Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
At the current time, the field of vaccinology remains empirical in many respects. Vaccine development, vaccine immunogenicity, and vaccine efficacy have, for the most part, historically been driven by an empiric “isolate-inactivate-inject” paradigm. In turn, a population-level public health paradigm of “the same dose for everyone for every disease” model has been the normative thinking in regard to prevention of vaccine-preventable infectious diseases. In addition, up until recently, no vaccines had been designed specifically to overcome the immunosenescence of aging, consistent with a post-WWII mentality of developing vaccines and vaccine programs for children. It is now recognized that the current lack of knowledge concerning how immune responses to vaccines are generated is a critical barrier to understanding poor vaccine responses in the elderly and in immunoimmaturity, discovery of new correlates of vaccine immunogenicity (vaccine response biomarkers), and a directed approach to new vaccine development.

The new fields of vaccinomics and adversomics provide models that permit global profiling of the innate, humoral, and cellular immune responses integrated at a systems biology level. This has advanced the science beyond that of reductionist scientific approaches by revealing novel interactions between and within the immune system and other biological systems (beyond transcriptional level), which are critical to developing “downstream” adaptive humoral and cellular responses to infectious pathogens and vaccines. Others have applied systems level approaches to the study of antibody responses (a.k.a. “systems serology”), high-dimensional cell subset immunophenotyping through CyTOF, and vaccine induced metabolic changes. In this turn, this knowledge is being utilized to better understand the following: identifying who is at risk for which infections; the level of risk that exists regarding poor immunogenicity and/or serious adverse events; and the type or dose of vaccine needed to fully protect an individual. In toto, such approaches allow for a personalized approach to the practice of vaccinology, analogous to the substantial inroads that individualized medicine is playing in other fields of human health and medicine. Herein we briefly review the field of vaccinomics, adversomics, and personalized vaccinology.
development of predictive immune signatures in response to vaccines. Indeed, we have previously published what we believe is the first draft of a mathematical model and predictive equation describing the non-random events that lead to a pre-determined immune response [6]:

\[ y = \beta_0 + \sum_{i=1}^{p} \beta_i X_i + \varepsilon \]

- \( y \) = measure of immune response
- \( \beta_0 \) = intercept
- \( \beta_i \) = coefficient for the \( i \)th variable \( X_i \) and indicates the amount of change in \( y \) for a 1 unit change in \( X_i \)
- \( \varepsilon \) = random deviations from the model

We recognize that such an equation, given the current state of the science, is incomplete and cannot yet predict immune responses. But we present it as an early directional attempt to quantify such an equation. Such an approach begins to move us into a 21st-century model of directed vaccine development and an advanced understanding of how, and by what mechanisms, vaccines and vaccine adjuvants trigger both useful and maladaptive innate and adaptive immune responses. We believe that vaccinomics and adversomics represent approaches counter to the standard methods of vaccine development until recently. Historically, vaccine development has been empirical, despite many emerging and re-emerging complex, hyper-variable pathogens—many with elaborate immune escape mechanisms. In addition, vaccine coverage rates continue to suffer as society is risk-averse toward vaccines and demands levels of safety that may not be achievable. Finally, the “one-size-fits-all” approach to the practice of vaccinology ignores the complexity and diversity of the human immune system and host genome. Thus, the promise of vaccinomics and related paradigms is to identify specific immune response profiles, immunosignatures, and biomarkers that predict vaccine safety and/or efficacy, and which may lead to new vaccine candidates.

2. Rationale and examples of vaccinomics and adversomics

Vaccinomics provides the opportunity to examine not only immune response genes likely to be involved in vaccine response, but also the possibility of identifying the influence of new (uncharacterized) genes on vaccine-induced immunity. In turn, the identification and directed study of such genetic variants allows recognition, often at the molecular level, of the effects of differential binding, processing, and expression/presentation of antigenic viral peptides used in vaccine development, identification of the differential range of presented peptides (genetic restriction), altered secretion patterns (cytokines) in response to vaccines or vaccine adjuvants, altered transcription of important genes (signaling molecules) and gene products, altered binding of virus/antigens by membrane-based receptors (TLRs, other), differential receptor function, expression, and affinities, and the impact of epigenetics on vaccine-induced immune responses. We have utilized this knowledge in our own laboratory to create a research-oriented paradigm of “discover-validate-characterize-apply,” which may be used in new candidate vaccine development (Fig. 1) [6]. In this paradigm, we have been able to utilize vaccinomics approaches to discover genetic variants that are significantly associated with subsequent downstream immune responses, validate that such variants are indeed associated, then seek to characterize the mechanism whereby such effects occur and, finally, apply this knowledge—often in functional studies that confirm the effect on immunity. Such knowledge can be exploited in developing immune strategies to enhance or circumvent genetic restrictions, for example, in triggering vaccine-associated immune responses, by “reverse engineering” around a given genetic or other obstacle to generating protective immune responses.

There are a growing number of studies reporting unbiased genome-wide assessments of genetic variation and its influence on adaptive (humoral and cellular) vaccine-induced immune responses across multiple viral and bacterial vaccines. For example, candidate and GWAS immunogenetic and phamacogenetic studies have identified polymorphisms in HLA, KIR, MICA, and BTN genes associated with immune responses to pathogens causing disease in humans, such as hepatitis C [16], Mycobacterium leprae [17,18], human immunodeficiency virus [19], and measles [20–22]. Similar studies have identified novel genes impacting immune responses to vaccines, including hepatitis B, rubella, influenza A, smallpox, anthrax, and mumps [23–33]. Our gene association studies of measles-mumps-rubella (MMR) vaccines have demonstrated that inter-individual variations in measles vaccine virus-induced humoral and cellular responses are significantly associated with polymorphisms in immune response genes and, together with HLA alleles, explain ~30% of the inter-individual variability in humoral response [34–36]. These findings, which illustrated the importance of key HLA alleles in the adaptive immune response to measles vaccine, led to the identification of naturally processed and presented measles-derived peptides isolated from specific HLA polymorphisms associated with vaccine non- and hyper-response [37,38]. These peptides containing specific components (adjuvants and biodegradable nanoparticles) are now being utilized in a reverse-engineering strategy to develop peptide-based candidate measles vaccines. Likewise, Homann et al. have attributed diminished protection to differential HLA presentation of T and B cell epitopes between vaccine and wild type strains of mumps virus [39]. This diminished efficacy could theoretically be overcome by incorporating defined critical immunogenic peptides into an improved vaccine.

TLR genes represent an important link between the innate and the adaptive immune system [40,41]. As an example, we have demonstrated that measles vaccine-induced humoral responses are significantly associated with coding polymorphisms in the TLR2 (rs3804100) and TLR4 (rs5030710) genes [42]. For the rubella vaccine and TLR3 gene, a TLR3 gene SNP rs5743305 was associated with rubella-specific GM-CSF production [43]. Our recent mumps vaccine study has identified and replicated TLR4 SNPs associated with a ~45% decrease in antibody titer, and a TLR5 SNP associated with a 64% increase in T cell response (unpublished data). These data strongly suggest that robust TLR activation by measles, mumps, and rubella viruses is crucial for optimal vaccine response. Supporting these findings is a study demonstrating that an inactivated mumps vaccine containing a protollin-based TLR2/4 adjuvant is highly immunogenic in a mouse model; it led to superior total IgG levels, higher neutralizing antibody titers, greater mucosal IgA production, and enhanced Th1/Th2 cytokine secretion [44]. One potential application of this finding is to identify the specific and critical interactions between TLRs (and other genes) and virus, leading to advances in our knowledge of the precise mechanisms driving immunity to MMR vaccine.

3. Sex-based differences in immune responses to vaccines

Significant sex differences in humoral and cellular immune responses to vaccines are apparent [45,46]. Additionally, local and systemic adverse rates are generally higher in females versus males. Protective antibody responses are significantly higher in females than males after vaccination against influenza, yellow fever, measles, mumps, rubella, hepatitis A and B, herpes simplex (HSV) 2, rabies, smallpox, and dengue viruses [47–55]. Sex-based differences in humoral immune responses are observed through various age groups [47–50,52–57], suggesting that sex steroid...
hormones are not the singular mediators of sex differences in humoral immune responses to vaccines [45,58]. This suggests that genetic, or other, factors may be an important driver of sex-related differences in humoral immune response [59]. Despite significant evidence of immune response differences between the sexes, for the most part, vaccine studies have not examined and analyzed immune response outcomes by sex [60,61]. In fact, little information is known about potential mechanisms for sex-based effects, which should be a priority for vaccine research studies. Discovery of specific factors involved in sex-based differences in immune response may allow the identification of new correlates of vaccine immunogenicity.

In a cohort of 556 older (ages 50–64) and 558 younger (ages 18–49) previously vaccinated individuals, the seasonal trivalent influenza vaccine induced >1.5-fold higher A/H3N2-specific HAI antibody titers in women than men across both age groups [47]. Similarly, a study of standard seasonal influenza vaccine and high-dose influenza vaccine responses in a sex-balanced cohort of 414 elderly subjects (ages 65–95) demonstrated significantly higher rates of seroconversion in females than in males [48]; however, no significant differences in antibody measures were found between males and females after seasonal influenza vaccination in another cohort of 158 older adults (ages 50–74) [62]. A study by Furman et al. examining gene expression, serum cytokines/chemokines, cell subsets, and phosphorylation events found several serum markers (LEPT, IL-1RA, CRP, GM-CSF, and IL-5) to be more highly expressed in females than males after influenza vaccine [51]. This same report used a systems biology approach to identify a gene cluster involved in lipid biosynthesis that is regulated by testosterone and significantly correlated with poor humoral responses following influenza vaccination in men [51]. These data suggest that this gene cluster (e.g., genes involved in lipid metabolism) could be an important driver of sex-related differences in humoral immune response. This collective knowledge could substantially assist future personalized vaccine development efforts through the generation of new knowledge and the identification of targets and biomarkers that predict vaccine responses in specific populations (e.g., females vs. males; young vs. old; obese vs. lean). Further research is needed to clarify the effects of sex on immune response. Identification of molecular immune signatures of sex differences in innate and adaptive immune responses to vaccines may provide evidence necessary for additional efforts in designing personalized vaccination and vaccinomics approaches (i.e., in which males and females might be vaccinated differently using different doses or different vaccines) to provide equal protection while reducing side effects [46,63,64].

4. Immune responses to vaccines in the elderly

A significant global public health issue is the aging of the population. As individuals age, immunosenescence develops, leading to poorer immune responses to vaccines. Immunosenescence is an age-related dysregulation of the immune system due to age-associated changes in innate and adaptive immune system components, which leads to impaired immunity and protection following immunization or infection [65–67]. Published data reveal that innate and adaptive immunity is decreased with age, but the systems-level mechanisms for these findings are unclear [66,68], particularly in regard to influenza and other viral vaccine responses where the morbidity, mortality, and associated healthcare costs are greater in older individuals [11]. Major signs of innate immune dysfunction commonly observed in the elderly include, but are not limited to, altered cytokine secretion; decreased NK cell activity; reduced TLR expression; and a chronic inflammatory state (elevated levels of IL-1β, MCP-1, TNF-α, and serum IL-6) known as “inflamm-aging” [8,69–71]. Age-related humoral immune dysfunction, for example, might be overcome through optimal stimulation of innate and/or Th cell-specific genes, which may be different in males and females. For example, adjuvanted zoster subunit vaccine (Hz/su) reduced the risks of herpes zoster, and postherpetic neuralgia in immunocompetent persons 70 years of age and older [72]. This Hz/su vaccine contains varicella zoster virus glycoprotein E and a novel AS01b adjuvant system aimed to improve and preserve with age zoster-specific CD4+ T cell responses [73]. A TLR4 agonist GLA-SE (glucopyranosyl lipid adjuvant formulated in a stable emulsion) has been shown to enhance Th1 responses to influenza vaccine in older adults [74], suggesting a potential mechanism for targeting innate receptor agonists (e.g., TLRs) that enhance innate

---

**Fig. 1. Personalized Vaccinology Paradigm.**
immune responses against influenza. Given the substantially diminished efficacy of influenza and other vaccines with age and the importance of developing improved vaccines [75], data from vaccinomics studies could be used to inform directed and rational development of next-generation influenza vaccines—potentially circumventing immunosenescence-related factors.

Systems biology approaches provide a unique opportunity to identify biomarkers likely to be involved in immune responses to vaccination [1–4, 8, 76, 77]. Fourati et al. applied a systems vaccinology approach to examine gene signatures and molecular pathways of age-related hypersensitive response to hepatitis B vaccine (HBV) in naïve older adults [78]. They observed the B cell signaling pathway (and higher memory B cell frequencies) and inflammatory pathway (and increased frequencies of activated pro-inflammatory innate cells) were strongly correlated with higher and low antibody responses to HBV, respectively. This signature, including serum cytokine profiling and flow cytometric correlates of response, predicted the antibody response to HBV with up to 65% accuracy [78]. This study demonstrates that a systems biology approach can be used to predict age-related immune response to vaccination.

5. Obesity and immune responses to vaccines

Obesity is another major public global health concern. In the US, 68% of adults and nearly 32% of children and adolescents are now overweight or obese [79]. Weight gains across all countries have been demonstrated to be associated with increasing socioeconomic status. Obesity has been shown to be a predictor of impaired immunogenicity (e.g., decreased antibody response) to hepatitis B, tetanus toxoid, rabies, and influenza vaccines [80–83], and as such can be considered a marker, or state, of immunosuppression at its extremes. These data suggest that obesity is correlated with poorer vaccine-induced immune responses in humans, and further research is required to understand the immune mechanisms that are altered in obesity.

As individuals age, their circulating leptin levels rise with a concomitant reduction in leptin signaling; this results in leptin resistance, which is a finding associated with obesity [84]. Leptin resistance has been shown to adversely affect the immune response in obese subjects, including responses to influenza virus [85, 86]. For example, obese individuals demonstrate decreased activation of influenza-specific CD8+ T cells compared to healthy-weight persons, including decreased production of IFN-γ and granzyme B, suggesting that influenza vaccination may not be as effective in the obese population as in healthy-weight individuals [87]. Given only moderate seroprotection of influenza and other vaccines in obese older adults [83], and the importance of developing improved influenza vaccines [75], systems biology studies designed to identify the mechanisms for improved immune response are needed. In fact, data from vaccine studies could be used to inform directed and rational development of personalized vaccines that optimally stimulate innate and adaptive immune responses in males and females and overcome immune deficiencies induced by obesity [88]. Careful vaccine studies comparing lean and obese persons could provide foundational data used to improve vaccine-induced protection in the obese, a subpopulation with an elevated risk for serious vaccine-preventable illnesses and suboptimal vaccine-induced protective responses [10].

6. Adversomics

Adversomics utilizes tools—much like those used in vaccinomics—to identify, characterize, and predict adverse, or maladaptive, immune responses to vaccines [6, 89, 90]. The promise of adversomics would be to develop or identify either predictors or immune signatures of maladaptive immune responses that lead to harm rather than benefit, and to better understand the generation and mechanisms of such maladaptive immune responses.

We have asked the question, as have other scientists, “does it make sense in the 21st century to give the same vaccine, dose, and at the same frequency to everyone, regardless of age, weight, gender, race, genotype, and medical condition?” For example, we give adult males and females the same dose, and the same number of doses of vaccines, ignoring the findings that females nearly always have superior humoral immune responses to males for all vaccines studied, and yet experience significantly more side effects—more adverse events, of greater duration, and of higher intensity [47, 55, 60].

While the field is young in implementation, research has already revealed associations between specific genes or SNPs and adverse immune outcomes. For example, associations between cytokine gene expression and fever after smallpox vaccine have been identified [91]. Other studies have demonstrated correlations between smallpox vaccine-induced fevers and IL1A and IL18 SNPs [92]. Other smallpox vaccine-induced adverse events such as fever, rash, and enlarged lymph nodes have been significantly associated with MTHFR, IRF1, and IL4 SNPs haplotypes [93]. While smallpox vaccine is not used in the general population, such studies stand as examples of the usefulness of vaccinomic approaches. Finally, other recent studies have identified generic fever gene networks (TNFA) after vaccine administration [94], and relationships between MMR vaccine administration and SNPs in IFI44L, CD46, SCN1A, 2A, and TMEM16 (ANO3) genes [95].

7. Challenges in personalized vaccinology

Despite the tremendous success of vaccines, vaccinologists face several current challenges, including difficulty in developing vaccines for hypervariable viruses (HIV, rhinovirus, hepatitis C virus, coronavirus) and complex pathogens (malaria, Mycobacterium tuberculosis); newly emerging pathogens, such as Zika virus (ZIKV); complications imposed by aging and immunosenescent populations; inadequate understanding of the neonatal and newborn immune systems; increasingly immune deficient or immunocompromised populations due to HIV, cancer, or medications; sex-based differences in vaccine response and adverse-event rates; enhanced scrutiny of vaccine safety; and as noted global increases in age and weight. In addition, vocal and active anti-vaccine groups whose messages are not easily countered by facts or scientific studies have materially and detrimentally affected vaccine coverage rates [96–98]. Vaccinomic approaches can be utilized to better understand these issues; this information can then be used to inform new approaches, new understandings, and new vaccine candidates.

Just as new technologies have created exciting new opportunities in personalized medicine, they have brought with them novel challenges in addition to those mentioned above. In order for the full potential of personalized vaccines to be achieved, we must overcome additional challenges, such as the need for the following:

- Larger genotype:phenotype datasets (often in the many thousands to ten thousands)
- Integrating increasingly diverse high-throughput, high-dimensional data types
- Biomarkers that can reliably distinguish which product patients receive based on the likelihood of their response or an adverse side effect
- Vaccines with different mechanisms of action may require a move away from humoral correlates of protection for licensure; in this regard, correlates of protection based on cellular immune outcomes are likely to play an important role in future vaccines
8. Vaccine development

Personalized vaccination is the goal of applying the concept of personalized medicine to vaccines. Rapid strides in omics technologies and foundational work applying systems biology, computational immunology and reverse vaccinology have facilitated modern approaches to vaccine design and development enabling us to create vaccine formulations for new and re-emerging pathogens. Egg-based influenza vaccines take >6 months to create. The recent licensure of cell culture-based influenza vaccines demonstrates the potential of this field of science, vaccinomics and adversomics will advance vaccinology to the benefit of human health. As part of the development of this field of science, vaccinomics and adversomics will move the field away from the post-WWII population-level paradigm of "one dose of every vaccine for everyone," toward an individualized or personalized approach based on the unique factors relevant to a given individual. In his book, The Structure of Scientific Revolutions [123], Thomas Kuhn recognized that "we wrongly believe science is predicated on the belief that the scientific community understands what the world is like, and that we suppress or resist 'fundamental novelties' because they are seen as subversive to our firmly held beliefs of what the world is like." Later in his book, he suggests that "new advances always have and always will reveal that science and medicine includes bodies of belief

Another example of modern vaccine development being applied to a new pathogen can be seen with the response to Zika virus. A purified, formalin-inactivated vaccine (ZIKV PIV) has been developed by the Walter Reed Army Institute of Research (WRAIR) [112] and is being evaluated in several clinical trials (NCT02963909, NCT02952833, NCT02937233), while other inactivated vaccines are in preclinical development [113]. Two variants of a plasmid DNA vaccine containing the prM-ENV proteins have been developed by NIAID and one of the formulations is currently in a phase I clinical trial (NCT02840487) [114]. Inovio Pharmaceuticals developed their own plasmid DNA vaccine (also expressing prM-ENV), which is currently in two clinical trials (NCT02809443, NCT02887482). RNA-based vaccines [115] and a variety of subunit and viral vector-based vaccines are also in development [113,116,117]. DNA and RNA-based vaccines can be rapidly made at minimal costs compared to other formulations and are fairly stable, without the cold-chain requirements of live virus-based vaccines.

Subunit vaccines are typically safer than whole virus-based products, which represents an active area of investigation not only for pathogens with no existing vaccines, but also for improving on established vaccines. Our group and others have identified pathogen-derived epitopes as preliminary steps in the development of safe, stable, and effective peptide- and protein-based vaccines for smallpox, influenza, measles, tuberculosis, staphylococcus, and myriad other viral and bacterial pathogens [38,118–122].

Parallel efforts by different groups to create new vaccines result in a spectrum of potential products that can be uniquely tailored to specific population groups. Live viral vaccines rapidly inducing robust immunity can be used in healthy individuals where time is of the essence (e.g., in outbreak scenarios), while inactivated or subunit vaccines can be used in vulnerable populations such as pregnant women or those with immunocompromising conditions, or in young children where the presence of maternal antibody interferes with whole virus vaccines. Vaccines based on different viral vector backbones can be combined into effective prime-boost regimens. Vaccines with specific adjuvants may be most appropriate for the elderly in order to overcome immunosenescence, or in the very young in order to compensate for immune system immaturity.

9. Conclusion

We, along with increasing numbers of other scientists, believe that personalized vaccinology will revolutionize the practice of vaccinology to the benefit of human health. As part of the development of this field of science, vaccinomics and adversomics will allow us to develop molecular immune signatures of adaptive and maladaptive immune responses to vaccines, develop early biomarkers of vaccine response in vaccine trials, identify who should get what vaccine and at what dose, and increase safety and public confidence in vaccines by reducing the likelihood of serious adverse events related to vaccines. In many ways, however, personalized vaccinology is most challenged by the difficulty in moving the field away from the post-WWII population-level paradigm of “one dose of every vaccine for everyone,” toward an individualized or personalized approach based on the unique factors relevant to a given individual. In his book, The Structure of Scientific Revolutions [123], Thomas Kuhn recognized that “we wrongly believe science is predicated on the belief that the scientific community understands what the world is like, and that we suppress or resist 'fundamental novelties' because they are seen as subversive to our firmly held beliefs of what the world is like.” Later in his book, he suggests that “new advances always have and always will reveal that science and medicine includes bodies of belief
incompatible with beliefs we hold today, and that advancements come when we reject a time-honored scientific theory in favor of another incompatible with it.” These cognitive biases have, in our opinion, been manifest in our discussions with scientific colleagues as we developed this field of science. Schopenhauer, the German philosopher, suggested that new discoveries are at first ridiculed, then opposed, and finally accepted as self-evident. Vaccinomics and adversomics appear to be moving from the ridiculed and opposed steps, and into the not-yet quite self-evident phase of the continuum.

Part of the challenge is that often the concept of personalized vaccinology suggests to the reader that a unique vaccine will be developed for each individual. While that is one tactic being used in the cancer-vaccine field, it is neither necessary nor practical for the prevention of infectious diseases. Rather, the personalized vaccinology approach would suggest the development of specific vaccines based on factors that relate to overcoming the potential for poor immunogenicity and the potential for adverse events. An excellent example is influenza vaccines. A mere decade or so ago, only a trivalent injectable influenza vaccine was available. Quadrivalent vaccines were unavailable. For with one exception, everyone received the same vaccine and dose, regardless of age, weight, immunosuppression state, etc. At the current time in the US, multiple influenza vaccines are available so that the right vaccine, for the right patient, can be given at the right time. For example, LAIV (live attenuated influenza vaccine) can be used in younger subjects or the needle-phobic. High-dose or MF59-adjuvanted vaccines can be chosen for the elderly. Recombinant vaccines can be chosen for those with egg allergy, and so on. This is the approach that should be taken with all vaccines. In some cases it may mean merely adjusting the dose based on weight, gender, or age. In other cases it may mean utilizing an adjuvanted or non-adjuvanted vaccine based on immune status. Other examples include the recently licensed MF59 adjuvanted influenza vaccine (FlumHV), which has demonstrably higher immunogenicity and efficacy than its non-adjuvanted counterparts, [124–126] or the highly effective AS01-adjuvanted zoster glycoprotein E vaccine, which does not contain live virus and may be more broadly suitable for administration to older individuals [72,73].

Thus, the movement toward a new paradigm of vaccine practice, based on a personalized approach, is occurring in the 21st century based on new scientific knowledge, market demand, safety considerations, immunogenicity concerns, public health trends (age, obesity, other), and the simultaneous pull of individualized medicine in other medical arenas. The net result is likely to be higher vaccine coverage rates, increased public confidence in vaccines, improved immunogenicity and adverse event rates, and a reduction or elimination in the morbidity and mortality related to vaccine-preventable diseases. As a result, we anticipate a new era of personalized “Predictive Vaccinology,” whereby we abandon a “one size and dose fits all vaccine approach” in order to design and develop new vaccines, and acquire the ability to make the following predictions for each individual: whether to give a vaccine based on likelihood of response (and perhaps need); the likelihood of a significant adverse event to a vaccine; and the number of doses likely to be needed to induce a protective response to a vaccine [63].

Current vaccine development is largely empirical. Vaccines are tested by trial and error, are mass produced, and given to the entire population using the same antigen dose, route of administration, number of vaccinations, and at the same age. In contrast, the new vaccine-development paradigm begins with the “Discovery” of new knowledge by integrating unbiased, comprehensive analysis of the genome, transcriptome, proteome, metabolome, microbiome, and immunome—along with the assessment of multiple measures of immune function—in order to under-

stand and evaluate perturbations of the immune system. Findings are then “Validated” in replication cohorts or additional model systems. The new knowledge is then “Applied” to the creation of new vaccine formulations that can undergo additional testing to start a new round of “Discovery,” or can move into clinical trials in order to develop vaccine products engineered to elicit (or avoid) specific effects on the immune system. Each product is tailored to specific subgroups such that robust, protective immunity can be elicited in the old and young, lean and obese, or male and female, while avoiding inappropriate immune responses due to genetics, metabolism, race, gender, malnutrition, immunosuppression, and other host factors or underlying conditions.
