Center for Theoretical Physics, College of Physics, Sichuan University, Chengdu, 610064, China

Recently, the image of a Schwarzschild black hole with an accretion disk has been revisited, and it showed that the “photon ring”, defined as highly bent light rays that intersect the disk plane more than twice, is extremely narrow and makes a negligible contribution to the total brightness. In this paper, we investigate the observational appearance of an optically and geometrically thin accretion disk around a hairy black hole in an Einstein-Maxwell-scalar model. Intriguingly, we find that in a certain parameter regime, due to an extra maximum or an “ankle-like” structure in the effective potential for photons, the photon ring can be remarkably wide, thus making a notable contribution to the flux of the observed image. In particular, there appears a wide and bright annulus, which comprises multiple concentric bright thin rings with different luminosity, in the high resolution image.

I. INTRODUCTION

The announcement of the first angular resolution image of the supermassive black hole M87* by the Event Horizon Telescope (EHT) collaboration is a significant event in observing astrophysical black holes [1–8], which opens a new window to test general relativity in the strong field regime. The image contains two prominent features, a circular dark interior, dubbed “shadow”, and a bright ring which is closely relevant to a class of circular photon orbits (i.e., photon sphere). The shadow and photon sphere are originated from the light deflection by the strong gravitational field near the black hole [9–12]. Thus, it is believed that the shadow image encodes valuable information of the geometry around the black hole, especially in the vicinity of the horizon.

Modelling the M87* with the Kerr black hole geometry, the observation was found to be in good agreement with the prediction of general relativity. Nevertheless, due to finite resolution of the M87* image, there still exists some space for alternative models to simulate the black hole image within observational uncertainty tolerance. To explore these possibilities, one can parameterize the deviations from the Kerr metric and compare the corresponding shadow image with the observed image [13–18]. Alternatively, shadows and photon spheres of black holes are widely studied in the context of various specific theories including new physics, e.g., the nonlinear electrodynamics [19–23], the

§ hyanga@scu.edu.cn
Gauss-Bonnet theory [24–27], fuzzball [28], the Chern-Simons type theory [29, 30], f(R) gravity [31, 32], and string inspired black holes [33–36]. Moreover, there could exist some exotic ultra-compact objects acting as black hole mimickers [37]. The gravitational lensing by various horizonless objects, such as wormholes [38–40] and bosonic stars [41, 42], has been detailedly analyzed. Their shadow images are usually distinct from those of black holes, but it is hard to distinguish between them at the current EHT resolution. Interestingly, it was argued in [43–45] that naked singularities can cast a shadow in the absence of the photon sphere. Furthermore, the EHT observation can also be applied to impose constraints on the cosmological parameters [46–51] and the size of extra dimensions [52–54], test the equivalence principle [55–57], and probe some fundamental physics issues including dark matter [21, 58–63] and dark energy [64–67].

On the other hand, an astrophysical black hole is generally believed to be surrounded by a luminous accretion flow, which is an essential ingredient in obtaining the black hole image. In fact, the realistic image is a result of the complex interactions between the strong gravitational lensing of the black hole and the electromagnetic plasma in the accretion flow, which requires intensive numerical general relativistic magnetohydrodynamic (GRMHD) simulations [68]. Nevertheless, simplified accretion models usually suffice to capture major features of black hole images, and hence have been widely investigated in the literature, e.g., spherical accretion flows [26, 43, 63, 65, 66, 69], thin or thick accretion disks [70–77]. In particular, the authors in [72] considered the emission from an optically and geometrically thin disk around a Schwarzschild black hole, which is divided into three classes by the number $m$ of half-orbits that an emitted photon completes around the black hole before reaching the observer: the direct emission ($m \leq 1$), the lensing ring ($m = 2$) and the photon ring ($m \geq 3$). It showed that the lensing ring superimposed upon the direct emission produces a thin ring of twice the background intensity in the black hole image, while the photon ring, which picks up larger intensity, makes negligible contributions to the total observed brightness due to its exponential narrowness. Nevertheless, observations of the photon ring would provide a new and powerful tool to probe a black hole spacetime [78]. Recently, experimental methods have been proposed to detect the photon ring by measuring its interferometric signatures [79] and two-point correlation function of intensity fluctuations [80].

No-hair theorem states that a black hole can be completely characterized by only three observable classical parameters: mass, electric charge, and spin [81]. However, various models of hairy black holes (HBHs) have been proposed to circumvent the no-hair theorem (see [82] for a review). Testing the no-hair theorem with observations would provide powerful probes of alternative theories of gravity. The observation of the black hole shadow would enable tests of the no-hair theorem, and therefore studying shadows of HBHs with various hairs has attracted great attention, e.g., axion-like hairs [83, 84], dilaton-like hairs [85–87] and others [88–94]. Interestingly, in [95] we found that there can exist two unstable photon spheres outside the event horizon for the HBH solutions in the Einstein-Maxwell-scalar (EMS) theory proposed in [96]. This novel feature results in two concentric bright rings of different radii in the observed image of the HBH surrounded by an optically thin, spherical accretion flow. Note that the presence of more than one photon sphere has also been reported in other scenarios, e.g., horizonless ultra-compact objects [97], Morris-Thorne type wormholes [38, 98], reflection-asymmetric wormholes [39, 40, 99, 100], and a Schwarzschild black hole surrounded by a certain matter distribution [101].

To investigate the effects of two unstable photon spheres on the photon ring, we consider the observational appearance of the aforementioned HBH surrounded by an optically and geometrically thin accretion disk. Remarkably, we show that, in a certain parameter regime, the existence of two photon spheres or its reminiscence can significantly extend the photon ring band, which thus makes a non-trivial contribution to the total observed intensity, comparable to that of the lensing ring. The rest of the paper is organized as follows. In Sec. II, we briefly review the HBH solutions, the behavior of null geodesics and the observed intensity of the accretion disk. Sec. III contains our main numerical results, which include effective potentials for photons, accretion disk images seen by a distant observer and the dependence of the photon ring on the HBH charge and scalar coupling. We conclude with a brief discussion in Sec. IV. We set $16\pi G = 1$ throughout the paper.

II. SET UP

Consider a specific 4D EMS theory with an exponential scalar-electromagnetic coupling given by [96]

$$S = \int d^4x \sqrt{-g} \left[ R - 2\partial_\mu \phi \partial^\mu \phi - e^{\alpha \phi^2} F_{\mu\nu} F^{\mu\nu} \right],$$

where $R$ is the Ricci scalar, the scalar field $\phi$ is minimally coupled to the metric $g_{\mu\nu}$ and non-minimally coupled to the electromagnetic field $A_\mu$, and $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is the electromagnetic tensor. Many properties of this model and its extensions have been explored in the literature, e.g., various non-minimal coupling functions [102, 103], dyons including magnetic charges [104], axionic-type couplings [105], massive and self-interacting scalar fields [106, 107], horizonless reflecting stars [108], stability analysis of the HBHs [109–113], higher dimensional scalar-tensor models...
quasinormal modes of the HBHs [115, 116], two U(1) fields [117], quasi-topological electromagnetism [118], topology and spacetime structure influences [119], the Einstein-Born-Infeld-scalar theory [120] and with a negative cosmological constant [121, 122]. Starting with the static and spherically symmetric black hole solution ansatz,

\[ ds^2 = -N(r)e^{-2\delta(r)}dt^2 + \frac{dr^2}{N(r)} + r^2 (db^2 + \sin^2 \theta d\varphi^2), \quad A = A_t dt = V(r)dt, \]  

we obtain the equations of motion

\[ 2m'(r) - r^2N(r)\phi'(r)^2 - e^{2\delta(r)+\alpha\phi(r)^2}r^2V'(r)^2 = 0, \]
\[ \delta'(r) + r\delta'(r)^2 = 0, \]
\[ \left[e^{-\delta(r)}r^2N(r)\phi'(r)\right]' - \alpha e^{\delta(r)+\alpha\phi(r)^2}\phi(r)r^2V'(r)^2 = 0, \]
\[ \left[e^{\delta(r)+\alpha\phi(r)^2}r^2V'(r)\right]' = 0, \]  

where \( N(r) \equiv 1 - 2m(r)/r \) can be expressed in terms of the Misner-Sharp mass function \( m(r) \), and primes denote derivatives with respect to \( r \). The last equation in Eq. (3) yields \( V'(r) = -e^{-\delta(r)-\alpha\phi(r)^2}Q/r^2 \), where the constant \( Q \) can be interpreted as the electric charge of the black hole. To solve the above non-linear ODEs, suitable boundary conditions at the event horizon of radius \( r_h \) and spatial infinity shall be imposed as

\[ m(r_h) = \frac{r_h}{2}, \quad \delta(r_h) = \delta_0, \quad \phi(r_h) = \phi_0, \quad V(r_h) = 0, \]
\[ m(\infty) = M, \quad \delta(\infty) = 0, \quad \phi(\infty) = 0, \quad V(\infty) = \Psi, \]  

where \( \delta_0 \) and \( \phi_0 \) are two positive constants, \( M \) is the ADM mass, and \( \Psi \) is the electrostatic potential. The scalar-free black hole solution with \( \phi = 0 \) corresponds to Reissner-Nordström black holes (RNBHs). When the dimensionless coupling \( \alpha \) is larger than 1/4, there exist HBH solutions with a non-trivial profile of the scalar field \( \phi(r) \) [96, 102, 120]. In this paper, we focus on the fundamental state of the HBH solutions, which means that \( \phi(r) \) remains positive outside the event horizon.

The behavior of a photon traveling outside the HBH can be encapsulated in the null geodesic equation,

\[ \frac{d^2 x^\mu}{d\lambda^2} + \Gamma^\mu_{\rho\sigma} \frac{dx^\rho}{d\lambda} \frac{dx^\sigma}{d\lambda} = 0, \]  

where \( \lambda \) is the affine parameter, and \( \Gamma^\mu_{\rho\sigma} \) is the Christoffel symbol. In the appendix, we show that light rays propagating in the HBH spacetime indeed are determined by the null geodesic equation. Due to the spherical symmetry, we only consider light rays moving on the equatorial plane with \( \theta = \pi/2 \). Combining \( ds^2 = 0 \) and Eqs. (2) and (5), one obtains the time, azimuthal and radial components of the null geodesic,

\[ \frac{dt}{d\lambda} = \frac{1}{bN(r)e^{-2\delta(r)}}, \]
\[ \frac{d\varphi}{d\lambda} = \pm \frac{1}{r^2}, \]
\[ e^{-2\delta(r)} \left( \frac{dr}{d\lambda} \right)^2 = \frac{1}{b^2} - \frac{e^{-2\delta(r)}N(r)}{r^2}, \]  

where \( \pm \) in the second line corresponds to the light rays moving in the counterclockwise (+) or clockwise (−) along \( \varphi \)-direction. The impact parameter \( b \) is defined as \(|L|/E\), where \( L \) and \( E \) are the conserved angular momentum and energy of the photons, respectively. Note that we use a redefined affine parameter \( \lambda \rightarrow \lambda/|L| \) in Eq. (6). From the last equation of Eq. (6), one can define the effective potential of light rays as

\[ V_{\text{eff}}(r) = \frac{e^{-2\delta(r)}N(r)}{r^2}. \]  

Particularly, an unstable photon sphere (or equivalently, a circular and unstable null geodesic) is determined by

\[ V_{\text{eff}}(r_{ph}) = \frac{1}{b_{ph}^2}, \quad V_{\text{eff}}'(r_{ph}) = 0, \quad V_{\text{eff}}''(r_{ph}) < 0, \]
where $r_{ph}$ is the radius of the photon sphere, and $b_{ph}$ is the corresponding impact parameter. In this paper, we focus on unstable photon spheres since they play an important role in determining the accretion disk image seen by a distant observer. For convenience, photon spheres are referred to unstable photon spheres in the remainder of this paper unless we make an explicit statement.

In this paper, we consider that the HBH is surrounded by a static and geometrically thin accretion disk, which is assumed to radiate isotropically in the rest frame of the matter. In addition, we take the disk emission to be optically thin by neglecting the absorption effect. Note that there exist compelling evidences indicating that an optically thin hot accretion flow may surround M87* or Sgr A* [123, 124]. To obtain the accretion disk image perceived by a distant observer, we evolve light rays from the observer’s position backwards in time. Furthermore, one can use $m$, the times that a certain ray intersects with the disk plane outside the horizon, to distinguish light rays’ behavior. Following the definitions in [72], light rays with $m \leq 1$, $m = 2$ and $m \geq 3$ constitute the direct emission, the lensing ring and the photon ring, respectively. The observed total intensity $F_\nu(b)$ generated by a light ray of impact parameter $b$ is a sum of the intensities from each intersection with the disk plane outside the horizon,

$$F_\nu(b) = \int \nu_\nu d\nu_\nu I_{\nu_\nu}(b) = \sum_m \int g(r) d\nu_\nu g^3(r) I_{\nu_\nu}(r) \bigg|_{r=r_m(b)} = \sum_m g^4(r) F_\nu(r) \bigg|_{r=r_m(b)},$$  

where $g(r)$ is the red-shift factor, $I_{\nu_\nu}$ is the specific intensity at the emission frequency $\nu_\nu$, $I_{\nu_\nu}$ is the specific intensity at the observed frequency $\nu_\nu$, and $F_\nu = \int_{\nu_\nu} I_{\nu_\nu} d\nu_\nu$ is the total emitted intensity. Here, we have applied the $I_{\nu_\nu} = g^3(r) I_{\nu_\nu}$ by Liouville’s theorem in the second equality. The function $r_m(b)$ ($m = 1, 2, 3...$), dubbed the transfer function, is the radial coordinate of the light ray crossing the disk plane at the $m$th time. Moreover, the slope of the transfer function, $dr_m/db$, is the demagnification factor of the $m$th image of the accretion disk. For simplicity, we set the total emitted intensity $F_\nu(r) = 1/r^2$ with $r > r_h$, which suffices to illustrate the major features of the accretion disk image. In this case, the observed total intensity is given by

$$F_\nu(b) = \sum_m N^2(r) e^{-\delta(r)} \bigg|_{r=r_m(b)},$$  

where we use $g(r) = \sqrt{N(r)} e^{-\delta(r)}$ [95]. When viewed in a face-on orientation, the 2D image of the accretion disk is circularly symmetric. Taking account of the geometric interpretation of $b$, we can depict the 2D face-on image by employing $F_\nu(b) = F_\nu(\sqrt{X^2 + Y^2})$, where the coordinates $(X, Y)$ span the observer’s celestial plane.

**III. NUMERICAL RESULTS**

In this section, we present the numerical results about the optical appearance of the accretion disk surrounding the HBH black hole, viewed face-on. In the left panel of Fig. 1, we first display the domain of existence for HBH
solutions to the action (1), which is bounded by the sets of existence and critical solutions, denoted by $Q_{\text{exi}}$-line (red line) and $Q_{\text{cr}}$-line (blue line) in the $Q$-$\alpha$ plane, respectively. On the $Q_{\text{cr}}$-line, the black hole horizon radius vanishes with the black hole mass and charge remaining finite. Furthermore, this domain can be divided into four parameter space regions, in one of which the effective potentials (7) have distinct profiles, e.g., the number of the maxima. In particular, we obtain four families of the HBH solutions,

1. Single-peak I (green region): The potential has a single maximum, which is similar to Schwarzschild and RN black holes [69, 125]. For instance, the $\alpha = 10$ case (black line) in the middle panel of Fig. 1.

2. Single-peak II (blue region): The potential has a single maximum and an “ankle-like” structure, e.g., the $\alpha = 0.9$ case (green line) in the middle panel. The ankle-like structure is characterized by a flattening of the potential, and corresponds to a transition between convexity and concavity of the effective potential. More precisely, its presence can be determined by the appearance of $V'_{\text{eff}}(r) > 0$ in the region where $V'_{\text{eff}}(r) < 0$.

3. Double-peak I (orange region): The potential has two maxima at two different radii, and the peak of the potential at the smaller radius is lower than that at the larger radius, e.g., the $\alpha = 0.6$ case (pink line) in the middle panel.

4. Double-peak II (red region): The potential has two maxima at two different radii, and the peak of the potential at the smaller radius is higher than that at the larger radius, e.g., the $\alpha = 0.7$ case (orange line) in the middle panel.

It is observed that the single-peak I family occupies almost the whole HBH existence regime, whereas the other three families only exist in a small $\alpha$ region near the $Q_{\text{cr}}$-line. To illustrate how the potential profile changes among different families, we display a set of potentials along the lines with fixed $Q_r \equiv (Q - Q_{\text{exi}})/(Q_{\text{cr}} - Q_{\text{exi}}) = 0.98$ and fixed $\alpha = 0.9$ in the middle and right panels of Fig. 1, respectively. As $\alpha$ increases with $Q_c = 0.98$, the middle panel (specifically, the inset therein) shows that the potential first has a single peak, then another peak at a smaller radius appears and grows, meanwhile the peak at the larger radius shrinks until disappears, indicating the single-peak I $\rightarrow$ double-peak I $\rightarrow$ double-peak II $\rightarrow$ single-peak II $\rightarrow$ single-peak I transition. When $Q_r$ increases with fixed $\alpha = 0.9$, the right panel and the inset therein present the single-peak I $\rightarrow$ double-peak I $\rightarrow$ double-peak II $\rightarrow$ single-peak II transition. In what follows, we display several representative cases to show the main features of each family. Note that the HBH mass $M$ is set to 1 without loss of generality in the rest of this section.

A. Single-peak potential

For the single-peak I family, we consider a HBH with $\alpha = 0.9$ and $Q = 1.03$ in Fig. 2. The potential with one maximum indicates a single photon sphere with radius $r_{\text{ph}}$ and the corresponding impact parameter $b_{\text{ph}}$. To consider the accretion disk viewed from a face-on orientation, we assume that an observer is placed at the far right of the upper-right panel, corresponding to the “north pole direction”, and the disk lies in the equatorial plane with respect to the observer’s orientation (dashed green line in the upper-right panel). Tracing a light ray backwards from the observer, the total orbit number $n$ is related to the total disk-crossing times $m$ as $n < 0.5 \rightarrow m = 0$, $0.5 \leq n < 0.75 \rightarrow m = 1$, $0.75 \leq n < 1.25 \rightarrow m = 2$ and $n \geq 1.25 \rightarrow m \geq 3$. By definition, $m \leq 1$, $m = 2$ and $m \geq 3$ correspond to the direct emission, the lensing ring and the photon ring, respectively [72]. In the upper-middle panel, we plot $n$ as a function of $b$ and depict the direct, lensing and photon ring bands in gray, orange and red, respectively.

To obtain the observed intensity, we first calculate the transfer functions $r_m(b)$ with $m = 1, 2, 3, \cdots$. In the lower-left panel of Fig. 2, we depict the transfer functions for $m = 1, 2$ and 3, which are associated with the direct, lensing and photon ring bands, respectively. Since the average slope of $r_m(b)$ roughly reflects the demagnified level of the $m^{th}$ image of the disk plane, it shows that the secondary image is highly demagnified, and the tertiary image is extremely demagnified. Via Eq. (10), the observed intensity $F_o$ as a function of $b$ is shown in the lower-middle panel, which presents a narrow spike-like photon ring (red) and a broader bump-like lensing ring (orange) superimposed on the direct emission (gray). One can see that the direct emission makes the dominant contribution to the overall intensity flux, whereas the lensing\photon ring makes modest\little contributions. To present the 2D image of the accretion disk seen by a distant observer, we project $F_o(b)$ to the observer’s celestial $(X, Y)$-plane via $b^2 = X^2 + Y^2$. In the lower-right panel, the observational appearance of the photon ring is shown to be a thin bright ring of radius $b_{\text{ph}}$, which suggests that the photon ring makes a very small contribution to the total flux. Moreover, there exists a completely dark area with vanishing intensity inside the photon ring, which is determined by the $m = 0$ band.

On the other hand, the photon ring can play a non-trivial role in the observational appearance of an accretion disk around a HBH in the single-peak II family. A HBH with $\alpha = 0.9$ and $Q = 1.074$ is considered in Fig. 3, the upper-left
FIG. 2. Behavior of photons in a HBH with $\alpha = 0.9$ and $Q = 1.03$, which is in the single-peak I family, and the observational appearance of an optically and geometrically thin accretion disk around the HBH, viewed from a face-on orientation. **Upper Left:** The profile of the effective potential, which possesses a single maximum. **Upper Middle:** The total number of orbits $n = \Phi/(2\pi)$, where $\Phi = \Delta \varphi$ is the total change of the azimuthal angle outside the event horizon. The direct emission, the lensing ring and the photon ring correspond to $n < 0.75$ (gray), $0.75 \leq n < 1.25$ (orange), and $n \geq 1.25$ (red), respectively. **Upper Right:** A selection of photon trajectories within the direct, lensed and photon ring bands. The blue dashed circle is the photon sphere, and the green line denotes the cross section of the disk plane. **Lower Left:** The first three transfer functions $r_m(b)$ with $m = 1$ (gray), $m = 2$ (orange) and $m = 3$ (red), representing the radial coordinates of the first, second and third intersections with the accretion disk. **Lower Middle:** The observed total intensity $F_\alpha(b)$ and the net contributions to the total flux from the direct (gray), lensed (orange) and photon ring (red) bands. **Lower Right:** The 2D image of the accretion disk viewed in the observer’s sky. A bright and narrow ring appears at the location of the photon ring.

panel of which shows that the effective potential has an ankle-like structure around $\log r \sim 1$. This distinctive feature results in more complicated behavior of null geodesics and observational appearance of emission from an accretion disk. Indeed, due to the flattening of the ankle-like structure, photons can revolve around the ankle-like structure multiple times, and cross the disk plane more than twice. So the upper-middle panel displays that, in addition to the sharp peak determined by the photon sphere at $b = b_{ph}$, the $n(b)$ curve also possesses a much broader peak of finite height at $b > b_{ph}$, which significantly widens the photon ring band. Note that a similar phenomenon has been reported in a wormhole scenario [38]. Consequently, as shown in the lower-middle pane, the photon ring makes a noticeable contribution to the total intensity flux, comparable to that of the lensing ring. Therefore, the photon ring plays an important role in determining the observational appearance of the accretion disk, leading to the presence of a bright ring and a concentric bright annular region, which can be observed in the lower-right panel. While the bright ring at the smaller radius, corresponding to the photon sphere, is barely visible due to the sharpness of the peak of $F_\alpha(b)$ at $b = b_{ph}$, the wide bright annular region at the larger radius is quite noticeable and comprises multiple concentric thin bright rings with different luminosity. Interestingly, the second and third transfer functions both exist over a larger range of $b$ than those in the single-peak I family (lower-left panels of Figs. 2 and 3), thus resulting in less demagnification for secondary and tertiary images in the single-peak II family.
The prominent character of a double-peak potential is the presence of two maxima at \( r = r_{ph1} \) and \( r = r_{ph2} \) with \( r_{ph1} < r_{ph2} \), corresponding to two photon spheres of radii \( r_{ph1} \) and \( r_{ph2} \) outside the horizon, respectively. The associated maximum values of the potential are \( 1/b_{ph1}^2 \) and \( 1/b_{ph2}^2 \), where \( b_{ph1} \) and \( b_{ph2} \) are the impact parameters of the photon spheres (see the upper-left panels of Fig. 4 and 5). As mentioned before, there are two families of double-peak potentials according to the magnitudes of the two maximum values of the potentials. For the double-peak I potential, the maximum at the smaller radius is lower than that at the larger radius (or equivalently, \( b_{ph1} > b_{ph2} \)). So the light rays revolving around the photon sphere of smaller radius can not escape to the infinity, rendering this photon sphere invisible to a distant observer. As a result, accretion disk images in the double-peak I family closely resemble those in the single-peak I family. On the other hand, both photon spheres can be responsible for obtaining the image of an accretion disk in the double-peak II family. In fact, two bright rings of arbitrarily large brightness, whose radii are \( b_{ph1} \) and \( b_{ph2} \), respectively, can appear in the image of the accretion disk. In what follows, we display two representative cases of the double-peak II family.

In Fig. 4, we consider a HBH with \( \alpha = 0.9 \) and \( Q = 1.064 \), for which the difference between \( b_{ph1} \) and \( b_{ph2} \) is small. As expected, the existence of two photon spheres endows both \( n(b) \) and \( F_o(b) \) curves with two infinite peaks at radii \( b_{ph1} \) and \( b_{ph2} \). As shown in the upper-middle panel, this two-peak structure extends the width of the photon ring band, compared to the single-peak I case. It is observed in the lower-middle panel that the photon ring can make a non-negligible contribution to the observed intensity, which is comparable to that of the lensing ring. Moreover, the

FIG. 3. Behavior of photons in a HBH with \( \alpha = 0.9 \) and \( Q = 1.074 \), which is in the single-peak II family, and the observational appearance of an optically and geometrically thin accretion disk around the HBH, viewed from a face-on orientation. The effective potential shows a flattening around \( \log r \sim 1 \) (Upper Left), which leads to a finite broad peak in the \( n-b \) plane (Upper Middle). As a result, the width of the photon ring is significantly increased, and comparable to that of the lensing ring. Therefore, the photon ring can make a non-trivial net contribution to the observed flux \( F_o(b) \) (Lower Middle). Specially, a bright and wide annulus, consisting of multiple concentric bright thin rings, appears outside the bright ring, corresponding to the photon sphere, in the accretion disk image (Lower Right). Moreover, as indicated by the transfer functions, the secondary and tertiary images are less demagnified than those in the single-peak I family (Lower Left).

B. Double-peak potential
FIG. 4. Behavior of photons in a HBH with $\alpha = 0.9$ and $Q = 1.064$, which is in the double-peak II family, and the observational appearance of an optically and geometrically thin accretion disk around the HBH, viewed from a face-on orientation. The upper-left panel shows that the effective potential has two peaks of similar heights at $r = r_{ph1}$ and $r = r_{ph2}$, respectively. These two peaks correspond to two photon spheres (blue dashed circles), leading to two infinite peaks in $n(b)$ and $F_o(b)$ curves and a narrow photon ring (Upper Middle and Lower Middle). Due to the two photon spheres, the contribution from the photon ring to the observed flux $F_o(b)$ is comparable to that of the lensing ring, and hence is non-negligible (Lower Middle). However, the internal structure of the photon ring is hardly visible in the accretion disk image because of the narrowness of the photon ring (Lower Right).

 photon ring leads to some internal structure between the two peaks for the observed intensity. However, since the photon ring is not wide enough, the lower-right panel shows that the internal structure can hardly been seen in the 2D image, and the observational appearance of the photon ring is almost indistinguishable from that of a thin bright ring.

In Fig. 5, we consider another HBH with $\alpha = 0.9$ and $Q = 1.07$, for which the difference between $b_{ph1}$ and $b_{ph2}$ is large. As shown in the upper-left panel, the two maximum values of the effective potential are quite different, thus leading to a remarkably wider photon ring. The lower-middle panel exhibits that the lensing and photon rings both contribute appreciably to the total observed intensity, and the photon ring is notably wider than that in Fig. 4. In the lower-right panel, the 2D observed image is shown to have a bright thin ring at $b = b_{ph1}$ and a bright annulus around $b = b_{ph2}$, which consists of a bright ring at $b = b_{ph2}$ and multiple concentric bright rings with different luminosity. In other words, the inner structure of the photon ring can be seen in the observed image since the photon ring is wide enough. From the lower-left panels in Figs. 4 and 5, it shows that the secondary and tertiary images in Fig. 5 are less demagnified than those in Fig. 4. It is noteworthy that the ankle-like structure of the potential in Fig. 3 is reminiscent of the maximum of the potential at $r = r_{ph2}$ in Fig. 5.
FIG. 5. Behavior of photons in a HBH with $\alpha = 0.9$ and $Q = 1.07$, which is in the double-peak II family, and the observational appearance of an optically and geometrically thin accretion disk around the HBH, viewed from a face-on orientation. Compared to Fig. 4, the photon ring here becomes significantly wider (Upper Middle and Lower Middle) since the two maximum values of the effective potential are well separated (Upper Left). Therefore, the photon ring can make a sizable contribution to the total flux (Lower Middle), and the internal structure of the photon ring, which is made up of multiple concentric bright rings, can be observed in the 2D image (Lower Right).

C. Dependence on black hole charge and scalar coupling

Here, we turn to investigate the dependence of the size of the photon ring and shadow on the HBH charge $Q$ and the scalar coupling $\alpha$. To study the dependence on $Q$, we consider two cases with fixed $\alpha = 0.9$ and $\alpha = 10$ in the upper and lower rows of Fig. 6, respectively. Note that the allowed parameter regions are bounded by the $Q_{\text{crI}}$-line and/or the $Q_{\text{crII}}$-line, which are shown in Fig. 1. The upper-left panel of Fig. 6 displays that, when $\alpha = 0.9$, the HBHs belong to the single-peak I (region on the left of the orange region), single-peak II (region on the right of the red region), double-peak I (orange region) or double-peak II (red region) families, depending on the value of the HBH charge. From the upper middle panel, one can see that the photon ring (red region) of the HBHs in the single-peak II and double-peak II families are quite wide, thus indicating that the photon rings can play a relevant role in determining the observed accretion disk images. Moreover, as the HBH charge increases toward the $Q_{\text{cr}}$-line, the width of the photon ring grows until the photon ring splits into a narrow photon ring of smaller radius and a broad one of larger radius in the image plane. While the photon ring of smaller radius is barely visible in the observed 2D image, the one of larger radius can make a non-negligible contribution to the total intensity and the accretion disk image. Therefore, it is expected that the accretion disk image in the two photon rings scenario is quite similar to those shown in Figs. 3 and 5. On the other hand, the HBH with $\alpha = 10$ is always in the single-peak I family, which is shown in the inset of the left panel of Fig. 1. In this case, the lower-middle panel of Fig. 6 displays that the photon ring is always very narrow, and the lensing (orange and red regions) and photon rings decrease in size with $Q$ increasing toward $Q_{\text{cr}}$. Around $Q = Q_{\text{cr}}$, the lensing ring also becomes very narrow, and makes a negligible contribution to the observed intensity.

In this paper, the term “standard shadow” is used to refer to the area inside the (smaller) photon sphere (i.e., the
FIG. 6. Dependence of quantities of interest on the black hole charge $Q$ for HBHs with $\alpha = 0.9$ (Upper) and $\alpha = 10$ (Lower). **Left:** The photon sphere radii, $r_{ph}$, $r_{ph1}$ and $r_{ph2}$, the associated impact parameters, $b_{ph}$, $b_{ph1}$ and $b_{ph2}$, and the horizon radius $r_h$ as functions of $Q$. As shown in Fig. 1, the range of $Q$ is bounded by the existence charge $Q_{exi}$ (black dashed) and critical charge $Q_{cr}$ (red dashed). With increasing $Q$ from $Q_{exi}$, the HBH with $\alpha = 0.9$ undergoes the single-peak I (region between the $Q_{exi}$-line and the orange region), double-peak I (orange region), double-peak II (red region) and the single-peak II (region between the red region and the $Q_{cr}$-line) families, while the HBH with $\alpha = 10$ remains in the single-peak I family. The impact parameter of the (smaller) photon sphere is identified as the radius of the HBH standard shadow, which decreases in size as $Q$ increases, and disappears at $Q = Q_{cr}$. **Middle:** The ranges of the direct emission (black, gray, orange and red regions), the lensing ring (orange and red regions) and the photon ring (red region) as functions of $Q$. The black region denotes the $m = 0$ band, corresponding to the completely dark region. When $\alpha = 0.9$, the range of the photon ring can be quite noticeable for large enough $Q$ (e.g., in the single-peak II and double-peak II families), thus indicating that the photon ring contributes non-trivially to the observed flux. When $\alpha = 10$, the photon ring always has a very narrow range, and hence makes a negligible contribution to the flux. **Right:** The impact parameters of the RNBH (red) and HBH (green) versus $Q$ in the coexistence region (yellow region). For a given $Q$, the HBH/RNBH has a smaller standard shadow for $\alpha = 0.9/\alpha = 10$.

apparent boundary [10, 11]). Specifically, the radius of the standard shadow is the impact parameter of the smaller photon sphere if there exist two photon spheres [95]. From the left column of Fig. 6, it is observed that the standard shadow of a HBH in the $\alpha = 0.9$ and $\alpha = 10$ cases shrinks with increasing $Q$ and vanishes at $Q = Q_{cr}$, where the HBH horizon becomes zero. For $\alpha = 0.9$, the standard shadow radius decreases at a larger decreasing rate in the single-peak II and double-peak II families. In the middle column of Fig. 6, the black regions denote the completely dark area with vanishing intensity, and are also shown to decrease in size with increasing $Q$ and vanishes at $Q = Q_{cr}$. For comparison, we also plot the impact parameters of the photon spheres of RNBHs with $M = 1$ in the right column of Fig. 6. In the coexisting $Q$-range of the RNBH and HBH, one can see that the standard shadow of the RNBH is larger than that of the HBH in the $\alpha = 0.9$ case (upper-right panel of Fig. 6), and vice versa in the $\alpha = 10$ case (lower-right panel of Fig. 6), which is consistent with the result in [91].

In Fig. 7, three cases with fixed $Q = 0.8$ (left column), $Q = 1.06$ (middle column) and $Q = 2$ (right column) are
FIG. 7. Dependence of quantities of interest on the scalar coupling $\alpha$ for HBHs with $Q = 0.8$ (Left), $Q = 1.06$ (Middle) and $Q = 2$ (Right). For the $Q = 0.8$ and $Q = 2$ cases, the HBHs are always in the single-peak I family. As $\alpha$ increases, the HBH with $Q = 1.06$ belongs to the double-peak II, double-peak I and single-peak I families, respectively. The allowed range of $\alpha$ is bounded from below by the $Q_{\text{exi}}$-line in the $Q = 0.8$ case, and by the $Q_{\text{cr}}$-line in the $Q = 1.06$ and $Q = 2$ cases. **Upper:** The event horizons radii (black), the photon spheres radii (blue) and the corresponding impact parameters (green) versus $\alpha$. The standard shadow grows as $\alpha$ increases. **Lower:** The ranges of the direct emission (black, gray, orange and red regions), the lensing ring (orange and red regions) and the photon ring (red region) as functions of $\alpha$. The black region denotes the completely dark region. The photon ring can play a relevant role for a HBH with $Q = 1.06$, that is close enough to the $Q_{\text{cr}}$-line.

presented to study the dependence on the scalar coupling $\alpha$. As shown in the upper row, the size of the standard shadow becomes larger for a stronger scalar coupling in all cases. For $Q = 0.8$, the ranges of the photon and lensing rings are fairly insensitive to $\alpha$. In the near $Q_{\text{cr}}$-line regime, HBHs with $Q = 1.06$ are in the double-peak II family, and the photon ring’s contribution to the observed intensity can not be neglected. On the other hand, the ranges of the photon and lensing rings of HBHs with $Q = 2$ become zero at the $Q_{\text{cr}}$-line. Finally, it is interesting to note that the stronger $\alpha$, the larger the completely dark area becomes.

**D. Blurred accretion disk images**

So far, we have considered high resolution images of HBHs surrounded by an accretion disk, which present some interesting features of the photon ring. To gain some insight into the effects of the photon ring on a realistic observation, we blur the images of the accretion disk in Figs. 2-5 with a Gaussian filter with standard derivation equal to $1/12$ the field of view to mimic the EHT resolution [72], as shown in the lower row of Fig. 8. In Fig. 8, the white dotted circles represent critical circles, whose radii are the impact parameters of photon spheres, and the standard shadow is defined as the region inside the critical circle or that of smaller radius if there exist two photon spheres.
FIG. 8. High resolution and blurred images of the HBHs from Fig. 2 (First Column, the single-peak I solution with $Q = 1.03$), Fig. 4 (Second Column, the double-peak II solution with $Q = 1.064$), Fig. 5 (Third Column, the double-peak II solution with $Q = 1.07$) and Fig. 3 (Last Column, the single-peak II solution with $Q = 1.074$). The high resolution images are blurred to correspond roughly to the EHT resolution. The white dotted circles denote critical circles associated with photon spheres, and the (smaller) critical circle is identified as the boundary of the standard shadow, which shrinks in size with increasing $Q$. For the HBHs with $Q = 1.07$ and $Q = 1.074$, the photon ring is wide enough to leave imprints on the blurred images, where brighter and wider blurred rings are observed.

In the first column of Fig. 8, we display the high resolution and blurred images of the HBH from Fig. 2, which is in the single-peak I family. The blurred image is primarily determined by the direct emission and the lensing ring, and has a blurred bright ring at the location of the lensing ring, which indicates that the observed shadow almost coincides with the standard shadow. In the second column, we exhibit the high resolution and blurred images of the HBH of the double-peak II family from Fig. 4, which has two critical circles of similar radii. Compared with the single-peak I family, the existence of two photon spheres slightly increases the brightness of the blurred bright ring. In addition, the observed shadow in the blurred image is almost same as the standard shadow.

On the other hand, when the photon ring is wide enough (e.g., Figs. 3 and 5), its effects can become quite noticeable in the blurred images. Indeed, the high resolution and blurred images of the HBH of the double-peak II family from Fig. 5 are shown in the third column of Fig. 8. In this case, the radii of the two critical circles are quite different, which significantly increases the width of the photon ring. Although the internal structure of the photon ring is washed out by the blurring, the wide photon ring leads to a brighter and wider blurred ring than in the single-peak I family. Since the inner edge of the blurred bright ring is at the smaller critical circle, the observed shadow nearly matches the standard shadow. In the last column, the high resolution and blurred images of the HBH of the single-peak II family from Fig. 3 are presented. The ankle-like structure of the effective potential also notably increases the brightness and width of the blurred bright ring. Moreover, the blurred bright ring is at the location of the ankle-like structure, and hence has a larger radius than the critical circle, which means that the observed shadow is larger than the standard shadow.

IV. CONCLUSION

In this paper, we investigated the behavior of null geodesics and observational appearance of a HBH surrounded by an optically and geometrically thin accretion disk in the EMS model with an exponential scalar coupling. Depending on the profile of the effective potentials for photons, we found that the HBH solutions are categorized into four different families, namely single-peak I, single-peak II, double-peak I and double-peak II. The single-peak I family dominates the allowed parameter space, while the other three families exist in a small region with small $\alpha$ and large $Q$. For the single-peak I solution, the photon ring is very narrow and makes little contribution to the total brightness. Therefore,
the accretion disk images bear much similarity to those of various static black holes with a single-peak potential [65, 72, 74, 75], e.g., a bright ring due to the lensing ring shows up (Fig. 2). On the other hand, an additional ankle or peak-like structure emerges in the single-peak II and double-peak II solutions, and results in the appearance of a new finite or infinite peak in the \( n(b) \) curve. Consequently, the photon ring can become sufficiently broader, and its inner structure comes into play, resulting in two bright annuluses in the observed image (Figs. 3 and 5). The annulus of smaller radius is quite narrow, while the one of larger radius is much wider, comprising multiple concentric thin bright rings with different luminosity. To illustrate effects of the photon ring on observations, we presented the images of the HBHs at low resolutions, roughly corresponding to the EHT resolution (Fig. 8). For the single-peak II and double-peak II solutions, the details of bright annuluses are washed out, giving a considerably bright and wide ring in the blurred image.

We end with some comments on future studies from several perspectives. In this paper, we considered the concept “photon ring”, which is defined as the collection of all \( m \geq 3 \) bands [72]. Since we observed the complicate inner structure inside the wide photon ring (Figs. 3 and 5), it would be interesting to study this rich structure by performing detailed analysis on each \( m \geq 3 \) band. Moreover, the ankle- and peak-like structures in the effective potentials in the aforementioned two cases behave like plateaus (upper-left panels of Figs 3 and 5), which is reminiscent of the potential profiles reported in [126, 127]. It suggests that a marginally unstable photon sphere is likely to appear during the transition between the single-peak II and double-peak II families. In addition, apart from the exponential coupling of the EMS model considered in this paper, exploring other coupling functions may provide us more novel phenomena about the photon spheres and disk images. Finally, it would gain more insights into the modified gravity by considering a rotating HBH surrounded by an accretion disk and comparing it with black hole images released in future observations, such as the Next Generation Very Large Array [128], the Thirty Meter Telescope [129], and the BlackHoleCam [130].

Appendix A: Light Propagation in the EMS Model

In this appendix, we use the geometric optics approximation [131–133] to derive the equations of geometric optics governing light propagation in the EMS model with the action

\[
S = \int d^4x \sqrt{-g} \left[ R - 2\partial_\mu \phi \partial^\mu \phi - e^{\alpha \phi^2} F_{\mu \nu} F^{\mu \nu} \right].
\] (A1)

The equation of motion for the electromagnetic field \( A^\mu \) is then given by

\[
\partial_\mu \left( \sqrt{-g} e^{\alpha \phi^2} F^{\mu \nu} \right) = 0.
\] (A2)

Assuming the wavelength of the photon is much smaller than the other physical scales of the system (i.e., the geometric-optics limit), we consider the ansatz

\[
A^\mu = \text{Re} [A^\mu \exp (i\psi)],
\] (A3)

where \( A^\mu \) is the slowly evolving amplitude, and \( \psi \) is a rapidly oscillating function of time and space. The wave vector \( k_\mu \) of light rays is identified as

\[
k_\mu \equiv \partial_\mu \psi.
\] (A4)

Putting the ansatz (A3) into Eq. (A2), we obtain the term of order \( k^2 \), which is the leading term in the eikonal approximation,

\[
k^\mu k_\mu = 0,
\] (A5)

where the Lorentz gauge \( \nabla_\mu A^\mu = 0 \) is used. Acting on the above equation with a covariant derivative leads to

\[
k^\mu \nabla_\mu k_\nu = 0,
\] (A6)
where we use $\nabla_{\mu} k_{\nu} = \nabla_{\nu} k_{\mu}$. From Eq. (A6), it shows that light rays of the EMS model are described by null geodesics in the geometric-optics limit.
