty \)
\[
\frac{1}{\sqrt{n}} \int_\tau^{\tau^*} (\Xi(n) - S_n(t)) \, dt \Rightarrow \alpha p\hat{\tau}^* - \mu \hat{\tau}^*.
\]

Now, using (84) it can be shown that
\[
\frac{1}{\sqrt{n}} \int_\tau^{\tau^*} (\Xi(n) - S_n(t)) \, dt
\]
is uniformly integrable, so that
\[
E\left[ \frac{1}{\sqrt{n}} \int_\tau^{\tau^*} (\Xi(n) - S_n(t)) \, dt \right] \to E[\alpha p\hat{\tau}^* - \mu \hat{\tau}^*] = 0 \quad \text{as} \quad n \to \infty.
\] (105)

Returning to (104), consider the term
\[
\sqrt{n} \left( \frac{1}{n} \int_H (\Xi(n) - S_n(t)) \, dt - \int_H (\alpha p - \mu t) \, dt \right) = \sqrt{n} \left( \int_H (\hat{\Xi}_n(\alpha) - \hat{S}_n(t)) \, dt \right).
\]
It is straightforward to see that this sequence of RVs converges weakly to \( \int_H (X^{(1)}(\alpha) - X^{(2)}(t)) \, dt \).
Furthermore, it is again true that the pre-limit integral is uniformly integrable, implying that, as \( n \to \infty \)
\[
E \left[ \sqrt{n} \left( \int_H (\hat{\Xi}_n(\alpha) - \hat{S}_n(t)) \, dt \right) \right] \to E \left[ \int_H (X^{(1)}(\alpha) - X^{(2)}(t)) \, dt \right] = 0.
\] (106)

From (103) and (106) it follows that \( \gamma_{n,H}^{CI} \to 0 \quad \text{as} \quad n \to \infty \) for all \( H > 0 \). \( \square \)

5 Conclusions

Exact solutions for the optimal scheduling problem studied in this paper are intractable in general. The analytical results provide the first rigorously justified approximate solutions to this problem, in the large population limit. We have taken the approach of first formulating an optimization problem which is expected to govern the asymptotics in the respective scales (based on formal limits), then solving it, and finally proving that the value of these limit problems indeed gives the limit of the values for the rescaled scheduling problems. A byproduct of the last step, that is important in its own right, is to derive asymptotically optimal schemes for the prelimit scheduling problems.

It is customary to distinguish a control problem, where online information on the state of the system is available to the decision maker, from an optimization problem, where decisions are made at the initial time. A natural decision/optimization model of the job scheduling problem is a single-stage stochastic program without recourse [20]. The latter paradigm, however, assumes that the distribution of the workload is fully specified. In general, it is much more natural to describe the arrival and service processes and then infer the distribution of the workload process. The three-step approach alluded to above is well established in work on control in asymptotic regimes, specifically in the heavy traffic literature, but is less studied in optimization problems. As far as the authors know, an optimization problem involving diffusion, of the type of the BOP we have formulated, has not been considered before in relation to heavy traffic applications, or in the context of solving stochastic programs without recourse. It seems that versions of this problem might be relevant in applications far beyond the present model. We also believe that our three-step approach to solving
the optimization problem may be used to analyze and solve single-stage stochastic programs, where
the stochasticity is driven by functionals of multiple RVs.

While the FOP is easy to solve, we have not been able to find an explicit solution to the BOP
over a time interval of finite horizon. As we have mentioned, the BOP is a convex optimization
problem, and thus it is plausible that one could treat it via numerical schemes; this is left for future
work. However, one of our main findings is that, when set on an infinite time horizon, this BOP is
solvable explicitly. Its solution, in the form of a reflected BM with constant drift, is rather simple.
The form of the optimal drift captures the tradeoff between the two parts of the cost.

Another main ingredient of our work is the notion of a SG, that we have introduced as a means
of quantifying the performance loss due to the inherent stochasticity in the model, as compared
to the complete information problem. As one may expect, we have shown that the gap converges
to zero in the fluid limit but remains positive in the diffusion limit. It is natural to associate this
to (but it certainly does not automatically follow from) the fact that the FOP is a deterministic
problem whereas the BOP is stochastic. Moreover, our calculation of the gap in the diffusion limit
shows that it is proportional to the diffusion coefficient $\sigma$. Thus the loss in performance due to
stochasticity is proportional to the standard deviation of the underlying noise. It is also interesting
to note that the CI problem can be viewed as a single-stage stochastic program with recourse \cite{20},
since the optimization is conducted after the stochastic values are revealed to the decision-maker.
The SG thus provides a useful measure of the impact of recourse on such problems.

A possible source of uncertainty not accounted for in this work, but that is important in practice,
is that of non-punctual arrivals. This aspect may be addressed in future work. Moreover, the
analysis has focused exclusively on a single server queue, and consequently the limit optimization
problems are one-dimensional. Traffic scheduling in multi-queue networks are natural to consider
next, where the limit problems are concerned with multidimensional diffusion processes that are
constrained to lie within a quadrant or, more generally, a cone.
