We investigate the power-dependent photoluminescence spectra from a strongly coupled quantum dot-cavity system using a quantum master equation technique that accounts for incoherent pumping, pure dephasing, and fermion or boson statistics. Analytical spectra at the one-photon correlation level and the numerically exact multi-photon spectra for fermions are presented. We compare to recent experiments on a quantum dot-micropiller cavity system and show that an excellent fit to the data can be obtained by varying only the incoherent pump rates in direct correspondence with the experiments. Our theory and experiments together show a clear and systematic way of studying stimulated-emission induced broadening and anharmonic cavity-QED.

Introduction. – Single quantum dot (QD) - cavity systems facilitate the realization of solid state qubits (quantum bits) and have applications for producing single photons [1, 2, 3] and entangled photons [4, 5]. Rich in physics and potential applications, the coupled QD-cavity has been inspiring theoretical and experimental groups to probe deeper into the underlying physics of both weak and strong coupling regimes of semiconductor cavity-QED (quantum electrodynamics). Key signatures of cavity-QED include the Purcell effect and vacuum Rabi oscillations. Although a well known phenomenon in atomic cavity optics [6], vacuum Rabi splitting in a semiconductor cavity was only realized a few years ago [7, 8, 9]. Inspired by the recent surge of related experiments, many researchers have been working hard to develop new theoretical tools to understand the semiconductor cavity-QED systems. For example, the persistent excitation of the cavity mode for large exciton-cavity detunings was measured [10, 11], and qualitatively explained by extended theoretical approaches that account for coupling between the leaky cavity mode and the exciton, and by showing that the main contribution to the emitted spectrum comes from the cavity-mode emission [12, 13, 14, 15, 16]. These formalisms assume an initially excited exciton or an initially excited leaky cavity mode, and they are valid for low pump powers. However, an interesting question that has been posed recently, e.g., see Refs. [17, 18, 19], is what is the role of an incoherent pump on the photoluminescence (PL) spectra, where the pump can excite the exciton or cavity mode? To experimentally investigate the pump-dependent spectra, two recent experiments have been respectively reported by Münch et al. [20] for a QD-micropiller system, and by Laucht et al. [21] for a QD-photic crystal system; these measurements show the pump-induced crossover from strong to weak coupling.

In this work, we present a master equation (ME) theory that self-consistently includes incoherent pumping, stimulated emission, and pure dephasing. We derive analytical results at the level of one-photon correlations and present numerically exact results for the multi-photon spectra. We analyze the Würzburg [20] experiments directly and show the striking differences with previous models that neglect the direct influence of stimulated emission [18, 19, 24]. For the incoherent pumping of the exciton, we present two ME models: a thermal bath model (c.f. a two-level system) and a heat bath model at large negative temperature (c.f. a multi-level laser system). Accounting for fermion statistics, pure dephasing, and the thermal bath model, an excellent fit to the data is obtained by only changing the incoherent pump rates in direct correspondence with the experiments.

Cavity system and model. – The system investigated here is shown as a scanning electron microscope (SEM) image in Fig. [1] along with the extended experimental data of Ref. [20]. We make the following assumptions: the cavity is single-mode in the frequency of interest; the coupling between the cavity and target QD exciton is described through a coupling rate $g$; the decay rate of cavity is $\Gamma_c$; the coupling between the cavity and target QD exciton is described through a coupling rate $g$; the decay rate of cavity is $\Gamma_c$; for the strongly coupled QD, we include only the target exciton as a system operator, and consider both radiative decay, $\Gamma_x$, and pure dephasing, $\Gamma_x'$. The QD-cavity system is driven simultaneously by an exciton pump, $P_x$, and a cavity pump, $P_c$; the former is caused by the incoherent relaxation of electron-hole pairs from the higher energy level, and the latter is due to the cavity coupling with off-resonant excitons (probably coming from other QDs in the cavity layer). To treat the incoherent excitation, we consider a system-reservoir interaction [22], apply a Born-Markov approximation, and trace over the cavity and target exciton pump reservoirs (bath
exciton, there are a series of other exciton levels that can also be considered as resonating with the cavity mode.

FIG. 1: (Color online) Typical broadband PL spectrum that is observed when a target exciton is closely resonant with the cavity mode (near $\omega_0 = 1331.355$ meV); away from the target exciton, there are a series of other exciton levels that can also couple, off-resonantly, to the cavity mode. The SEM image shows our micropillar cavity and the QD layer. The emitted photons from the QDs are detected through vertical emission.

We have

$$\frac{dp}{dt} = -\frac{i}{\hbar}[H_s, p] + \mathcal{L}(p), \quad (1)$$

with the system Hamiltonian, $H_s = \hbar \omega_c \sigma^+ \sigma^- + \hbar \omega_c \tilde{a}^+ \tilde{a} + \hbar g (\sigma^- \tilde{a}^+ + \sigma^+ \tilde{a})$, where $\tilde{a}$ represents the cavity mode operator, $\sigma^+ / \sigma^-$ are the Pauli operators of the target QD exciton (with resonance frequency $\omega_x$), and $\omega_c$ is the eigenfrequency of the leaky cavity mode. The target exciton and cavity mode get pumped incoherently through the corresponding reservoirs. The state of the reservoirs can be written as $\rho_{kk}^O = \sum_k \rho_{kk}^O \langle n_k^O \rangle \langle n_k^O \rangle$, where $\rho_{kk}^O$ is the density of reservoir modes and $n_k^O$ is the number of photons in the mode of wave vector $k$. The correlations for the photon reservoir operators $\hat{a}_k$ are given by $\langle \hat{a}_k \rangle = 0$, $\langle (\hat{a}_k)^\dagger \hat{a}_k \rangle = n_k^c \delta_{kk'}$, and $\langle (\hat{a}_k^\dagger \hat{a}_k) \rangle = (n_k^c + 1) \delta_{kk'}$. Defining the average pump photon number around the cavity frequency as $\bar{n}^c = \bar{n}_k^c$, at $k = \omega_c / c$, yields the effective incoherent cavity pump rate: $P_c = \Gamma_c \bar{n}^c$. This incoherent pump process agrees with the model of Tan and Carnichael [23]. The super-operator in Eq. (1) becomes

$$\mathcal{L}(p) = \frac{P_c}{2} (2\hat{a}^\dagger \rho \hat{a} - \hat{a}^\dagger \rho \hat{a} - \rho \hat{a}^\dagger \rho) + \frac{\Gamma_c + P_c}{2} (2\hat{a} \rho \hat{a}^\dagger - \hat{a} \rho \hat{a}^\dagger - \hat{a}^\dagger \rho \hat{a} + \hat{a}^\dagger \rho \hat{a}) + \frac{P_{21}}{2} (2\hat{a}^\dagger \sigma^+ \rho - \hat{a}^\dagger \rho \sigma^+ - \sigma^+ \rho \sigma^+), \quad \text{(2)}$$

which is in Lindblad form. For the exciton pump we consider two different models: model-1 (thermal bath):

$$P_{21} = P_x = P_{21} = \Gamma_x + P_x; \quad \text{model-2 (heat bath at large negative temperatures)} \quad \text{(24)}: \quad P_{21} = P_x \quad \text{and} \quad P_{21} = \Gamma_x; \quad P_x \quad \text{is the target exciton pump rate which is presumed to proportionally follow the experimental pump power.}$$

One can next derive analytical spectra at the level of one-photon correlations, or compute the exact numerical spectra for $n$-photon correlations, e.g., see Refs. [18, 24]. We will present both approaches. Using Eq. (2), adopting the one-photon-correlation approximation $\langle \sigma^+ \sigma^- \rangle = \langle \sigma^- \rangle \langle \sigma^+ \rangle$, and applying fermion statistics $[\sigma^-, \sigma^+]_+ = 1$, we exploit the quantum regression theorem [22] to derive the equation of motion for the two-time correlation functions, $d (\langle \hat{a}^\dagger (t) \hat{a} (t + \tau) \rangle / d\tau$ and $d (\langle \hat{a}^\dagger (t) \sigma^- (t + \tau) \rangle / d\tau$).

Subsequently, the steady-state form of the dominant cavity-emitted spectrum [10] is obtained from $S_{cav}(R, \omega) = F_{cav}(R) S_{cav}(\omega)$, with $S_{cav}(\omega) = \Gamma_c / \pi \lim_{\tau \to -\infty} \Re \int_0^\infty \langle \hat{a}^\dagger (t) \hat{a} (t + \tau) \rangle e^{i\omega \tau} d\tau$, where $F_{cav}(R)$ is a geometrical factor that depends on the detector/collection optics. One obtains

$$S_{cav}(\omega) = \frac{\Gamma_c}{\pi} \Re \left\{ \frac{i (\langle \hat{a}^\dagger \hat{a} \rangle_{ss} D(\omega) + i \langle \hat{a}^\dagger \sigma^- \rangle_{ss} C(\omega) D(\omega) - g^2 + i \langle \hat{a}^\dagger \hat{a} \rangle_{ss} C(\omega) D(\omega) - g^2)}{C(\omega) D(\omega) - g^2} \right\}, \quad (3)$$

where $C(\omega) = \omega - \omega_c + \frac{i}{\Gamma_c}$, and $D(\omega) = \omega - \omega_c + \frac{i}{\Gamma_c + \Gamma_x}$. The subscript ‘ss’ represents the steady-state solutions, that are given by

$$\langle \hat{a}^\dagger \hat{a} \rangle_{ss} = \frac{g^2 \Gamma (P_{21} + P_x) + P_c (P_{21} + P_x)}{g^2 \Gamma (P_{21} + P_x) + P_c (P_{21} + P_x) + (\Gamma_c + \Gamma_x)} \left( \frac{\gamma_x + \Delta_{xx}^c}{\gamma_x + \Delta_{xx}^c} \right), \quad \text{(4)}$$

$$\langle \hat{a}^\dagger \sigma^- \rangle_{ss} = \frac{-2 \langle \hat{a}^\dagger \hat{a} \rangle_{ss}}{(\Gamma_c + \Delta_{xx}^c)^2 + \Delta_{xx}^c + \frac{g^2}{\Gamma_c + \Gamma_x} \Gamma_{21} + \frac{g^2}{\Gamma_c + \Gamma_x} P_{21}}, \quad \text{(5)}$$

$$\langle \hat{a}^\dagger \hat{a} \rangle_{ss} = \frac{P_{21} + i g \langle \hat{a}^\dagger \sigma^- \rangle_{ss} - \langle \hat{a}^\dagger \hat{a} \rangle_{ss}}{P_{21} + P_{21}}, \quad \text{(6)}$$

where $\Gamma = P_{21} + P_{21} + \Gamma_c + \Gamma_x$, and $\Delta_{xx} = \omega_x - \omega_c$. To recover boson statistics, one simply replaces the $P_{21} + P_{21}$ terms above by $P_{21} - P_{21}$ and sets $\Gamma_x$ to zero: We stress that the above formulas are substantially different to previous models that neglect stimulated emission [18, 19, 21]; in particular, we have no unphysical behavior as $\Gamma_c = P_c$, and we get qualitatively different saturation behavior of the QD exciton. Similar incoherent pump models, with pump-induced stimulated emission, have also been proposed recently by Ridolfo et al. [20], though they concentrate exclusively on the model-2 exciton pump and they neglect pure dephasing; thus their analytical formula applies only to a boson system.

The power dependent PL—To highlight the underlying physics of pump-induced PL, we proportionally change $P_c$ (and $P_x$) in our model, and keep all other parameters fixed (i.e., $g$, $\Gamma_c$, $\Gamma_x$). The fixed parameters are either known for our experimental system, e.g., $\Gamma_x = 0.002$ meV [23], or are accurately obtained from the fitting the experimental data at low powers, where $g = 0.045$ meV and $\Gamma_c = 0.08$ meV. We have also included a dominant pure dephasing exciton decay, $\Gamma_x = 0.035$ meV;
FIG. 2: (Color online) The on-resonance ($\omega_c \approx \omega_\text{ph}$) PL spectra, for different excitation powers. (a) Solution of our ME with model 1 (left) and model 2 (right). The red curve is the one photon spectra and the blue curve is the multi-photon case. The bottom-to-top panels have $P_x = [0.12, 0.5, 4, 16, 64] \times 0.02125g (0.0003 - 1.36g)$, and $P_y = 1.6 P_x$. (b) ME solution without stimulated emission. (c) Mean exciton number (dashed) and photon numbers (solid), for our ME with model 1 (left); ME solution without stimulated emission using model 1 (right). (d) Experimental data corresponding to $P_{\text{exp}} = [0.12, 0.25, 0.5, 2, 4, 8, 16, 32, 64] \mu$W, and model-1 fits (multi-photon and stimulated emission included), where $P_x$ proportionally follows the experimental values; the inset shows the integrated PL (experiment and theory).

FIG. 3: (color online) The on-resonance ($\omega_c \approx \omega_\text{ph}$) PL spectra, for different excitation powers, but for a boson model. (a) ME with stimulated emission, using exciton-pump model-1 (blue) and model-2 (red). (c) Corresponding mean density plots: exciton number (dashed) and photon numbers (solid); for clarity the model-1 densities are multiplied by 100. (b,d) As in (a,c), but without stimulated emission.

caused by electron-phonon scattering and spectral diffusion. The chosen values of $P_x$ range from $0.003 - 1.36g$, and $P_x = 1.6 P_x$. The justification for allowing $P_x$ to also follow the power of the laser is due to the fact that our micropillar measurements show a clear linear dependence with power for the cavity mode. For other QD-cavity systems, such as for a few QDs in a photonic crystal cavity, $P_x$ may saturate at much lower powers. In Fig. 2(a), we first show the power-dependent spectra for model-1 (left) and model-2 (right); and in Fig. 2(b), we compare the trend expected from a ME model that neglects stimulated emission processes. The red curves show the one photon results and the blue curves show the multi-photon case. Although all figures show a similar trend of the doublet becoming a singlet as a function of power, the high power linewidths are substantially different. In particular, the model with stimulated emission predicts a much larger pump-induced broadening as a function of power. In the absence of stimulated emission, the pump-induced broadening is suppressed, and the larger pump rates result in negative exciton and photon densities. The mean exciton number (dashed) and photon number (solid) are shown in Fig. 2(c) using the multi-photon model. Here we see the drastic influence on the predicted densities if stimulated emission is not included (right), where negative photon densities are predicted in addition to regimes of $\eta_x > 1$, both of which are obviously unphysical; though we model-1 densities, model-2 gives similar unphysical results [27]. Of course, with stimulated emission neglected in the model, the regime of $P_x > \Gamma_c$ is phenomenologically not allowed [10], so the top spectra in Fig. 2(b) are not reliable. It is interesting to note that, even for pump rates as small at $P_x = 0.085g$, multi-photon states (c.f. Jaynes-Cummings model [22]) are already important contributions to the nonlinear spectra, and we find that 2-4 photon states are enough to get good convergence.

The experimental data is shown in Fig. 2(d), alongside our fermion model-1, and there is an excellent correspondence. We stress that the only fitting parameter is a proportionality constant. Although $\Gamma_c$ may also be pump-dependent, we find that increasing its value by 1-2 orders of magnitude has little influence on our high-power PL, as the stimulated-emission-induced broadening is far the dominant source of broadening. To have further confidence in the theory, it is important that the models consistently fit the normalized PL, on and off-resonance, as well as the integrated PL. We obtain very good fits to the spectra when the cavity and exciton are off resonance (not shown) and the integrated PL [shown as an inset in Fig 2(d)], without changing any parameters.

Since our QDs are rather large, e.g., elongated with lengths on the order of 100 nm and widths of about 30 nm [7], it is natural to present the nonlinear boson PL calculations as well. In Fig. 3 we display the exact boson PL using exciton-pump models 1 and 2, again with and without stimulated emission terms. Since pure dephasing cannot be included, we set $\Gamma_x \rightarrow \Gamma_x + \Gamma'_x$. Clearly, none of the PL follow the trends of the experiments, and only the thermal bath models produce net positive densities for all pump rates. Moreover, even the low PL have different lineshapes due to the important effect of pure dephasing, which acts to suppress the Rabi.
oscillations without affecting the envelope of the population decay. While it has been discussed before that the boson model (with model-2) \cite{20} apparently fits well to the same data under variation of the coupling constant $g$ and three other free parameters ($\Gamma_x, P_z, P_c$): we believe that having so many free parameters can be detrimental to highlighting the underlying physics. We conclude that our nonlinear PL spectra unambiguously follow the presented fermion model, and we are thus well into the regime of anharmonic cavity QED.

High pump-power inversion and lasing—Finally, we briefly connect to the prospects for observing one exciton lasing in such a QD system. It is well known in the field of atomic optics, e.g., see Ref. \cite{24}, that the spectral properties of pump-dependent PL can be investigated to explore the regime of single atom lasing. Characteristic signatures of single state lasing in atomic physics include spectral narrowing, inversion, and a regime of linearly increasing mean photon number as a function of pump power. On the other hand, an incoherent pump of thermal photons will naturally be detrimental to the prospect of achieving single photon lasing. In Fig. 4(a) we use model-1 (solid) and model-2 (dashed) to investigate the pump-dependent mean exciton number and the mean photon number (panel (b)). As expected model-1 (thermal bath) does not exhibit any inversion, though model-2 does allow inversion. Both models allow a mean photon number of greater than 1. However, the Fano function (photonic number variance) \cite{28} shows no evidence of a maximum, and thus there is no lasing threshold in this system. To achieve single exciton lasing with the present model/system, we have numerically verified that one requires a much smaller $P_z/P_x$ ratio and a significantly smaller $\Gamma_c$; for example, $P_z = 0$ and $\Gamma_c = 0.01$ meV gives a very clear lasing threshold and order-of-magnitude reductions in the PL linewidth. Experimental activity on single QD lasers has begun \cite{29}, and, in future work, we will explore the key signatures of single exciton lasing using a more detailed multi-level excitation scheme.

Conclusions.—A master equation formalism, with incoherent pumping, pure dephasing, and a QD fermion model, has been introduced and used to investigate the power-dependent PL spectrum of a QD exciton under steady-state pumping. We have shown the importance of self-consistently including stimulated emission, and validated our model by directly comparing with recent experimental data on semiconductor micropillar-cavities. Using the proposed thermal bath model, an excellent fit to the data is obtained by only changing the pump rates in direct correspondence with the experiments, showing that we are well into the elusive regime of anharmonic cavity-QED. Moreover, we have shown that our excitation models produce positive-definite densities for all pump rates.
