GRAVITATIONAL DESCENDANTS AND LINEARIZED CONTACT HOMOLOGY

JIAN HE

Abstract. In this paper we prove a recursion relation between the one-point genus-0 gravitational descendants of a Stein domain \((M, \partial M)\). This relation is best described by the \(-2\) map \(D\) in the linearized contact homology of \(\partial M\), arising from the Bourgeois–Oancea exact sequence between symplectic homology of \(M\) and linearized contact homology of \(\partial M\). All one-point genus-0 gravitational descendants can be reduced to the one-point Gromov–Witten invariants via iterates of \(D\).

1. Introduction

Let \((M^{2n}, \omega)\) be a closed symplectic manifold with a compatible almost complex structure \(J\). Define \(\mathcal{M}_{g,n}(M, \beta)\) to be the moduli space of stable \(J\)-holomorphic maps \(u: S \rightarrow M\) in the homology class \(\beta \in H_2(M)\). More precisely, \(\mathcal{M}_{g,n}(M, \beta)\) consists of maps \(u: S \rightarrow M\) such that

\[ J \circ du = du \circ i \]

where \(S := (S; p_1, \ldots, p_n; i)\) is a Riemann surface of genus \(g\), with \(n\) marked points \(\{p_1, \ldots, p_n\}\); and complex structure \(i\). Let \(\overline{\mathcal{M}}_{g,n}(M, \beta)\) be the compactification in the sense of Gromov.

At each element \(u: (S; p_1, \ldots, p_n; i) \rightarrow M\) of \(\overline{\mathcal{M}}_{g,n}(M, \beta)\), the cotangent space to \(S\) at the point \(p_i\) is a complex line. These cotangent spaces patch together to form a complex line bundle \(L_i\) over \(\overline{\mathcal{M}}_{g,n}(M, \beta)\), called the \(i\)-th tautological line bundle. Denote its first Chern class by \(\psi_i = c_1(L_i)\).

Given classes \(\{\theta_i\}_{i=1}^n\) in \(H^*(M)\), the gravitational descendants of \(M\) are defined by

\[ \langle \tau_{a_1}(\theta_1) \cdots \tau_{a_n}(\theta_n) \rangle^M_{g,\beta} := \int_{\overline{\mathcal{M}}_{g,n}(M, \beta)} \text{ev}_1^*(\theta_1) \cup \psi_1^{a_1} \cup \cdots \cup \text{ev}_n^*(\theta_n) \cup \psi_n^{a_n}. \]  

Gromov–Witten invariants, or correlators, are those where \(a_1 = \cdots = a_n = 0\). Descendants are symplectic invariants of \(M\), their values are independent of the compatible complex structure \(J\).

In the framework of Symplectic Field Theory (SFT) of Eliashberg, Givental and Hofer [EGH00], the theory of \(J\)-holomorphic curves, and hence gravitational descendants, can be generalized to symplectic manifolds \(M\) with contact type boundary \(\partial M\). The full SFT
contains information about all the moduli spaces, and is therefore difficult to access. How-
ever invariants can still be extracted by considering various simplifications of the full SFT
model.

One such invariant is the linearized contact homology of \( \partial M \) with respect to the filling
\( M, HC(\partial M) \). In [BO09], Bourgeois and Oancea established a Gysin-type exact sequence
relating the symplectic homology of \( M, SH(M) \), and the linearized contact homology of
\( \partial M \). Furthermore, the degree \(-2\) map \( D \) can be described purely by counts of holomorphic
curves in \( M \), without reference to symplectic homology.

**Theorem 1.1.** There exists a long exact sequence

\[
\cdots \to SH^+_{k-(n-3)}(M) \to HC_k(\partial M) \xrightarrow{D} HC_{k-2}(\partial M) \to SH^+_{k-1-(n-3)}(M) \to \cdots
\]

**Remark 1.2.** Since we do not assume \( c_1(M) \) to vanish, it is necessary to define \( HC(\partial M) \)
over the Novikov ring \( \Lambda_\omega \) with \( \mathbb{Q} \)-coefficients, consisting of formal linear combinations

\[
\lambda := \sum_{A \in H_2(M;\mathbb{Z})} \lambda_A e^A, \quad \lambda_A \in \mathbb{Q}
\]
such that

\[
\# \{ A | \lambda_A \neq 0, \omega(A) \leq c \} < \infty, \quad \forall c > 0
\]

Multiplication in \( \Lambda_\omega \) is given by formal power series multiplication.

In this paper we will focus on the genus-0 one-point invariants of \((M, \partial M)\), from now on \( g = 0 \)
and \( n = 1 \) will be omitted from subscripts. As we will see in section 2, each gravitational
descendant can be interpreted as a homomorphism

\[
\langle \tau_l(\theta) \rangle : HC(\partial M) \longrightarrow \Lambda_\omega
\]

**Theorem 1.3.** Let \( M^{2n}, n \geq 3 \) be a subcritical Stein domain, \( c \in HC(\partial M), \theta \in H^*(M, \partial M) \),
and \( D \) the degree \(-2\) map of Bourgeois–Oancea, then

\[
\langle \tau_l(\theta) \rangle(c) = \frac{1}{l} \langle \tau_{l-1}(\theta) \rangle(Dc)
\]

**Remark 1.4.** This fits into the works of Bourgeois and Oancea as follows. Linearized contact homology is isomorphic to the \( S^1 \)-equivariant symplectic homology of \( M, SH^+_{S^1}(M) \), defined in [BO]. On the symplectic homology side, the exact sequence (2) becomes very
much like the Gysin sequence for ordinary and \( S^1 \)-equivariant homology for a space \( X \) with
an \( S^2 \)-action, where the degree \(-2\) map is given in spirit by “capping with an Euler class”:

\[
\cdots \to SH^+(M) \to SH^+_{S^1}(M) \xrightarrow{\partial} \to SH^+_{S^2}(M) \to SH^+_{S^2-1}(M) \to \cdots
\]

We also have the tautological long exact sequence

\[
\cdots \to SH^-_{S^1}(M) \to SH^S_{S^1}(M) \to SH^+_{S^1}(M) \xrightarrow{\partial} \to SH^-_{S^1}(M) \to \cdots
\]
Since the $S^1$-action on $SH^-$ is trivial, $SH^{-,S^1}(M) = H(M)[t]$ is the Morse homology of $M$ tensored with the homology of $\mathbb{C}P^\infty$, where $t$ is the degree 2 generator of $H_2(\mathbb{C}P^\infty)$. The two long exact sequences form a commutative diagram in which one square has the form

$$
\begin{array}{ccc}
SH^{+,S^1}(M) & \xrightarrow{\cap e} & SH^{+,S^1}(M) \\
\downarrow \partial & & \downarrow \partial \\
H(M)[t] & \xrightarrow{\cap e} & H(M)[t]
\end{array}
$$

where on $H(M)[t]$, capping with the Euler class is division by $t$. This is equivalent to Theorem 1.3 if on the linearized contact homology side, the map $\partial$ is given by gravitational descendants. More precisely, if $c \in HC(\partial M)$ and $b \in H_*(M)$ is the Poincaré dual of $\theta \in H^*(M, \partial M)$, then the coefficient of $b \otimes t^a$ in $\partial(c)$ is $\langle \tau_a(\theta) \rangle(c)$. However in this paper we do not prove this correspondence and instead work purely on the side of linearized contact homology.

**Remark 1.5.** Equation (11) was first observed in [He12] for subcritical Stein manifolds with vanishing first Chern class. The proof however relied on explicit knowledge of the structure of the moduli spaces. We remove the vanishing Chern class condition in this paper. Furthermore, the proof is sufficiently general so that the subcritical assumption is only needed to avoid the technical issue of bad orbits. Theorem 1.3 is expected to hold for a much wider class of exact symplectic fillings. We keep the subcritical assumption for a concise exposition of the main argument.

**Remark 1.6.** It is well known that for $M$ closed, the genus-0 gravitational descendants satisfy relations known as the string, dilaton, and divisor equations. A further relation, known as topological recursion, together with those three equations, reduces descendant invariants to the Gromov–Witten invariants [KM98]. Theorem 1.3 also allows the reconstruction of descendants from correlators. However Equation (11) is not a consequence of the generalizations of the known relations in the closed case. When $M$ is closed, to compute a one-point invariant with a high power of $\psi$, it is necessary to introduce extra marked points. Hence $\langle \tau_a(\theta) \rangle$ depends on the multi-point Gromov–Witten invariants. On the other hand, Theorem 1.3 allows the one-point invariants to be computed without introduction of extra marked points.

**Remark 1.7.** Throughout this paper we assume the polyfold theory of Hofer, Zehnder and Wysocki, [HWZ06], [HWZ07], [HWZ08], which forms the analytical foundation of SFT. Therefore we will treat all moduli spaces as being transversely cut out, knowing an abstract perturbation scheme exists under which all moduli spaces become branched manifolds with boundaries and corners of the expected dimension. Any argument used on the moduli spaces can be applied without change to the perturbed moduli spaces.

This paper is organized as follows: in section 2 we define the relevant objects, and then in section 3 we prove Theorem 1.3.
2. Preliminaries

2.1. Linearized Contact Homology. We will give a quick sketch of linearized contact homology following [BEE12]. Novikov ring coefficient were not used in [BEE12] but the necessary modification is well known and can be found in [EGH00]. Details can also be found in section 3 of [BO09].

Let \((V^{2n-1}, \xi)\) be a contact manifold with a contact 1-form \(\alpha\), i.e., \((d\alpha)^{n-1} \wedge \alpha\) is a volume form and \(\xi = \text{Ker}(\alpha)\). The Reeb vector field is the unique vector field \(R\) such that

\[
d\alpha(R, -) = 0, \quad \alpha(R) = 1.
\]

The flow of the Reeb vector field preserves the contact structure \(\xi\). A (possibly multiply covered) Reeb orbit \(\gamma\) is non-degenerate if the linearized Poincaré return map of the Reeb flow has no eigenvalue equal to 1. For a generic choice of \(\alpha\), there are countably many closed Reeb orbits, all of which are non-degenerate. Let \(\kappa_{\gamma}\) denote the multiplicity of the orbit \(\gamma\).

**Definition 2.1.** A Reeb orbit is good if it is not an even multiple of another orbit \(\gamma\) such that the linearized Poincaré return map along \(\gamma\) has an odd total number of eigenvalues (counted with multiplicity) in the interval \((-1, 0)\).

The symplectization of a contact manifold \((V^{2n-1}, \xi, \alpha)\) is the manifold \(V \times \mathbb{R}\) with the symplectic form \(d(e^t \alpha)\), where \(t\) is the coordinate of \(\mathbb{R}\).

An almost complex structure \(J\) on a symplectization \((V \times \mathbb{R}, d(e^t \alpha))\) is compatible if

- \(J^2 = -\text{Id}\),
- \(d\alpha(v, Jv) > 0\) for all non-zero \(v \in \xi\),
- \(J\) is invariant under translation in the \(\mathbb{R}\)-direction,
- \(J\xi = \xi\), and \(J\partial_t = R\).

A symplectic filling \((M, \omega)\) of a contact manifold \((V, \xi, \alpha)\) is an open symplectic manifold with one open cylindrical end of the form \(E = V \times [0, \infty)\). On the cylindrical end, \(\omega|_E = d(e^t \alpha)\). The complement of \(E\) is compact. A filling is exact if \(\omega\) is exact.

An almost complex structure \(J\) on a filling \((M, \omega)\) is compatible if

- \(J^2 = -\text{Id}\),
- \(\omega(v, Jv) > 0\) for all non-zero \(v \in TW\),
- on the cylindrical end \(E\), \(J\) is invariant under translation in the \(\mathbb{R}\)-direction,
- on \(V = V \times \{0\}\), \(J\xi = \xi\), and \(J\partial_t = R\).

We are only interested in the Reeb orbits on \(\partial M\) which are contractible in \(M\). For each such orbit \(\gamma\), choose a capping disk \(D_{\gamma}\) in \(M\). There is a homotopically unique symplectic trivialization of the contact distribution \(\xi\) on \(\gamma\), which, together with the trivial symplectic subbundle spanned by the Reeb field \(R\) and Liouville field \(Y\), extends to a symplectic trivialization of \(TM\) on \(D_{\gamma}\). With respect to this trivialization, the linearized Reeb flow along \(\gamma\) defines a path of symplectic matrices, which has a Conley–Zehnder index \(\mu(\gamma)\).

A finite energy holomorphic curve in the symplectization \(\partial M \times \mathbb{R}\) is a holomorphic map \(u\) from a punctured Riemann surface \((S, i)\) with some positive punctures \(\{p_i^+\}\) and negative
punctures \{q_j\}. Near each positive puncture, the map \(u\) is asymptotic to a trivial cylinder \(\gamma_i^+ \times \mathbb{R}\) at the positive end of \(\partial M \times \mathbb{R}\) for some Reeb orbit \(\gamma_i^+\). Similarly negative punctures are asymptotic to Reeb orbits at negative infinity. We then take equivalence classes of such holomorphic maps where \((u, (S, i)) \cong (u', (S, j))\) if there is a diffeomorphism \(\phi: S \to S'\) such that \(u = u' \circ \phi\) and \(i = \phi^* j\).

Each holomorphic curve carries a homology class \(A \in H_2(M)\), obtained by add to \(u\) the capping disks \(\{-D_{\gamma_i}\}\) for the positive punctures and \(\{D_{\gamma_i}\}\) for the negative punctures. Homology class for a holomorphic curve in the filling \(M\) is defined identically, where only positive punctures exist.

**Remark 2.2.** For readability we omit some details such as asymptotic markers and the combinatorial coefficients they bring, only commenting on them when necessary. We will pretend our orbits are simple unless otherwise stated.

Let \(\mathcal{M}^A(\Gamma^+, \Gamma^-)\) denote the moduli space of genus-0 holomorphic curves in \(\partial M \times \mathbb{R}\), in the homology class \(A\), asymptotic to the set of orbits \(\Gamma^+ = \{\gamma_i^+\}_{i=1}^k\) at positive infinity, and \(\Gamma^- = \{\gamma_i^-\}_{i=1}^l\) at negative infinity, where \(\Gamma^-\) is allow to be the empty set. The expected dimension of \(\mathcal{M}^A(\Gamma^+, \Gamma^-)\) is given by the index formula

\[
\dim \mathcal{M}^A(\Gamma^+, \Gamma^-) = \sum_{i=1}^k \mu(\gamma_i^+) - \sum_{i=1}^l \mu(\gamma_i^-) + 2\langle c_1(TM), A \rangle + (n-3)(2-k-l)
\]

where \(n\) is the complex dimension of \(M\).

The index formula holds for holomorphic curves in the filling \(M\) as well, where \(\Gamma^-\) is always empty. Note that holomorphic curves in \(\partial M \times \mathbb{R}\) always come in one-parameter families since the almost complex structure \(J\) is invariant under translation in the \(\mathbb{R}\) direction. Therefore we will mod out by this \(\mathbb{R}\)-action, when we refer to a rigid curves in the symplectization, the index is 1.

The chain group for linearized contact homology of \(\partial M\) is freely generated by the good Reeb orbits over the the Novikov coefficient ring \(\Lambda_\omega\). Define a grading on \(\Lambda_\omega\) by

\[
|e^A| := -2\langle c_1(TM), A \rangle.
\]

And a grading on the orbits by

\[
|\gamma| = \mu(\gamma) + (n - 3).
\]

The differential is given by the count of rigid holomorphic cylinders in the symplectization \(\partial M \times \mathbb{R}\) anchored in \(M\). Let \(\gamma^+\) and \(\gamma^-\) be two Reeb orbits. An element \(u\) in the moduli space \(\mathcal{M}^A(\gamma^+, \gamma^-)\) is a pair of holomorphic curves \(u = (u_1, u_2)\) such that

- \(u_1\) is a genus-0 holomorphic curve in the symplectization \(\partial M \times \mathbb{R}\) with one positive puncture asymptotic to \(\gamma^+\), one distinguished negative puncture asymptotic to \(\gamma^-\), and any number of other negative punctures asymptotic to orbits \(\gamma_1, \ldots, \gamma_k\). \(u_1\) has homology class \(B\).
- \(u_2\) is a collection of holomorphic planes \(u_2^1, \ldots, u_2^k\) in the filling \(M\) asymptotic to the Reeb orbits \(\gamma_1, \ldots, \gamma_k\). The total homology class is \(C\).
\( A = B + C. \)

The expected dimension of \( \mathcal{M}_c^A(\gamma^+, \gamma^-) \) is \( \mu(\gamma^+) - \mu(\gamma^-) + 2\langle c_1(TM), A \rangle \). We are interested in rigid pairs, hence \( u_1 \) has index 1 and \( u_2 \) is a collection of rigid planes.

The linearized contact homology differential is given by

\[
\partial \gamma = \sum_{(\gamma', A): \mu(\gamma') - 2\langle c_1(TM), A \rangle = \mu(\gamma) - 1} n_{\gamma, \gamma'} c^A \gamma'
\]

where \( n_{\gamma, \gamma'} \) is the algebraic count of \( \mathcal{M}_c^A(\gamma, \gamma')/\mathbb{R} \).

**Remark 2.3.** Asymptotic markers will introduce a factor of \( \frac{1}{\kappa_{\gamma'}} \) into \( n_{\gamma, \gamma'} \). This factor comes from the fact that when asymptotic markers are include, there are \( \kappa_{\gamma'}^2 \) ways to glue along \( \gamma' \) but only result in \( \kappa_{\gamma'} \) distinct glued curves. Please see [EGH00] for more detail.

### 2.2. Gravitational Descendants

If we generalize the definition for Gromov–Witten invariants and their gravitational descendants directly to the SFT setting, we immediately run into the problem that the moduli spaces in SFT have codimension-1 boundary, therefore even though the tautological line bundle \( L \) still exists, its Chern class is not well defined. Instead the \( \psi \) class should be viewed as the zero set of a generic section \( s \) of \( L \). The main idea is that these sections should not be chosen completely independently across different moduli spaces, but should satisfy a compatibility condition on the boundary. This is carried out in full detail in [Fab10].

We will keep to simple case of one marked point. Let \( \mathcal{M}^A(\gamma) \) be the moduli space of holomorphic planes in \( M \) asymptotic to the Reeb orbit \( \gamma \) in homology class \( A \). Then \( \psi \) is the zero sets of a collection of generic coherent sections \( \{ s(\mathcal{M}^A(\gamma)) \} \) over all orbits and homology classes, which is compatible with the restriction maps to boundary strata. For example, if a boundary stratum of \( \mathcal{M}^A(\gamma) \) is of the form \( \mathcal{M}^{A-B}(\gamma, \gamma') \times \mathcal{M}^B(\gamma') \), then \( s(\mathcal{M}^A(\gamma)) \) restricted to that stratum is the pull back of \( s(\mathcal{M}^B(\gamma')) \) under the projection map \( \mathcal{M}^{A-B}(\gamma, \gamma') \times \mathcal{M}^B(\gamma') \to \mathcal{M}^B(\gamma') \). In general if there are more than one marked points, there will be further compatibility conditions for the symmetry of relabeling marked points.

Higher powers of \( \psi \) are inductively defined. More precisely, \( \psi^l \) is the zero sets of a collection of coherent sections of \( L^{\otimes l} \) over the zeros sets representing \( \psi^{l-1} \), with a factor of \( \frac{1}{l} \) since \( c_1(L) = \frac{1}{l} c_1(L^{\otimes l}) \).

For a compactly supported form \( \theta \in H^*(M, \partial M) \), the gravitational descendant

\[
\int_{\mathcal{M}^A(\gamma)} \text{ev}^*(\theta) \cup \psi^l
\]

is defined to be the integral of \( \text{ev}^*(\theta) \) over the subset representing \( \psi^l \). Note that this subset is of codimension-2l in \( \mathcal{M}(\gamma) \).

The value of such a descendant will not be an invariant. However certain linear combinations of descendants will be, if we make sure their codimension-1 boundary strata cancel out.
Proposition 2.4. Let $(M,\partial M)$ be an exact symplectic filling. If $a = \sum_{i=1}^{k} c_{i} e^{A_{i} \gamma_{i}} \in H_{C}(\partial M)$ is a cycle in linearized contact homology, $A \in H_{2}(M)$ a homology class, and $\theta$ a compactly supported closed form on $M$, then the value of the linear combination of descendants

$$\langle \tau_{l}(\theta) \rangle^{A}(a) := \sum_{i=1}^{k} c_{i} \int_{M^{A,-A_{i} \gamma_{i}}} \text{ev}^{*}(\theta) \cup \psi^{l}$$

is independent of all choices.

Proof. It is enough to prove the case $l = 0$. The higher $\psi$ classes will follow in identical fashion, replacing each moduli space $\mathcal{M}^{A}(\gamma)$ by the codimension 2l zero sections representing $\psi^{l}$ in $\mathcal{M}^{A}(\gamma)$. By the compatibility condition for coherent sections, the boundary strata of these zero sections have the same structures as their parent moduli spaces.

We will show that under the evaluation map, $\sum c_{i} \text{ev}(M^{A,-A_{i} \gamma_{i}}) \in H_{*}(M,\partial M)$ is a relative homology cycle in $H_{*}(M,\partial M)$, which we can then intersect with the Poincaré dual of $\theta$. This intersection number is the same as the descendant integral, and is independent of choices.

By the compactness theorem of [BEHWZ03], a codimension-1 stratum of $M^{A,-A_{i} \gamma_{i}}$ consists of 2-story curves $(u_{1}, u_{2})$, such that $u_{1} \in M^{A,-A_{i},-B}((\gamma); \{\beta_{1}, \ldots, \beta_{i}\})$ is a genus-0 holomorphic curve in the symplectization $\partial M \times \mathbb{R}$ with several negative punctures; and $u_{2}$ consists of $l$ holomorphic planes in the filling $M$, one asymptotic to each $\beta_{i}$ and in homology class $B_{i}$, with total homology class $B$. The marked point can be located on $u_{1}$ or on any one of the holomorphic planes of $u_{2}$.

Consider the image of such a stratum under the evaluation map. If the marked point is on $u_{1}$, then the stratum is mapped to infinity (in other words to $\partial M$), which does not affect $H_{*}(M,\partial M)$. Suppose the marked point lies on the plane asymptotic to $\beta_{1}$. If the other planes in $u_{2}$ are not rigid, then the dimension of $M^{B_{1}}(\beta_{1})$ is at least 2 less than that of $M^{A,-A_{i} \gamma_{i}}$. Therefore this stratum is mapped under the evaluation map to a chain of codimension at least 2, so has no effect on homology.

The only codimension-1 strata must have $u_{1}$ an index-1 holomorphic curve between $\gamma$ and $\gamma'$, and $u_{2}$ contains all but one rigid holomorphic planes. Evaluation map takes this stratum to $\text{ev}(M^{B_{1}}(\beta_{1}))$. This is exactly the configuration appearing in the linearized contact homology differential. Since $a$ is a cycle, there is another boundary stratum in some $M^{A,-A_{j} \gamma_{j}}$ which evaluates to $-\text{ev}(M^{B_{1}}(\beta_{1}))$. Therefore $\sum c_{i} \text{ev}(M^{A,-A_{i} \gamma_{i}})$ is a relative homology cycle.

Remark 2.5. The unfortunate negative sign for the homology class $A$ is due to the fact that $|e^{A} \gamma| = \mu(\gamma) - 2\langle c_{1}(TM), A \rangle + (n-3)$, but the moduli space $\mathcal{M}^{A}(\gamma)$ has dimension $\mu(\gamma) + 2\langle c_{1}(TM), A \rangle + (n-3)$.

Definition 2.6. Define $\langle \tau_{l}(\theta) \rangle : HC(\partial M) \to \Lambda_{\omega}$ by

$$\langle \tau_{l}(\theta) \rangle(a) = \sum_{A \in H_{2}(M)} \langle \tau_{l}(\theta) \rangle^{A}(a) \cdot e^{A}$$
2.3. Stein Domains. An open complex manifold \((M^{2n}, J)\) is Stein if it can be realized as a properly embedded complex submanifold of some \(\mathbb{C}^N\). A smooth function \(f: M \to \mathbb{R}\) is exhausting if it is proper and bounded from below. Let \(d^J f\) denote \(df \circ J\). The function \(f\) is plurisubharmonic if the associated 2-form \(\omega_f = -dd^J f\) is a symplectic form taming \(J\), i.e., \(\omega_f(v, Jv) > 0\) for every non-zero tangent vector \(v\). Plurisubharmonicity is an open condition. We can therefore assume \(f\) to be Morse. By a theorem of Grauert, an open complex manifold is Stein if and only if it admits a plurisubharmonic function.

A Stein manifold \((M^{2n}, J)\) with an exhausting plurisubharmonic function \(f\) admits the following associated structures:

- a symplectic form \(\omega_f = -dd^J f\) which is \(J\)-invariant,
- a primitive \(\alpha = -d^J f\),
- a vector field \(Y\) such that \(\alpha = \iota_Y \omega\),
- a metric \(g(v, w) = \omega(v, Jw)\).

Since \(L_Y \omega = \iota_Y d\omega + d(\iota_Y \omega) = d\alpha = \omega\), the vector field \(Y\) is Liouville, i.e., the flow of \(Y\) expands the symplectic form. In fact \(Y\) is the gradient vector field of \(f\) with respect to the metric \(g\). The unstable submanifolds of the critical points are isotropic, therefore the Morse index is at most \(n\).

A Stein domain \((M, \partial M)\) is a compact submanifold of a Stein manifold \(W\) of the same dimension, such that \(\partial M\) is transverse to the Liouville vector field \(Y\). A Stein domain becomes a symplectic filling if we complete it by attaching the symplectization \(\partial M \times [0, \infty)\) to the outside of \((M, \partial M)\). Note that such a Stein filling is always exact. We will abuse notation and denote the completion by \((M, \partial M)\) also.

Definition 2.7. A Stein domain \(M^{2n}\) is subcritical if there exists a plurisubharmonic Morse function with all critical points having Morse index strictly less than \(n\); and is of finite type if the number of critical points is finite.

Remark 2.8. For a subcritical Stein manifold of finite type, we may assume that all orbits are good by action filtration. More precisely, we can construct a decreasing sequence of contact 1-forms \(\alpha_n\) with an increasing sequence of real numbers \(b_n \to \infty\) such that all Reeb orbits for \(\alpha_n\) with action less than \(b_n\) are good. Then the linearized contact homology is the limit of \(HC^{\leq b_n}(\partial M, \alpha_n)\). From now on we will assume that all orbits are good.

The core of a Stein domain \(M\) with a plurisubharmonic function \(f\), \(C_M\), is the union of all the unstable submanifolds of \(f\) in \(M\). The integrable complex structure on \(M\) is not compatible in the sense of a symplectic filling, because it is generally not invariant under the flow of the Liouville field. However perturbations can be chosen to be made only on the cylindrical end of the filling, keeping \(J\) integrable near the core of the manifold. Since \(C_M\) consists of cells of dimension at most \(n\), but \(M\) has dimension \(2n\), standard homotopy theory shows there is no obstruction in choosing a trivial complex line subbundle of \(TM\) over \(C_M\). Hence there is a consistent way to pick a complex line \(\mathbb{C}_p\) at each \(p \in C_M\).

In this setting there is a geometric interpretation of the gravitational descendants. For each \(\theta \in H^*(M, \partial M)\), choose a homology cycle representing the Poincaré dual of \(\theta\), say \(\alpha\), such
that $\alpha$ lies in $C_M$. First we restrict to curves passing through $\alpha$. Let $\mathcal{M}^A(\gamma; \alpha)$ be the moduli space of holomorphic planes with one marked point, in the homology class $A$, asymptotic to $\gamma$, and the marked point is mapped to $\alpha$. We can normalize so that the marked point is 0.

For $u \in \mathcal{M}^A(\gamma; \alpha)$, choose a small neighborhood of $u(0)$ where $J$ is integrable, then in that neighborhood project $u$ onto the chosen complex line $C_{u(0)}$. Denote this projection by $\rho_{u(0)}$. For $u \in \mathcal{M}^A(\gamma; \alpha)$, choose a small neighborhood of $u(0)$ where $J$ is integrable, then in that neighborhood project $u$ onto the chosen complex line $C_{u(0)}$. Denote this projection by $\rho_{u(0)}$. Then $\rho_{u(0)} \circ u$ is a holomorphic map $\mathbb{C} \to \mathbb{C}$ and we can compute its vanishing order at 0. If the first $l$ derivative vanish then we say $u$ has ramification index $(l+1)$. A coherent collection of sections for gravitational descendants can be chosen to be the curves of ramification index $l$.

To be more precise, the domain of our holomorphic curves, $\mathbb{C}$ with one marked point, is not stable. The automorphism group is exactly $\mathbb{C}^*$. The addition of an extra marked point makes the domain stable. We will call the space of holomorphic planes with one marked point the unparametrized curves, and the space of holomorphic planes with two marked points the parametrized curves.

The tautological line bundle $L$ over $\mathcal{M}^A(\gamma; \alpha)$ is the dual of the bundle of parametrized curves over unparametrized curves. The fiber over each element $u$ of $\mathcal{M}^A(\gamma; \alpha)$ consists of a holomorphic map $\tilde{u} : \mathbb{C} \to M$, together with the $\mathbb{C}^*$-family of reparametrizations of $\tilde{u}$, $\{\tilde{u}(cz), c \in \mathbb{C}^*\}$. We can fill in the zero section by observing that $c = 0$ corresponds precisely to the nodal curve $\mathbb{C} \cup \mathbb{C}P^1 \to M$, where a constant ghost bubble is attached to $u$.

The derivative at 0 of the projection of $u$ to the chosen complex direction $C_{u(0)}$, $\tilde{u} \to \frac{\partial}{\partial z}(\rho_{u(0)} \circ \tilde{u})|_{z=0}$, is a section of the dual of the tautological line bundle. Furthermore such sections form a coherent collection over different $\mathcal{M}^A(\gamma; \alpha)$’s. The zero set of this section consists of (unparametrized) holomorphic curves $u$ whose representative $\tilde{u}$, after projection onto the chosen $\mathbb{C}$ direction, has the form $z \to cz^k$ for some $k \geq 2$. We will often suppress the chosen complex direction, and simply refer to this zero set as curves with ramification index 2.

Similarly, over the curves with ramification index 2, $\tilde{u} \to \frac{\partial^2}{\partial z^2}(\rho_{u(0)} \circ \tilde{u})|_{z=0}$ is a section of $L^\otimes 2$. The zero set of this section is referred to as curves with ramification index 3.

Therefore if $\theta$ is Poincaré dual to the point class, then $\int_{\mathcal{M}^1} ev^*(\theta) \wedge \psi$ can be interpreted as the count of holomorphic planes passing through $p$ with ramification index $(l+1)$, divided by $l!$.

**Remark 2.9.** This part of the setup works without any subcritical assumption.

### 3. Proof of Main Theorem

We first give the description of the map $D$ following section 7.2 of [BO09]. The map $D$ is described exclusively in terms of holomorphic curves in the symplectization $\partial M \times \mathbb{R}$ anchored in $M$. We assume that there are no bad orbits. In the presence bad orbits this description will need to be modified to include their contribution. Note that this is the only place where we use the subcritical assumption.
Identify the geometric image of each Reeb orbit $\gamma$ with the unit circle $S^1 = \mathbb{R}/2\pi\mathbb{Z}$ in $\mathbb{C}$, i.e. choose a point $P_\gamma$ which is identified with 0, and the Reeb flow is counterclockwise on $S^1$. Denote this by $S^1_\gamma$.

Let $u$ be an element of $\mathcal{M}_c^A(\gamma^+, \gamma^-)$. Take a \textit{parametrized} anchored holomorphic cylinder $(u_1, u_2)$ between $\gamma^+$ and $\gamma^-$ representing $u$. Choose a global polar coordinate $\mathbb{C} \setminus \{0\}$ for the domain of $u_1$, where the positive puncture is $\infty$, the distinguished negative puncture is 0, and the other negative punctures $\{z_i\}_{i=1}^k$ are on $\mathbb{C} \setminus \{0\}$. Let $H$ be the positive real axis.

Since $u_1$ is a curve in symplectization, it has the form

$$u_1 = (\overline{u}_1, f): \mathbb{C} \setminus \{0, z_1, \ldots, z_k\} \to \partial M \times \mathbb{R}.$$ 

Reparametrize the domain cylinder $\mathbb{C} \setminus \{0\}$ of $u_1$ by rotation, such that

$$\lim_{z \to \infty, z \in H} \overline{u}_1(z) = P^+_{\gamma}.$$ 

Then define

$$\text{ev}^-(u) = \lim_{z \to 0, z \in H} \overline{u}_1(z) \in S^1_{\gamma^-}.$$ 

Similarly after making $\lim_{z \to 0, z \in H} \overline{u}_1(z) = P^-_{\gamma}$, we define

$$\text{ev}^+(u) = \lim_{z \to \infty, z \in H} \overline{u}_1(z) \in S^1_{\gamma^+}.$$ 

\textbf{Remark 3.1.} Since $S^1_{\gamma}$ is only the geometric image of $\gamma$, it appears that when $\gamma^+$ is multiply covered, the reparametrization to make $\lim_{z \to \infty, z \in H} \overline{u}_1(z) = x$ is not unique, so $\text{ev}^\pm(u)$ is not well defined. This is due to us ignoring the asymptotic markers. The full definition of $\mathcal{M}_c^A(\gamma, \gamma')$ includes asymptotic markers at each puncture. Equivalence of holomorphic maps has to also preserve the markers. In particular this means each element in our moduli space without asymptotic markers actually corresponds to $\kappa^+_{\gamma^+} + \kappa^-_{\gamma^-}$ elements in the moduli space with markers. Every possible way to reparametrize is covered by exactly one such curve with markers. We will continue pretending the orbits are simple.

The map $D$ is induced by the chain level map

$$\Delta(\gamma) = \frac{1}{\kappa_{\gamma'}} \sum_{|\gamma| = |e^A_{\gamma'}|+2} c^A_{\gamma, \gamma'} e^{A_{\gamma'}},$$ 

where $c^A_{\gamma, \gamma'}$ is the sum of counts of two types of moduli spaces:

1. the moduli space $\mathcal{M}_1$ of anchored holomorphic cylinders $u$ in $\mathcal{M}_c^A(\gamma, \gamma')$ such that $\text{ev}^+(u) = 0$, or equivalently $\text{ev}^-(u) = 0$.
2. the moduli space $\mathcal{M}_2$ of parametrized broken holomorphic cylinders $u = (u_1, u_2) \in \mathcal{M}_c^B(\gamma, \beta), \ u' = (u'_1, u'_2) \in \mathcal{M}_c^{A-B}(\beta, \gamma')$ such that on the intermediate breaking orbit $S^1_{\beta^*}, \{0, \text{ev}^-(u) , \text{ev}^+(u')\}$ lie in anticlockwise order.
The moduli space $\mathcal{M}_c^A(\gamma, \gamma')$ consists of one parameter family of holomorphic cylinders, the boundary consists of a number of broken cylinders. Intuitively $\mathcal{M}_1$ counts the solutions of $ev^{-}(u) = 0$ in the interior of $\mathcal{M}_c^A(\gamma, \gamma')$, and $\mathcal{M}_2$ counts a subset of $\partial \mathcal{M}_c^A(\gamma, \gamma')$.

**Remark 3.2.** At first glance it seems $\mathcal{M}_2$ depends how we identify $\gamma$ with $S^1$, i.e., the the choice of $P_i$ to set as 0. It is true that chain map $\Delta$ depends on such choices. However $D$ is invariantly define on homology. This can be easily seen as follows, suppose we let the $P_i$'s move continuously. Then three different types of change can occur on some intermediate breaking orbit $\beta$:

- for some $u_0 \in \mathcal{M}_c^B(\gamma, \beta)$, $ev^{-}(u_0)$ moves pass 0 in clockwise direction. Then for all other $u' \in \mathcal{M}_c^C(\beta, \gamma')$, where $\gamma$ and $C$ vary over all possibilities, the broken cylinders $\{u_0, u'\}$ go from counting in $\mathcal{M}_2$ to not counting. Nothing else is changed. Hence $\Delta(\gamma)$ is changed by a boundary term $\partial \beta$, and therefore has no effect on homology.
- for some $u_0 \in \mathcal{M}_c^B(\gamma, \beta)$ and $u_0 \in \mathcal{M}_c^{A-B}(\beta, \gamma')$, $ev^{-}(u_0)$ moves pass $ev^{+}(u_0)$ in clockwise direction. Then the only change is $\{u_0, u_0'\}$ from not counting to counting. However, in the process, we crossed a cylinder where $ev^{-}(u_0) = ev^{+}(u_0')$. After gluing, the cylinder $\tilde{u} = u_0 \# u_0' \in \mathcal{M}_c^A(\gamma, \gamma')$ satisfies $ev^{-}(\tilde{u}) = 0$. Hence $\tilde{u}$ belongs to the moduli space $\mathcal{M}_1$. Therefore there is a corresponding change in $\mathcal{M}_1$ which cancels with this change in $\mathcal{M}_2$, so overall $\Delta(\gamma)$ remains unchanged.
- for some $u_0 \in \mathcal{M}_c^C(\beta, \gamma')$, 0 moves pass $ev^{+}(u_0)$ in clockwise direction. Then similar to the first case, for every $u \in \mathcal{M}_c^B(\gamma, \beta)$, the broken cylinders $\{u, u_0\}$ goes from counting to not counting. If $a = \sum_{i=1}^{k} c_i \gamma_i, c_i \in \Lambda \omega$ is a cycle in linearized contact homology, then by definition, each cylinder $u_0 \in \mathcal{M}_c^{B_i}(\gamma_i, \beta)$ will be cancel by some other cylinder $u_1 \in \mathcal{M}_c^{B_j}(\gamma_j, \beta)$. It follows that $\Delta$, when evaluated on a cycle, remains unchanged.

**Proof of Theorem 1.3** As in the proof of Proposition 2.4 for the case $l = 1$. For higher values of $l$ we simply repeat the argument with the coherent codimension-$2l$ zero sections of $L^{\otimes l}$ in place of the moduli spaces. As in Section 2.3, we can chose $l$-th derivative to be the coherent sections, and the curves with ramification index-$l$ are the coherent codimension-$2l$ zero sections sections.

Consider the gravitational descendant $\langle \tau_1 \theta \rangle^A$. Let $a = \sum_{i=1}^{k} \epsilon^{A_i} \gamma_i$ be a cycle in linearized contact homology. Let $\alpha$ be a homology cycle representing the Poincaré dual of $\theta$. For each $\langle \tau_1 \theta \rangle^A(\epsilon^{A_i} \gamma_i)$, we are interested in the number of holomorphic planes asymptotic to $\gamma_i$, in the homology class $-A - A_i$, and passing through $\alpha$ with ramification index 2.

Reduce the ramification index requirement by one, then the moduli space becomes two dimensional. In this case we have $\dim \mathcal{M}^{-A-A_i}(\gamma_i; \alpha) = 2$. Recall that $\mathcal{M}^{X}(\gamma; \alpha)$ is the moduli space of holomorphic planes with one marked point in homology class $X$, asymptotic to $\gamma_i$, and the marked point is mapped to $\alpha$.

First we trivialize the tautological bundle $L$ over $\mathcal{M}^{-A-A_i}(\gamma_i; \alpha)$. As explained in Section 2.3, this amounts to choosing a parametrized map $u : \mathbb{C} \to M = M' \times \mathbb{C}$ over each element of $\mathcal{M}^{-A-A_i}(\gamma_i; \alpha)$ (more precisely this gives a trivialization of the dual of $L$ and hence $L$).
To fix the $S^1$-component of the automorphism group, similar to the previous discussion on anchored cylinders, we may require that $\lim_{z \to \infty, z \in H} u(z) = P_\gamma$ (note that this does not uniquely determine $u$ if $\gamma$ is multiply covered, but Remark 3.1 applies here as well). To fix the $\mathbb{R}$-component of the automorphism group, we can simply require that $u(1)$ is always a distance of $\epsilon$ away from $u(0)$, for some sufficiently small constant $\epsilon$.

Under this trivialization of $L$, the coherent section is a map from $\mathcal{M}^{-A-A_1}(\gamma_i; \alpha)$ to $\mathbb{C}$:

$$f: u \mapsto \frac{\partial}{\partial z} (\rho_{u(0)} \circ u) (0)$$

Then $(\gamma_i \theta)^A(e^{A_1}; \gamma_i)$ is the number of zeroes of $f$. Since $\mathcal{M}^{-A-A_1}(\gamma_i; \alpha)$ is 2-dimensional, its boundary consists of a collection of circles, and the number of zeroes of $f$ is equal to the winding number of $f(\partial \mathcal{M}^{-A-A_1}(\gamma_i; \alpha))$ around 0.

The boundary of $\mathcal{M}^{-A-A_1}(\gamma_i; \alpha)$ consists of 2-story curves $(u_1, u_2)$ where

- $u_1 \in \mathcal{M}^B(\{\gamma_i\}, \{\beta_1, \ldots, \beta_k\})$ is a genus-0 holomorphic in the symplectization $\partial M \times \mathbb{R}$, with one positive puncture asymptotic to $\gamma_i$, and several negative punctures asymptotic to $\{\beta_j\}$.

- $u_2$ is a collection of holomorphic planes $u_2^j \in \mathcal{M}^{C_1}(\beta_j)$ in $\mathcal{M}$ asymptotic to the negative punctures of $u_1$. One of the planes, let us always use $u_2^1$, contains the marked point. Thus $u_2^1$ belongs to the cut down moduli space $\mathcal{M}^{C_1}(\beta_1; \alpha)$, other planes are unconstrained.

- $B + C_1 + \cdots + C_k = -A - A_1$.

The total index of $(u_1, u_2)$ is 2. There are a few different ways the index can distribute on the two stories:

1. $(u_1, u_2)$ has index-(1, 1): $u_1$ is rigid up to $\mathbb{R}$-translation. And the plane $u_2^1$ comes in a 1-parameter family, the others plane $u_2^j$’s are rigid.
2. $(u_1, u_2)$ has index-(1, 1): $u_1$ is rigid. However $u_2^1$ is also rigid, some plane $u_2^j$ without marked point has index-1.
3. $(u_1, u_2)$ has index-(2, 0): $u_1$ is a 1-parameter family. And all the $u_2^j$’s are rigid.

Therefore the boundary circles of $\mathcal{M}^{-A-A_1}(\gamma_i; \alpha)$ is divided into arcs and circles of these three types. Observe that the end points of these arcs, i.e. to cross from one type to another, are exactly the 3-story curves $(u_1, u_2, u_3)$, such that all three are rigid curves:

- $u_1$ is a curve with one positive puncture and several negative punctures in the symplectization $\partial M \times \mathbb{R}$;
- $u_2$ is also in the symplectization, it has several connected components, one of which is a curve with one positive puncture and several negative punctures, all other components are trivial cylinders;
- $u_3$ is a collection of rigid planes in the filling, with the marked point on one of them.

If we glue $u_1$ and $u_2$ first and leave $u_3$ fixed, we get a curve of type (3). If we glue $u_2$ and $u_3$ and leave $u_1$ fixed, we get a curve of type (1) or (2). Note that we cannot go from type (1) arcs directly to type (2) arcs.
Recall that the winding number for an arc $s: [0, 1] \to S^1$ is equal to $\tilde{s}(1) - \tilde{s}(0)$ where $\tilde{s}$ is the lift of $s$ to the universal cover $\mathbb{R}$. Hence the value of $\langle \tau_1 \theta \rangle_A(e^{\lambda t}, \gamma_i)$ is the total winding number of the derivative map $f$ on all three types of arcs.

For type (1) arcs or circles, observe that if we remove the plane $u'_2$, then $(u_1, u_2)$ is exactly the information for an anchored holomorphic cylinder between $\gamma_i$ and $\beta_1$, i.e.

$$(u_1, u_2) \in \mathcal{M}_c^{-A_i-A_j-B_1}(\gamma_i, \beta_1) \times \mathcal{M}^{B_1}(\beta; \alpha).$$

The winding of $f$ on this arc is determined by the 1-parameter family of planes in $\mathcal{M}^{B_1}(\beta; \alpha)$. However, we are interested not in $\langle \tau_1 \theta \rangle_A(e^{\lambda t}, \gamma_i)$, but $\langle \tau_1 \theta \rangle_A(\sum_{t=1}^k c_t e^{\lambda t}, \gamma_i)$, which is a cycle in linearized contact homology. Note that $\mathcal{M}_c^{-A_i-A_j-B_1}(\gamma_i, \beta_1)$ is exactly a term in the differential. Therefore there will be another arc on the boundary of some other $\mathcal{M}^{-A_i-A_j}(\gamma_j; \alpha)$ which has the form

$$(u'_1, u'_2) \in \mathcal{M}_c^{-A_i-A_j-B_1}(\gamma_j, \beta_1) \times \mathcal{M}^{B_1}(\beta; \alpha),$$

for some $j$, but with the opposite sign. It follows that the winding of $f$ on the type (1) arcs cancel out for $a \in HC(\partial \mathcal{M})$.

For type (2) arcs or circles, observe that $u_1$ is rigid, and so is $u'_2$, therefore the gluing reparametrization is the same over the entire 1-parameter family. Hence $f$ is constant and there is no contribution to the winding number.

For type (3) arcs or circles, once again after we remove the plane $u'_2$, then $(u_1, u_2)$ is now a 1-parameter family of anchored holomorphic cylinder between $\gamma_i$ and $\beta_1$, exactly as considered in the geometric description of the map $D$. When we glue $u'_2$ to $u_1$, we must reparametrize the domain of the rigid plane $u_2^1$ so that the limit of the positive $x$-axis of $u_2^1$ matches with $ev^-(u_1)$. It follows that the winding number of $f$ on the type (3) arcs or circles exactly agrees with the winding of number $ev^-(\mathcal{M}_c^{-A_i-A_j-B_1}(\gamma_i, \beta))$. Similar to the type (1) curves, we need to sum over all $i$.

Recall that the in the geometric description of the map $D$, moduli space $\mathcal{M}_1$ count the number of time the arc $ev^-(\mathcal{M}_c^{-A_i-A_j-B_1}(\gamma_i, \beta))$ crosses 0. It can be thought of as an integral approximation of the real winding number. We need to show that moduli space $\mathcal{M}_2$ exactly gives the right correction.

If a moduli space $\mathcal{M}_c^{-A_i-A_j-B_1}(\gamma_i, \beta)$ is a circle then the winding number is integral already, and $\mathcal{M}_1$ counts correctly. If $\mathcal{M}_c^{-A_i-A_j-B_1}(\gamma_i, \beta)$ is a path, then as discuss above, the two end point are 3-story curves. If an end is between a type (3) and a type (2) arc, then since type (2) arcs do not change the winding number, we may continue onto the other end of the type (2) arc, which must be a type (3) arc again. In other word, we may include type (2) curves as part of the type (3) curves. Therefore all ends of type (3) arcs are now between type (3) and type (1) arcs. In particular, this means in the 3-story curve $(u_1, u_2, u_3)$, the rigid plane $u_3$ with the marked point is not attached to a trivial cylinder in $u_2$. Hence both $u_1$ and $u_2$ are anchored holomorphic cylinders.

From now on we will use the short hand that $u(\delta_1, \delta_2)$ to be an anchored holomorphic cylinder between the orbits $\delta_1$, and $\delta_2$ in the suitable homology class, and $u(\delta)$ to be a rigid plane asymptotic to $\delta$ with the constrain of passing through $\alpha$. 
Suppose $\mathcal{M}_c^{A-A_i-B_1}(\gamma_i, \beta)$ has two ends $(u_1(\gamma_i, \delta), u_2(\delta, \beta))$, and $(u_1'(\gamma_i, \delta), u_2'(\delta, \beta))$. Furthermore assume $\mathcal{M}_c^{A-A_i-B_1}(\gamma_i, \beta)$ is oriented in that direction. Since $\mathcal{M}_1$ already counted the integral part of the winding number of $ev^{-}(\mathcal{M}_c^{A-A_i-B_1}(\gamma_i, \beta))$, the fractional part left is simply

$$ev^{-}(u_1'(\gamma_i, \delta), u_2'(\delta, \beta)) - ev^{-}(u_1(\gamma_i, \delta), u_2(\delta, \beta))$$

where each number is normalized to be in the range $[0, 2\pi)$.

We also have

$$ev^{-}(u_1(\gamma_i, \delta), u_2(\delta, \beta)) = ev^{-}(u_1(\gamma_i, \delta)) + ev^{-}(u_2(\delta, \beta)) \mod 2\pi$$

(8) where $ev^{-}(u_1(\gamma_i, \delta))$ and $ev^{-}(u_2(\delta, \beta))$ are normalized to lie in $[0, 2\pi)$ as well. Similarly for $u'$. Let us assume for now the all $ev^{-}(u(\gamma_1, \gamma_2))$ are small positive numbers, so that (8) is actual equality. This means every $\{0, ev^{-}(u_1), ev^{-}(u_2)\}$ lies in clockwise order, so $M_2$ is empty.

On the other hand, in this case the sum of the fraction winding numbers is

$$\sum_{\gamma_i, \delta, \beta} ev^{-}(u_1(\gamma_i, \delta)) + ev^{-}(u_2'(\delta, \beta)) - ev^{-}(u_1(\gamma_i, \delta)) - ev^{-}(u_2(\delta, \beta))$$

(9)

For each particular cylinder $v(\delta, \beta)$, since $a$ is a cycle in $HC(\partial M)$, every time $v(\delta, \beta)$ appears as part of the start of a moduli space $(u_1(\gamma_i, \delta), v(\delta, \beta))$, there is a canceling $(u_1'(\gamma_j, \delta), v(\delta, \beta))$ where it appears with the opposite sign as the end of a moduli space. Hence the contribution of $ev^{-}(v(\delta, \beta))$ is 0 in the sum (9).

Similarly suppose a cylinder $v(\gamma_i, \delta)$ appears in $(v(\gamma_i, \delta), u_2(\delta, \beta))$ as the start of a moduli space. Recall that there is a rigid plane $u(\beta)$ on the base of the 3-story curve

$$(v(\gamma_i, \delta), u_2(\delta, \beta), u(\beta)).$$

Glue $u_2(\delta, \beta)$ and $u(\beta)$, this is an end of a 1-parameter family of planes asymptotic to $\delta$. Let the other end of this family be $(u_2'(\delta, \beta'), u'(\beta))$. Then $(v(\gamma_i, \delta), u_2'(\delta, \beta'), u'(\beta))$ appears with the opposite sign to $(v(\gamma_i, \delta), u_2(\delta, \beta), u(\beta))$. Therefore the contribution of each $ev^{-}(v(\gamma_i, \delta))$ in the sum (9) is 0 as well.

It follows that the fractional winding numbers is also 0, if (8) is actual equality. Now it is easy to see that every time $\{0, ev^{-}(u_1), ev^{-}(u_2)\}$ lies in anticlockwise order, it means $ev^{-}(u_1(\gamma_i, \delta)) + ev^{-}(u_2(\delta, \beta)) > 2\pi$, so in the sum (9) we replace $ev^{-}(u_1(\gamma_i, \delta)) + ev^{-}(u_2(\delta, \beta))$ by $ev^{-}(u_1(\gamma_i, \delta)) + ev^{-}(u_2(\delta, \beta)) - 2\pi$ and therefore the winding number changes by one, exactly corresponding to the inclusion of that broken cylinder to $M_2$.

We showed that geometric count of the moduli spaces $M_1$ and $M_2$ exactly matches the winding number of the derivative map $f$. Theorem (1.3) follows immediately. □
