AKARI IRC survey of the Large Magellanic Cloud: 
Outline of the survey and initial results

Yoshifusa Ita

1 National Astronomical Observatory of Japan, 2-21-1 Osawa, Mitaka, Tokyo, 181-8588, Japan

Abstract

We observed an area of 10 deg$^2$ of the Large Magellanic Cloud using the Infrared Camera on board AKARI. The observations were carried out using five imaging filters (3, 7, 11, 15, and 24 micron) and a dispersion prism (2 – 5 micron, $\lambda/\Delta\lambda \sim 20$) equipped in the IRC. This paper describes the outline of our survey project and presents some initial results using the imaging data that detected over $5.9 \times 10^5$ near-infrared and $6.4 \times 10^4$ mid-infrared point sources. The 10 $\sigma$ detection limits of our survey are about 16.5, 14.0, 12.3, 10.8, and 9.2 in Vega-magnitude at 3, 7, 11, 15, and 24 micron, respectively. The 11 and 15 micron data, which are unique to AKARI IRC, allow us to construct color-magnitude diagrams that are useful to identify stars with circumstellar dust. We found a new sequence in the color-magnitude diagram, which is attributed to red giants with luminosity fainter than that of the tip of the first red giant branch. We suggest that this sequence is likely to be related to the broad emission feature of aluminium oxide at 11.5 micron. The 11 and 15 micron data also indicate that the ([11] – [15]) micron color of both oxygen-rich and carbon-rich red giants once becomes blue and then turns red again in the course of their evolution, probably due to the change in the flux ratio of the silicate or silicon carbide emission feature at 10 or 13.3 micron to the 15 micron flux.

1. Introduction

Owing to its proximity ($\sim 50$ kpc; e.g., Feast & Walker 1987) and face-on geometry, the Large Magellanic Cloud (LMC) is an ideal natural laboratory for the study of various astrophysical phenomena. It is located at a high Galactic latitude of $\sim -36^\circ$, and we expect less contamination of foreground stars and less interstellar extinction. It is far enough to neglect its depth so that we can reasonably assume that objects in the LMC are all at the same distance from us. The apparent size of the LMC is also in a size, for which the entire galaxy can be surveyed in a reasonable amount of time to study the material circulation processes and star-formation history in a galactic scale. In the meanwhile, it is close enough to resolve and study individual objects even with relatively small telescopes. Moreover, the mean metallicity of the LMC is known to be small ($\sim 1/4$) compared to the solar, intriguing us to study the influence of low metallicity on various astrophysical phenomena.

Because of these characteristics there have been a number of survey projects of the LMC in various wavelengths (Hard X-ray: Götz et al. 2006; Soft X-ray: e.g., Long, Helfand, & Grabelsky 1981 with Einstein, Sasaki et al. 2000, Haberl & Petsch 1999 with ROSAT, and Haberl, Dennerl, & Pietsch 2003 with XMM; UV: Smith, Cornett, & Hill 1987; Ho: Kennicutt & Hodge 1986, Gaustad et al. 2001; Optical: Zaritsky et al. 2004; NIR: e.g., Cioni et al. 2000a with DENIS, Nikolaev & Weinberg 2000 with 2MASS, and Kato et al. 2007 with IRSF/SIRIUS; MIR & FIR: e.g., Israel & Schwering 1986 with IRAS, Egan et al. 2003 with MSX, and Meixner et al. 2006 with Spitzer/SAGE; [CII]: Mochizuki et al. 1994; CO: e.g., Mizuno et al. 2001 with NANTEN; HI: Luks & Rohlfs
will give us a new insight into the various phenomena occurring in the LMC. In this paper, we provide an overview of our LMC survey project and present some initial results using the preliminary photometric catalog of bright point sources.

Then we will make general analyses using the catalog with an emphasis on the unique characteristics of the IRC observations compared to Spitzer observations. The first AKARI/IRC LMC point source catalog is planned to be released to the public in 2009.

2. The AKARI IRC LMC survey project

The Japan Aerospace Exploration Agency launched an Infrared Satellite, ASTRO-F (Murakami et al. 2007) at 21:28 UTC on February 21st, 2006 from the Uchinoura Space Center. Once in orbit ASTRO-F was renamed "AKARI". AKARI has a 68.5 cm telescope and two scientific instruments, namely the InfraRed Camera (IRC; Onaka et al. 2007) and the Far-Infrared Surveyor (FIS; Kawada et al. 2007). Both instruments have low- to moderate-resolution spectroscopic capability. The IRC has nine imaging bands and six dispersion elements covering from 2.5 to 26 \( \mu \text{m} \) wavelength range. Unfortunately, one of the dispersion elements that was expected to cover 11 to 19 \( \mu \text{m} \) range became opaque during the ground test operation, and defunct in orbit. The FIS will observe in 4 far-infrared bands between 50 and 180 \( \mu \text{m} \). One of the primary goals of the AKARI mission is to carry out an All-Sky survey with the FIS and the IRC at six bands from 9 to 180 \( \mu \text{m} \) (Ishihara et al. 2006; Kawada et al. 2007). As a result, the entire LMC has been mapped in 9, 18, 65, 90, 140, and 160 \( \mu \text{m} \) wavebands. The 5 \( \sigma \) detection limits for one scan observation of the All-Sky survey are shown in Figure 3. As described below, the LMC is located at a relatively high visibility region for AKARI’s orbit. AKARI scanned LMC several times and thus better detection limits should be obtained by further data reduction of the All-Sky survey data. The All-Sky survey observations of the LMC will be described elsewhere and will not be discussed in this paper.

In addition to the All-Sky survey in mid- and far-infrared, AKARI carried out two large-area legacy surveys (LS) in pointing mode. The LMC survey project (PI. T.Onaka) is one of the two LS programs. The other is the North Ecliptic Pole survey project (PI. H.Matsuhara; Matsuhara et al. 2007). These survey areas are located at high ecliptic latitudes, where the visibility is high for AKARI’s sun-synchronous polar orbit. Therefore a batch of observing time can be allocated for pointing observations in these areas after allocating scan paths for the All-Sky survey. We used the IRC to make imaging and spectroscopic mapping observations of the main part of the LMC.

The IRC is comprised of three independent channels; NIR, MIRS, and MIRL, which cover the 1.8 – 5.5 \( \mu \text{m} \), 4.6 – 13.4 \( \mu \text{m} \), and 12.6 – 26.5 \( \mu \text{m} \) wavelength range, respectively. Each of the three channels has three imaging bands and two dispersion elements, which can be switched during a pointed observation opportunity. Each of the

The thick dashed outline indicates the coverage of the Spitzer/SAGE survey (7°×7°, Meixner et al. 2006), the thick dash-dotted outline shows the coverage of the IRSF/SIRIUS near-infrared survey (6.3°×6.3°, Kato et al. 2007), and the thin solid outline represents the coverage of the Magellanic clouds optical photometric survey (8.5°×7.5°, Zaritsky et al. 2004).](image)
3. Scientific objectives

Interstellar matter in a galaxy is thought to evolve through various processes. Stars are born in interstellar clouds by accreting the interstellar matter and then appear as young stellar objects (YSOs), such as T Tauri stars or Herbig Ae/Be stars. Low- and intermediate-mass stars evolve into white dwarfs after spending most of their lives in the main sequence. During the course of their evolution to white dwarfs, they lose mass through so-called mass-loss process and supply dust grains and gas to the interstellar space. High-mass stars end their lives as supernovae and enrich the interstellar medium with a large amount of nuclear synthesized elements. They can also trigger the formation of next generation stars through their strong UV photons and stellar winds (Hosokawa & Inutsuka 2006; Koo et al. 2008). Interstellar grains play an important role in every aspect of these interstellar processes, including the star-formation. All of these phenomena can be studied most effectively in the infrared. The Spitzer SAGE project (Meixner et al. 2006) have provided IRAC (3.5, 4.5, 5.8, and 8.0 μm) and MIPS (24, 70, and 160 μm) images for a wide area (7° × 7°) of the LMC. Adding to the SAGE observation, the complementary AKARI IRC (3.2, 7.0, 9.0, 11.0, 15.0, and 18.0 μm) and FIS (65, 90, 140, and 160 μm) observations of the LMC will provide an opportunity to make a thorough study of these material circulation processes and local star-formation history of the LMC in a galactic scale owing to its wide spectral coverage and high sensitivities together with the sufficient spatial resolution.

Figure 3 is a diagrammatic representation of 5σ detection limits of our survey, Spitzer SAGE survey, and the IRSF/SIRIUS near-infrared survey. The 5σ detection limits of our survey are calculated by scaling the 10σ detection limits in Table 1 (see section 5.4.1). We take the 5σ detection limits for the SAGE survey from the "SAGE Data Description: Delivery 1"¹. The detection limits are expected to be further improved in the final catalog deliveries (Meixner et al. 2006). It is clear that the detection limits of our survey are comparable to that of the Spitzer SAGE survey. The ISO SWS spectra of galactic famous stars of known distances (the distances were taken from Cross & Menten 1997 for IRAC +10216, and Perryman et al. 1997 for others) are included for illustrative purposes after scaling their fluxes at the distance of the LMC. We assumed a distance modulus of 18.5 mag to the LMC. The figure indicates that all of red giants above the tip of the first red giant branch, and a large fraction of Herbig Ae/Be stars in the LMC are detected in our survey.

3.1. Star-formation and young stars

The LMC contains a class of so called populous clusters (e.g., Kumai, Basu, & Fujimoto 1993) that have no Galactic counterpart. They have masses intermediate between Galactic globular clusters and open clusters. Characteristic environments in the LMC, such as low
mean metallicity (about 1/4 of solar vicinity), low dust to gas ratio (about 1/4 of Milky Way; Koornneef 1982) and strong ultraviolet interstellar radiation (e.g., Cox & Spaans 2006), may play a key role in the star-formation process of populous clusters (Fukui 2005). Detailed studies of the star-formation in the LMC will provide insights into these processes. The IRAS survey has detected protostars in the LMC only brighter than $10^4 \sim 10^5 L_\odot$ (e.g., van Loon et al. 2005). Although only the brightest end of the YSOs in the LMC can be detected by the IRC (see the detection limits provided in Table 1), the IRC imaging data provide us with a valuable dataset to investigate the nature of such objects from the spectral energy distribution from near- to mid-infrared as well as the water ice feature at 3 $\mu$m and/or silicate absorption at 10 and 20 $\mu$m. AKARI observations of the LMC enable us to probe the luminosity function of protostars down to about 10 $L_\odot$.

The detection limits of IRC bands are not deep enough to detect T Tauri stars in the LMC. However the IRC observations can nearly completely detect young stars of intermediate mass (Herbig Ae/Be) as well as classical Be stars. It is difficult to separate Herbig Ae/Be stars from classical Be stars and another kind of young stars with different masses and ages, based on near-infrared data alone. Mid-infrared data provided by the IRC make clear identification of these objects. AKARI IRC observations are able to provide the initial mass function of objects later than the Class 1 phase for $M > 2 – 3 M_\odot$ except for dense clusters, where the source confusion limits the detection. They allow us to compare the spatial distribution of YSOs with that of CO clouds in a statistical way and investigate the star-formation history in the LMC. Particularly interesting is the search for embedded star clusters in "clusterless" giant molecular clouds (GMCs), such as N159S (Bolatto et al. 2000) and investigation of whether or not these clusterless GMCs are really not associated with star clusters. The 5 band IRC observations together with 4 band FIS All-Sky survey data allow us to distinguish these YSOs unambiguously and study the nature of detected objects in detail.

### 3.2. Evolved stars

Stars of low- to intermediate-mass (stars with main sequence masses $M_{\text{MS}}$ of about $0.8 – 8 M_\odot$) eventually evolve into white dwarfs. The mass $M_{\text{wd}}$ distribution of white dwarfs peaks around $0.6 M_\odot$ (e.g., Kepler et al. 2007). Therefore, the difference, $\Delta M = (M_{\text{MS}} - M_{\text{wd}})$ should be lost during their life in the mass-loss process, which enriches gas and dust in the interstellar medium. It is observationally known that the maximum mass-loss rate is attained at the latest stage of their Asymptotic Giant Branch (AGB) evolutionary phase, where stellar pulsation is usually associated. However, the onset and evolution of the mass-loss process and its relation to pulsation are not yet completely understood.

As described above, the LMC has a number of young clusters, which also provide a unique place to study the late evolutional stage of intermediate-mass stars. Star clusters of intermediate ages still contain a number of AGB stars that are losing mass. Since their ages and masses are well determined, the study of mass-losing AGB stars in the clusters can elucidate the mass-loss process for stars with given ages and masses quantitatively for the first time.

Blum et al. (2006) used Spitzer SAGE survey epoch 1 catalog to discuss and identify the evolved stars in the infrared color-magnitude diagrams. Ita et al. (2004a,b) studied OGLE variables in the Magellanic Clouds (Udalski, Kubiak & Szymanski 1997; Żebruś et al. 2001). They detected most of optical variable stars in the central parts of the Large and Small Magellanic Clouds. The association of the IRC data with these variability catalogs enables us to investigate the mass-loss phenomena in terms of the pulsation activity directly. The IRC observations can detect all mass-losing AGB stars in the LMC. It should be emphasized that the IRC band S11, L15, and L24 are particularly important to determine the chemistry of the envelope (O-rich or C-rich) and the mass-loss rate accurately because of the presence of the silicate bands at 10 and 18 $\mu$m and the silicon carbide band at 11.3 $\mu$m.

### 3.3. Supernova remnants

Supernovae (SNe) are believed to be a major source of interstellar dust since the expected supply rate from late-type stars is too short to balance with the dust destruction rate in the interstellar space (Jones et al. 1994; 1996). The role of the dust production in SNe is crucial to understand the circulation and evolution of materials in the interstellar medium (Dwek 1998). However, to date, no clear
observational evidence has been given for the large production of dust grains from SNe (Meikle et al. 2007). The condensation efficiency could be either very low (Clayton et al. 2001) or moderate (Todini & Ferrara 2001). A study of Cas A SNR by Spitzer clearly demonstrates the observational difficulty of dust grains associated with SNRs in our Galaxy (Krause et al. 2004). SNRs in the Galaxy are easily confused by the material on the line of sight because most of them are located on the Galactic plane. In this regard, the LMC provides an ideal opportunity to study material ejected in SNRs without suffering from serious confusion problems. Recent studies of SNRs in the LMC with Spitzer and AKARI provide significant information on the origin of the IR emission in SNRs and the interstellar dust lifecycle in terms of dust formation by SNe and dust destruction by SNR blast waves (e.g., Borkowski et al. 2006; B. Williams et al. 2006; R. Williams, Chu, & Gruendl 2006; Rho et al. 2008; Seok et al. 2008).

The interaction of SNRs with their surroundings is also an important phenomenon, providing opportunities for studying strong shocks and sometimes triggered star-formation (Koo et al. 2007; 2008). However, the observational study of the interaction is also hampered by confusion for Galactic SNRs. There are more than 40 SNRs known in the LMC (Filipovic et al. 1998; Haberl & Petsch 1999), and only 10 of them have been detected by IRAS. SNRs appear very patchy in the infrared (Douvion 1999), and only 10 of them have been detected by IRAS. The association of the emission with SNRs.

4. Observations

4.1. IRC astronomical observing template and pointing observation sequence

To cover a wide range of the spectral energy distribution of a celestial body, we use the AKARI IRC AOT02 observing template with a special option prepared only for the LMC survey. The AOT02 with the special option yields not only imaging data at 3 (N3), 7 (S7), 11 (S11), 15 (L15), and 24 µm (L24), but also low resolution (λ/Δλ ~ 20) 2.5 – 5 µm (NP) spectral data at three dithered sky positions in a pointing opportunity. Figure 4 shows an example of the NP spectroscopic data taken in our survey. The reduced spectrum of a red source indicated in the box is also shown in the figure. Discussions on spectroscopic data will be given in a future paper.

As described in the IRC data user’s manual (Lorente et al. 2007) the IRC observation produces short- and long-exposure data together. The long to short exposure time ratios in each channel are 9.5, 28, and 28 for NIR, MIRS, and MIRL, respectively. It enhances the dynamic range by combining photometric results of the two different exposure-time data. In this paper, we use the combined data of long- and short-exposure for N3, but only use long-exposure data for MIRS and MIRL.
4.2. Mapping strategy

Due to the focal-plane layout of AKARI, the NIR and MIRS channels share the same field of view (i.e., they observe the same sky position), but the MIRL channel observes a different sky position that is offset by 25 arcmin from the NIR/MIRS center in the direction perpendicular to the AKARI’s orbit. AKARI is in a sun-synchronous polar orbit at 700 km altitude along the twilight zone, and its orbit is approximately parallel to the ecliptic meridian lines with approximately 4.1 arcmin spacing at the ecliptic plane between successive orbits. We used this feature to map the LMC effectively. Each of the IRC channels has a field of view of 10' × 10' and adjacent fields are designed to overlap by ∼ 1.5. Since AKARI follows the Earth’s yearly round, the telescope points at the same celestial position every six months, but the direction of the satellite movement relative to the position is rotated by 180 degrees. Thus the position of the MIRL channel relative to the NIR and MIRS channels is also rotated by 180 degrees in projection on the sky. Therefore, we divide the observing area into several parts to maximize the observing efficiency to map a large part of the LMC with all three channels of the IRC. Observations were carried out in three separate seasons, from 6th May 2006 to 8th June 2006, from 2nd October 2006 to 31st December 2006, and from 24th March 2007 to 2nd July 2007. Over 600 pointing observations were devoted for this project, yielding about a 10 deg² imaging and spectroscopic map of the main part of the LMC.

5. Data reduction

5.1. Pipeline processing

Raw imaging data were processed with the IRC imaging toolkit, version 20071017 (see IRC Data User’s Manual Lorente et al. 2007 for details). In a pointing observation using IRC, one short-exposure and three long-exposure dark data are taken at the beginning (pre-dark) and the end of the operation for all of the three IRC channels. We made long-exposure dark images for MIRS and MIRL channels by averaging over three long exposure dark data. We refer to these averaged pre-dark images as the self-dark. We subtracted selfdarks from MIRS and MIRL long-exposure images and the pipeline default super-dark from the others.

As described above, we use the AKARI IRC AOT02 observing template that produces data at three different sky positions in a pointed observation. The data in each band are spatially aligned and then coadded by taking their median to eliminate array anomalies such as bad, dead, or hot pixels, cosmic rays, and so on. The resultant coadded images have pixel sizes of 1.′′446 pixel⁻¹, 2.′340 pixel⁻¹ and 2.′384 pixel⁻¹ for NIR, MIRS, and MIRL images, respectively.

5.2. Astrometry

After the coaddition process, we calculate the coordinate transform matrix that relates the image pixel coordinates to the sky coordinates by matching detected point sources with the Two Micron All Sky Survey (2MASS; Skrutskie et al. 2006) catalog. We use at least five matched point sources for the calculation. If matching with the 2MASS catalog is unsuccessful (such cases usually occur in L15 and L24 images), then we use the SAGE point source catalog (Meixner et al. 2006) as the positional reference. The root-mean-squares of the residuals between the input 2MASS/SAGE catalog coordinates and the fitted coordinates are smaller than 1.′′2, 2.′′6, and 2.′′9, for NIR, MIRS, and MIRL images, respectively. The coordinates of AKARI sources should be accurate to that extent relative to the 2MASS and SAGE catalog coordinates.

5.3. Photometry

After the coaddition process, we calculate the coordinate transform matrix that relates the image pixel coordinates to the sky coordinates by matching detected point sources with the Two Micron All Sky Survey (2MASS; Skrutskie et al. 2006) catalog. We use at least five matched point sources for the calculation. If matching with the 2MASS catalog is unsuccessful (such cases usually occur in L15 and L24 images), then we use the SAGE point source catalog (Meixner et al. 2006) as the positional reference. The root-mean-squares of the residuals between the input 2MASS/SAGE catalog coordinates and the fitted coordinates are smaller than 1′′2, 2′′6, and 2′′9, for NIR, MIRS, and MIRL images, respectively. The coordinates of AKARI sources should be accurate to that extent relative to the 2MASS and SAGE catalog coordinates.
was performed on the coadded images with the IRAF package DAOPHOT. We develop PSF fitting photometry software, which is similar to the one that the Spitzer GLIMPSE team uses. Our photometric process involves the following steps:

1. Source extractor (Bertin & Arnouts 1996) is used for each coadded image to extract sources whose fluxes are at least 3 $\sigma$ above the background. The saturated sources should not be extracted, since the central pixels of them are already masked by the IRC imaging toolkit. Even if they are detected by the source extractor, the PSF fitting does not work well for them, and they are not included in the following discussions.

2. Aperture photometry is performed on all of the sources found in step 1, using the task PHOT with aperture radii of 10.0 and 7.5 pixels for NIR and MIRS/MIRL images, respectively. We use the same aperture radii as have been used in the standard star flux calibration (Tanabé et al. in preparation), and the aperture corrections are not applied. The resultant arbitrary fluxes are converted into the physical units by using the IRC flux calibration constants version 20071112. Then the calibrated fluxes are converted into the magnitudes of the IRC-Vega system by using the zero magnitude fluxes listed in Table 1. The offsets between the arbitrary and the calibrated magnitudes are constants.

3. Several point sources with moderate flux (i.e., with a good signal-to-noise ratio and unsaturated) and without other sources within 7 pixels are selected from the results of step 2. At least 8 such “good” stars are selected in the NIR/MIRS (i.e., N3, N4, S7, and S11) images, and more than 5 good stars in the MIRL (i.e., L15 and L24) images. They are used for the aperture correction to the PSF fitting photometry in the following process.

4. Since the shapes of the PSFs measurably vary from pointing to pointing in NIR images possibly due to jitters in the satellite pointing, the selected good stars in step 3 are used to construct a model PSF for each image. We use DAOPHOT to choose the best fitting function by trying several different types of fitting functions. In MIRS/MIRL images, we use a “grand-PSF” for each band, which was built in advance. These grand-PSFs were made from “good” stars free from diffuse emission, carefully chosen by eyes from hundreds of images taken in the AKARI/IRC LMC survey data and other related ones.

5. The PSF fitting photometry is performed on all of the sources found in the coadded images using ALLSTAR. The PSF does not vary appreciably over the field of view. Hence a constant PSF is assumed over an image. This PSF fitting operation is iterated, in just the same way as the GLIMPSE team does.

6. Aperture correction is applied to the fit magnitudes by comparing them with the aperture magnitudes of good stars, which are selected in step 3. Then, the offset value obtained in step 2 is added to the aperture corrected fit magnitudes to derive calibrated fit magnitudes.

As indicated above, we use the zero magnitude fluxes (Tanabé et al. in preparation) to convert the photometric fluxes into the Vega magnitudes. These zero magnitude fluxes are tabulated in Table 1. It should be noted that the IRC absolute flux calibration assumes a spectral energy distribution (SED) of $f_\nu \propto \nu^{-1}$ or $f_\nu \propto \nu^{-1}$. Note that throughout this paper, we do not apply color corrections to the calibrated fluxes and magnitudes. No dereddening are applied either.

5.4. Compilation of a preliminary catalog

We carried out photometry on each coadded image as outlined in the previous section. It produced photometric catalogs for each band for individual images. At first, the catalogs for individual IRC imaging bands (i.e., N3, S7, S11, L15, and L24) are made. Because of the field overlap, there should be substantial multiple entries of a single source in the catalogs. We eliminate such multiple entries based on the spatial proximity ($|\Delta r| \leq 1.5$). We adopt the one with a better S/N and discarded the other(s). We use both long- and short-exposure data of N3, and we merged them using a positional tolerance of 1.5''. If a source is detected in both short and long exposure data, we adopt the one with a better S/N and discard the other. Then, two corresponding band catalogs are merged to make individual IRC channel catalogs. The, S7 and S11 (L15 and L24) catalogs are merged using a positional tolerance of 1.5''. If a source is detected in both short and long exposure data, we adopt the one with a better S/N and discard the other. Then, two corresponding band catalogs are merged to make individual IRC channel catalogs. The, S7 and S11 (L15 and L24) catalogs are merged using a positional tolerance of 1.5'' (1.5'') to make a MIRS (MIRL) channel catalog. For the matched sources, their coordinates are recalculated by taking an average of the coordinates of each band. In rare cases that more than two sources are present within the tolerance radius, the closest one is always adopted and the others were listed as solitary sources. The resultant individual channel catalogs are further merged to make a grand catalog using a positional tolerance of 1.5''.

5.4.1. Detection limits and completeness

The distributions of the photometric uncertainty versus the magnitude in the IRC bands are shown in Figure 5. The photometric uncertainty includes errors in the fitted magnitude calculated by IRAF/ALLSTAR, in the aperture correction factor, and also in the ADU-to-Jy conversion factor. The horizontal dashed lines show the signal to noise ratio (S/N) of 10, and the vertical solid lines show the 10 $\sigma$ detection limits, which are defined as the faintest magnitudes at which the mode of photometric uncertainties of the sources in 0.02 mag bins exceed 10 $\sigma$, except for the N3 data. In the calculation of the 10 $\sigma$ detection limit:

2 IRAF is distributed by the National Optical Astronomy Observatories, which are operated by the Association of Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.

| Number of detected sources         | >5.9×10⁵ | >8.8×10⁴| >6.4×10⁴| >2.8×10⁴| >1.5×10⁴|

¹ These are the most common values. Total exposure time per pixel can be different from coadded images to images, because some data badly damaged by cosmic-ray and/or hitting of charged particles are discarded.
² For point sources.
³ Numbers are taken from ASTRO-F Observer’s Manual version 3.2 (ASTRO-F Observer’s Manual. 2005).
⁴ Tanabé et al. in preparation.

for the N3 data, we use only data detected in long exposure images, and take a mean of photometric uncertainties in 0.02 mag bins instead of taking a mode of them. Visual inspections showed that sources can be detected only in short exposure images, and this is why there is a sequence around 15 mag in the N3 error plot. There seems to be several causes to explain this. For example, not a small number of long exposure images are damaged by column pulldowns caused by saturated stars, and sources in such polluted columns are not detected in the long exposure images. The estimated 10 σ detection limits are 16.50, 14.00, 12.54, 10.91, and 9.16 in N3, S7, S11, L15, and L24, respectively. These detection limits are comparable to that of the Spitzer SAGE survey (see Figure 3).

The magnitude distributions of the sources in the preliminary catalog are shown in Figure 6. The sizes of the bins are 0.1 mag for N3 and 0.2 mag for S7, S11, L15, and L24. The vertical solid lines show peak magnitudes, below which photometry is incomplete. The peak magnitudes are 15.9, 12.8, 12.2, 10.4, and 8.8 mag in N3, S7, S11, L15, and L24, respectively.

The 10 σ detection limits for point sources and source counts in each IRC band are summarized in Table 1 together with other properties of our survey.

5.4.2. Cross-identifications with the existing point source catalogs

We cross-identified our catalog with the following existing catalogs using a positional tolerance of 1."5, and use the result for discussion in the rest of the paper.

- The Magellanic Clouds Photometric Survey catalog (Zaritsky et al. 2004): It lists U, B, V, and I stellar photometry of the central 64 deg² area of the LMC.
- The IRSF Magellanic Clouds Point Source Catalog (Kato et al. 2007): The IRSF catalog lists JHK₉ photometry of over 1.4×10⁷ sources in the central 40 deg² area of the LMC. Compared to the contemporary DENIS (Cioni et al. 2000a) and 2MASS (Skrutskie et al. 2006) catalogs, the IRSF catalog is more than two mag deeper at K allied band and about four times finer in spatial resolution.
- The Spitzer SAGE catalog (Meixner et al. 2006): It lists near- to far-infrared photometry of sources in the central 49 deg² area of the LMC.

The observed regions of the above existing catalogs are indicated in Figure 1. The figure shows that a part of the AKARI IRC survey region is outside the bounds of the IRSF/SIRIUS survey area. We do not use the AKARI sources located outside the IRSF/SIRIUS area in the following discussions. Throughout this paper, the numbers bracketed by [ ] designates the data of the SAGE catalog, for example, [3.6] indicates the photometry in the IRAC 3.6 µm band.

5.4.3. Comparison to the Spitzer SAGE survey catalog

Although the bandpasses of the AKARI IRC and the Spitzer IRAC/MIPS bands are different, comparison of closely matched bands is useful to test the calibration of the AKARI IRC data. We compared the IRC N3, S7, L24 photometries in our catalog with the corresponding 3.6, 8.0, and 24 µm fluxes of the sources in the Spitzer SAGE catalog. Note that both of the IRC and IRAC absolute flux calibration assume a source spectrum of a 10,000 K blackbody (MIPS Data Handbook 2007). Therefore we converted MIPS scale into IRC/IRAC one by adding −0.043 mag (Bolatto et al. 2006) to the MIPS 24 catalog magnitudes to make a direct comparison between L24 and SAGE.
and MIPS 24 µm photometries. The distributions of the magnitude differences between the IRC and IRAC/MIPS fluxes as a function of the corresponding IRC magnitudes are shown in Figure 7. The triangles show the mean of the residual magnitudes in the corresponding 1 mag bin, and the error bars show their 1σ standard deviations. Taking account of the differences in the bandpass, the AKARI IRC and IRAC/MIPS photometries appear consistent with each other. Quantitatively, they are in agreement within 9, 10, and 11% in N3 vs [3.6], S7 vs [8.0], and L24 vs [24] comparisons, respectively, using the sources with S/N > 10σ and after subtracting systematic offsets.

In the comparison between N3 and [3.6] photometries, we find an interesting feature. It is seen that a group of bright sources (sources with 9 < N3 [mag] < 11) deviate from the overall trend. To explain the deviation, we cross-identified our sources with spectroscopically identified carbon stars (Kontizas et al. 2001), which are shown in blue dots. We photometrically select dusty carbon-rich AGB candidates that cannot be identified in the optical survey based on the following conditions.

- \((J - K_s) > 2.0\)
- \(K_s < (4/3)\times((J - K_s) - 2.0) + 12.0\)

These sources are indicated by red dots. The J and Ks fluxes are obtained by cross-identifying the IRC catalog with the IRSF/SIRIUS LMC near-infrared catalog (Kato et al. 2007, see next section). It is true that the above conditions may include some dusty O-rich AGB stars, but such stars are small in number compared to the carbon-rich AGB stars. It is clearly seen that red dots are the sources that show the deviation in the diagram. The deviation should be attributed to the fact that the passband of the IRC N3 band is slightly bluer than that of the IRAC 3.6 µm, and it is more sensitive to the 3.1 µm HCN+C2H2 absorption feature, which is usually seen in carbon-rich AGB stars (e.g., Yamamura & de Jong 2000). The N3 data, thus, enable us to select sources with carbon-rich circumstellar chemistry on the basis of their colors.
Table 2. Source Classification based on Kraemer et al. 2002.

| Grouped as                                                  | Classification in Kraemer et al. 2002 | Marks in Figure 8. |

6. General analysis using the AKARI LMC survey photometric catalog

6.1. Color-color diagram

6.1.1. Convolution of ISO SWS spectra

With an aim to help an interpretation of what types of sources are detected by the AKARI survey, we take fully calibrated ISO SWS spectra data from the on-line database\(^4\) available (Sloan et al. 2003). Then we estimate their fluxes in the AKARI IRC system by convolving the ISO SWS spectra with the response curves of the IRC bands using the following equation,

\[
    f_{\lambda_i}^{\text{reference}} = \frac{\int R_i(\lambda) f_\lambda(\lambda) d\lambda}{\int (\lambda) R_i(\lambda) d\lambda},
\]

where the suffix \(i\) denotes IRC bands, \(\lambda_i\) represents the reference wavelengths of each IRC band tabulated in table 1, and \(R_i(\lambda)\) indicates the spectral responses of each band. The calculated fluxes are further converted into the Vega-magnitudes. Note that the calculated magnitudes are in the IRC system (substituting \(\lambda f_\lambda(\lambda) = \text{constant}\) to equation (1) gives \(\lambda_i f_{\lambda_i}^{\text{reference}}\), which can be directly compared with the catalog values.

We divide ISO SWS sources into 10 main groups, based on the Table 6 in Kraemer et al. (2002). Sources that are classified as "uncertain classification" and "very uncertain classification" in Kraemer et al. (2002) are excluded in the following discussions. Table 2 summarizes how we group the ISO SWS sources.

6.1.2. \((S11 - L15)\) vs \((N3 - S11)\) diagram

Figure 8 shows the color-color diagrams of AKARI sources (upper panel) and ISO SWS sources (lower panel) using colors of \((S11 - L15)\) and \((N3 - S11)\). In the AKARI diagram, only stars with \(S/N > 5\) in all employed three bands are included. The numbers of sources in each \(0.05 \times 0.05 \text{mag}^2\) bin are counted and the fiducial color is applied according to their number densities (see the annotated color wedge). The solid gray line in the lower panel

\(^4\) http://isc.astro.cornell.edu/˜sloan/library/swsatlas/atlas.html
Fig. 8. The (S11 - L15) vs (N3 - S11) color-color diagram of AKARI/IRC sources (upper panel) and ISO SWS sources (lower panel). In the AKARI panel only sources with S/N > 5 are included, and the (S11 - L15, N3 - S11) plane is binned by 0.05 $\times$ 0.05 mag$^2$ to calculate number of sources in each bin. The number density levels are logarithmic (see the wedge). The meanings
shows the blackbody locus with the temperature ranging from 400 to 10000K in the IRC system.

It is obvious that a wide variety of sources are detected in our survey. Comparing the two diagrams we can statistically separate various types of objects. Two distinct main groups appear in the AKARI diagram: one centered around (S11 − L15, N3 − S11) of (0.1, 1.0) and the other centered around (1.0, 4.0).

The former group includes two peaks, one centered around (0.2, 0.2) and the other centered around (0.25, 0.8). Based on a comparison with the ISO SWS classification, the sources in the first peak are stars without circumstellar dust, and the second peak is associated to red giants with circumstellar dust emission. ISO SWS spectra indicate that red giants with O-rich dust as well as C-rich dust may once become blue in the (S11 − L15) color, and then turn red again in the course of their evolution. This can be explained by the change in strength of silicate or silicon carbide dust features in S11 band relative to the L15 flux.

According to the ISO SWS spectra, the red group may contain various types of objects such as PPNe, PNe, OH/IR stars, and YSOs. Also, the background galaxies may have similar colors (see the following), which makes the classification more difficult. The NP spectroscopic data, and follow-up spectroscopic observations are needed to make clear classification of these objects.

6.2. Color-magnitude diagrams

An advantage to study sources in the LMC is that we can build color-magnitude diagrams (CMD) and estimate their absolute magnitudes by adding the distance modulus, which is reasonably well known (e.g., Feast & Walker 1987). Based on the Spitzer SAGE catalog, Meixner et al. (2006) and Blum et al. (2006) presented infrared color-magnitude diagrams of LMC sources. Here we add S11 and L15 data, which are unique to the AKARI survey. We use intriguing combinations of the IRC, IRAC&MIPS and IRFS/SIRIUS bands and the results are shown in Figure 9. Units of vertical axes are the apparent magnitude, or red giants with circumstellar dust emission. ISO SWS spectra indicate that red giants with O-rich dust as well as C-rich dust may once become blue in the (S11 − L15) color, and then turn red again in the course of their evolution. This can be explained by the change in strength of silicate or silicon carbide dust features in S11 band relative to the L15 flux.

According to the ISO SWS spectra, the red group may contain various types of objects such as PPNe, PNe, OH/IR stars, and YSOs. Also, the background galaxies may have similar colors (see the following), which makes the classification more difficult. The NP spectroscopic data, and follow-up spectroscopic observations are needed to make clear classification of these objects.

tually infrared carbon stars, which are elusive in the above optical spectroscopic survey. According to Nikolaev & Weinberg (2000), stars with \((J - K_s) > 2.0\) in the LMC are primarily carbon-rich AGB stars. This can be explained as the \(J\) band flux of carbon-rich mass-losing red giants are attenuated by \(C_2\) and CN absorptions (Loidl et al. 2001). This criterion may be satisfied also by some dusty oxygen-rich AGB stars, but their number should be small compared to carbon stars. To confirm their circumstellar chemistry, our NP spectroscopic data would be effective. Sources in this category are shown by the red dots in Figures 10 and 11.

- YSO candidates: Based on the color-color diagram (Figure 8), we select sources that satisfy \((N3 - S11) > 2.0\) and \((S11 - L15) > 1.0\). As seen in the ISO SWS panel of Figure 8, sources selected by this criteria include not only YSOs but also other populations such as PPNe and PNe. Also, background galaxies may have colors similar to sources in this category (see the following). Sources in this category are shown by the blue dots in Figures 10 and 11.

Also, we calculated bolometric magnitudes for sources that satisfy the following conditions.

- Sources detected at least in two of four optical (U, B, V, and I) bands.
- Sources detected at least in three of seven near-infrared (\(J, H, K_s, N3, [3.6], [4.5]\), and \([5.8]\)) bands.
- Sources detected at least in three of four mid-infrared (\(S7, [8.0], S11,\) and \(L15\)) bands.
- Sources detected at \(L24\) and/or \([24]\) bands.

Table 3 summarizes the assumed zero magnitude fluxes and their corresponding reference wavelengths that we used to calculate the flux densities. For the IRC bands, we use the zero magnitude fluxes for the IRSF/SIRIUS \(JHK_s\) bands are not officially determined, we converted the IRSF system magnitudes into the 2MASS system by using the conversion equations provided in Kato et al. (2007) before calculating the flux densities. Then we use a cubic spline to interpolate the spectral energy distributions and integrate them from the shortest wavelength at which the flux is available to 24 \(\mu\)m to obtain the apparent bolometric magnitudes. Finally,
we scale them to the absolute magnitudes by assuming a distance modulus of 18.5 mag to the LMC. Figure 11 shows the result. For very red sources, such as galaxies, planetary nebulae, and extremely dusty AGB stars, the bolometric magnitudes may be underestimated to a large extent because the fluxes longward of 24 µm are not included. Therefore the bolometric magnitudes discussed here should be only lower limits.

It is apparent that optical carbon stars, dusty red giants, and YSO candidates are well separated from each other by color and luminosity. Except for the near-infrared CMD, YSO candidates have redder colors than that of the others, and dusty red giants are brighter in the mid-infrared bands than optical carbon stars. In the (N3 − [5.8]) vs [5.8] CMD, we see a group of sources that distribute along the vertical sequence around (N3 − [5.8] ≈ 0.0). These sources are likely to be foreground Galactic stars that are classified as dwarf or giant. There is another feature in the diagram. We see a sequence for dusty red giants (red dots), which grows toward the redder and brighter part of the CMD. Above the sequence, we see another branch that grows toward the redder and brighter part of the CMD. The brighter branch is clear in (N3 − [5.8]) vs [5.8] diagram, and is also seen in the (N3 − S11) vs S11 diagram. The corresponding bolometric magnitude CMDs tell us that most of dusty red giants have absolute bolometric magnitudes (M_{bol}) ranging from −4 to −5, while the sources on the brighter branch have M_{bol} brighter than −6 mag and they are saturated in the IRSF/SIRIUS bands. It is suggested that sources on the brighter branch have stellar masses heavier than those of the sources on the sequence for dusty red giants. Their bolometric magnitudes agree well with the bolometric magnitudes for 88 red supergiants in the LMC (Oestreicher & Schmidt-Kaler 1998). Therefore we conclude that the sources on the brighter branch are red supergiants.

As we suggested in section 6.1.2, the (S11 − L15) color of dusty red giants once becomes blue during their evolution due to the growth of silicate or silicon carbide emis-
sion in the S11 band. In fact most dusty red giants (red dots), if not all, are bluer in \((S11 - L15)\) than optical carbon stars (green dots).

| ID  | latitude [degree] | longitude [degree] |
|-----|-------------------|--------------------|
| 1   | 86.26824          | 34.38021           |
| 2   | 87.56487          | 34.71097           |
| 3   | 87.67876          | 35.02329           |
| 4   | 244.41766         | -34.71058          |
| 5   | 68.25446          | 35.19998           |

**Table 4.** Galactic coordinates of reference fields.

Using the data of the reference fields, we make CMDs that can be directly compared to Figures 9 and 10. They are shown in Figure 12. Most, if not all, of the sources in Figure 12 are expected to be background galaxies and foreground Milky Way stars, with a few possibility of stars in the outer skirts of target globular clusters. We check the tidal radii of the target globular clusters (Harris 1996), and they are about a half of the offset value of 25'. In the following analysis, we will ignore the small contribution from the stars in the outer skirts of each globular cluster. Due to the high source density, in particular in the central part of the LMC, the completeness limit of the LMC survey data must be shallower than that of the reference fields. Therefore, we only count the number of sources that satisfy the following conditions.

1. For presumable background galaxy:
   - \((N3 - S11) > 2\) [mag]
   - \(10 < S11\) [mag] < 12.2

2. For presumable foreground stars:
   - \((N3 - S11) < 2\) [mag]
   - \(9 < S11\) [mag] < 12.2

Then we found 72 background galaxies and 26 foreground stars in the reference fields. The differences in number counts for both populations among the reference fields are small. These results imply that we can expect about 500 background galaxies and 190 foreground stars in a square degree. This estimation agrees with the Spitzer results (Fazio et al. 2004b, Meixner et al. 2006). On the other hand, we found 4483 and 14951 sources in our catalog (compiled from 10 deg\(^2\) survey data) that satisfy the above conditions, respectively. Therefore most, if not all, of the sources that satisfy the condition (1) in our catalog should be background galaxies. Meanwhile, the fraction of foreground stars in the sources that satisfy condition (2) is estimated to be about 13%.

**7. Summary**

We carried out an imaging and spectroscopic survey of a 10 deg\(^2\) area of the LMC using IRC onboard AKARI. In this paper we discuss the imaging data obtained in the survey and describe a preliminary photometric catalog of bright point sources. The first point source catalog is planned to be released to the public in 2009. We cross-identified our catalog with the existing optical, near-infrared, and mid-infrared photometry catalogs, and used the combined data to build color-magnitude diagrams using several combinations of interesting wavebands and also to calculate absolute bolometric magnitudes. By virtue of the S11 and L15 bands that are unique to IRC, we found new interesting features in the color-magnitude diagrams. The present IRC data and the upcoming results from AKARI All-Sky survey together with existing radio and near-infrared ground-based observational results will provide a significant database to study the star-formation history and material circulation within a galaxy.
Acknowledgements

We thank the referee for providing constructive comments and help in improving this paper. Y.I. thank Dr. Gregory C. Sloan for helpful comments at the IAU Symposium 256 held in the Keele University. We acknowledge the use of Spitzer SAGE-LMC data in the assessment of the AKARI LMC results and thank the SAGE-LMC team, led by Dr. Margaret Meixner, for early access to data for this purpose. AKARI is a JAXA project with the participation of ESA. We are grateful to the members of AKARI stellar working group for providing us with their data, and also for valuable discussions that helped to improve this paper. This work is supported by a Grant-in-Aid for Scientific Research (A) No. 18204014 from Japan Society for the Promotion of Science and also supported by a Grant-in-Aid for Encouragement of Young Scientists (B) No. 17740120 from the Ministry of Education, Culture, Sports, Science and Technology of Japan. This work is partly supported by the JSPS grant (grant number 16204013). This publication makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation. This research has made use of the NASA/IPAC Infrared Science Archive, which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.
