Background: Conditioning regimens including total body irradiation (TBI) or cyclophosphamide can mobilize high-mobility group box 1 (HMGB1) to peripheral blood. Additionally, increased plasminogen activator inhibitor (PAI)-1 levels are associated with post-allogeneic hematopoietic stem cell transplantation (aHSCT). However, changes to circulating levels of HMGB1 after aHSCT are poorly understood.

Materials and methods: The study cohort included 289 patients who underwent aHSCT at one of 25 institutions in Japan. We have investigated the relationship between HMGB1 and PAI-1 following aHSCT. A significant increase in HMGB1 levels occurred after conditioning treatment. Additionally, levels of HMGB1 at day 0 were significantly increased in TBI patients and cyclophosphamide/ TBI patients.

Conclusion: Our data revealed that an increased level of HMGB1 at day 0 following aHSCT correlates with increased PAI-1 after aHSCT, which is consistent with previous reports. Increased HMGB1 at day 0 after a conditioning regimen may play a role in transplantation-associated coagulopathy following aHSCT, because PAI-1 can accelerate procoagulant activity.

Keywords: PAI-1, transplantation-associated coagulopathy, aHSCT, TBI, HMGB1

Introduction

Allogeneic hematopoietic stem cell transplantation (aHSCT) is a curative treatment for many hematological malignancies. Cyclophosphamide (CY) in combination with either ablative doses of total body irradiation (TBI) or the oral alkylating agent busulfan (Bu) is the most common conditioning regimen for aHSCT. However, TBI and CY can induce transplantation-associated coagulopathy (TAC) conditions such as veno-occlusive disease (VOD).

Several interactions between coagulation-related blood components and the fibrinolytic system are involved in the progression of vascular angiopathy. Notably, plasminogen activator inhibitor (PAI)-1 plays an important role in the pathophysiology of many vascular abnormalities. PAI-1 levels fluctuate following aHSCT, and increased PAI-1 levels are associated with post-aHSCT complications. Therefore, PAI-1 is a potential predictive marker for VOD following aHSCT.

High-mobility group box 1 (HMGB1) is a nuclear protein which binds nucleosomes and promotes DNA bending. HMGB1 plays a crucial role in the cellular response to tissue damage, and is secreted by multiple cell types. HMGB1 expression is detectable in various immune and inflammatory diseases, and it is sequestered by thrombomodulin in vivo. While PAI-1 may play an important role in TAC following aHSCT, a relationship between HMGB1 and PAI-1 following aHSCT has not been
previously reported. Here, we have investigated levels of HMGB1 and PAI-1 following aHSCT. To our knowledge, this multi-institutional joint study is the first report of the clinical significance of these biomarkers for aHSCT.

Materials and methods

The study cohort included 289 patients who underwent aHSCT between June 2011 and September 2014 at one of 25 institutions in Japan. The study protocol was approved by Institutional Review Board (IRB) of Kansai Medical University. Written informed consent was obtained from all patients who were registered by faxing documents to Kansai Medical University prior to HSCT. Patients comprised 175 male and 114 female individuals of 7–72 years (median: 45 years). Patient diagnoses were 108 acute myeloid leukemia cases, 66 acute lymphoblastic leukemia cases, 41 myelodysplastic syndrome cases, and 74 other diagnoses. Conditioning with TBI (dose range: 2–12 Gy) was performed in 192 patients, while 97 patients received non-TBI conditioning. Heparin or recombinant thrombomodulin was administered as a preventive therapy for TAC in 236 patients, while 53 patients received no anticoagulant therapy. Donor sources for transplantation were 175 bone marrow cells, 57 peripheral blood stem cells, and 79 cord blood cells. Written informed consent for participation in the study was obtained from all registered patients before HSCT. Clinical and biochemical data were obtained before aHSCT and on days 0, 4, 14, 21, and 28 after aHSCT.

Blood samples from patients were collected into tubes containing sodium citrate or tubes without any anticoagulant, and the blood was allowed to clot at room temperature for a minimum of 1 hour. Serum or citrated plasma was isolated by centrifugation for 20 minutes at 1,000×g at 4°C. Serum was divided into aliquots and frozen at −30°C until use. HMGB1 was measured using the HMGB1 enzyme-linked immunosorbent assay (ELISA) Kit II (Shino-Test Corporation, Kanagawa, Japan). PAI-1 ELISA kits were purchased from BioSource International Inc. (Camarillo, CA, USA). All ELISA kits were used according to the manufacturers’ instructions. As a positive control, recombinant proteins were used in each assay alongside the standard solutions that were provided with the commercial kits. Data are expressed as the means ± standard deviation. Comparisons between groups were made using the Student’s t-test.

We calculated the cutoff value for the HMGB1 level at day 0 using receiver operating characteristic curve analysis. This is because HMGB1 levels at day 0 were significantly elevated compared with levels before beginning the conditioning regimen (Table 1). Finally, patients were divided into two subgroups based on their HMGB1 levels at day 0 after aHSCT. Group A was defined as patients showing a >1.5-fold increase in plasma HMGB1 levels after aHSCT relative to levels before beginning the conditioning regimen. Group B was defined as those with a <1.5-fold increase in plasma HMGB1. Differences between PAI-1 levels in Groups A and B were evaluated by one-way analysis of variance followed by Dunnett’s test. All statistical analyses were performed using StatFlex (version 6) software (Artec Inc., Osaka, Japan), and P<0.05 indicated a statistically significant difference.

Results

Table 1 shows the levels of HMGB1 and PAI-1 before and after aHSCT. A significant increase in HMGB1 levels occurred after conditioning treatment, with peak levels observed at day 0 (Table 1). PAI-1 levels were significantly increased at days 14, 21, and 28 after aHSCT (Table 1).

Figure 1 depicts the elevation of HMGB1 levels at day 0 after aHSCT. The levels of HMGB1 at day 0 were significantly increased in TBI+ patients and CY/TBI patients (TBI+ vs TBI−, 12.7±2.3 vs 10.8±1.4 ng/mL, P<0.01; CY/TBI vs fludarabine/Bu, 13.3±2.6 vs 12.2±1.1 ng/mL, P<0.01; CY/TBI vs Bu/CY, 13.3±2.6 vs 12.6±0.8 ng/mL, P<0.05; Figure 1). Classification of patients by graft source or graft versus host disease prophylaxis did not reveal significant differences between patient groups (Figure 1).

We divided patients into two subgroups based on HMGB1 levels after aHSCT. Group A (increased HMGB1) had significantly increased plasma PAI-1 levels relative to baseline. Following aHSCT, PAI-1 levels were significantly

| Time of measurement | HMGB1 | PAI-1 |
|---------------------|--------|-------|
| Level (ng/mL)       | P-value| Level (ng/mL) | P-value |
| Day –7              | 7.6±2.2 | – | 15.3±5.5 | – |
| Day 0               | 12.2±2.6 | <0.001 | 16.7±6.1 | NS |
| Day 4               | 10.3±3.1 | <0.01 | 16.9±6.3 | NS |
| Day 7               | 8.7±2.2 | NS | 17.4±5.8 | NS |
| Day 14              | 7.4±2.3 | NS | 18.2±7.5 | <0.05 |
| Day 21              | 7.0±2.1 | NS | 19.5±7.3 | <0.01 |
| Day 28              | 6.6±2.5 | NS | 21.7±7.7 | <0.01 |

Notes: Data are shown as the mean ± SD. Values are compared with those from day 7. *Time of measurement is shown before and after aHSCT. –, indicates no entry.

higher in Group A compared with Group B (two-factor analysis of variance, \(P<0.05\); Figure 2).

**Discussion**

An increased risk of developing TAC is associated with the inclusion of TBI in the conditioning regimen for aHSCT. We identified increased levels of HMGB1 at day 0 in patients treated with conditioning regimens that included TBI or CY. This suggests that HMGB1 may be involved in the development of TAC following conditioning for aHSCT. Cutler et al\(^6\) reported that increased vascular endothelial cell dysfunction is a predictive indicator of VOD. Although the etiology of VOD remains unclear, we suspect that increased levels of proinflammatory cytokines – such as HMGB1 – contribute to VOD. HMGB1 is implicated in the pathophysiology of a variety of inflammatory and immunological diseases.\(^9,10\) Several previous reports have examined the role of HMGB1 in aHSCT.\(^11–13\) Tagami et al\(^11\) reported that HMGB1 may play a role during the mobilization of stem cells from the bone marrow into the systemic circulation. Additionally, Yujiri et al\(^12\) suggested that HMGB1 may be a useful marker of acute graft versus host disease. Furthermore, Kornblit et al\(^13\) proposed that an inherited variation in HMGB1 is associated with outcome after aHSCT. However, these previous reports did not examine changes in the level of HMGB1 after aHSCT. Our study details changes in HMGB1 levels postconditioning for aHSCT in a large patient cohort. Our results suggest that increased HMGB1 levels following myeloablative conditioning influence outcome after aHSCT.

PAI-1 is expressed by many cells, including endothelial cells, vascular smooth muscle cells, and platelets. In addition, PAI-1 expression can be regulated by many factors, including cytokines, oxidative stress, and cellular signaling molecules. Moreover, some previous reports have shown that all patients...
