ABSTRACT
Pneumonia is the respiratory infection disease, which is influenced by climatic variables and air quality. However, little is known how rainfall and air humidity influence on the disease situated in a high traffic density such as in Bogor, Indonesia. The research aims to analyze the influences of rainfall, air humidity, and air pollution on the incidence rate of pneumonia under 5-year-old children in Bogor. We used statistical approaches namely correlation and principal component analysis and combined with chart analysis to identify the influences. Our results revealed that high rainfall (high relative humidity) improved air quality by lowering the concentration of particulate matter. But, the indoor microorganism growth would increase, therefore it affects the incidence rate of pneumonia under 5-year-old children, especially in transition season from wet to dry. In dry season, high concentration of particulate matter in the air would increase the incidence rate of pneumonia. Other findings showed that climate (through humidity) and particulate matters have regulated the pneumonia incidence rate in Bogor. The rate was higher under high humidity. On other hand, in transition from dry to wet season, concentration of particulate matters was more dominant to influence the incident rate.

air pollution, humidity, particulate matter, principle component analysis, rainfall

INTRODUCTION
Pneumonia is an acute respiratory infectious (ARI) disease that infect humans from infants to adults. This disease is categorized as ARI with high severity, which infects the lungs tissues (lower respiratory tract). Based on WHO report, there were almost four million deaths worldwide caused by ARI each year, and 98% of them are caused by pneumonia (WHO, 2014). Biologically, children under 5-year old (toddlers) have a higher risk of pneumonia compared to adults. This is caused by the immature immune system and the absence of antibodies to fight the microorganisms causing pneumonia infection in toddlers (Popovsky and Florin, 2020; Rodrigues and Groves, 2018; Widoyo, 2016). On the contrary, adults have already developed a matured immune system. Adults who had been infected with pneumonia during their toddler may have natural antibodies, which is able to minimize the risk of a second infection (Quinton et al., 2018). In addition, toddlers more have physical contacts with peers in their neighborhood resulting in an even higher risk to be infected by pneumonia (Sidiq et al., 2016). Toddlers’ mobility is lower compared to adults, thus performing identification of pneumonia infection’s spread in a certain area will be easier when using the toddlers’ pneumonia case.

Pneumonia infection is caused by micro-sized viruses, bacteria, and fungi. These microorganisms spread through the air, with the transmission occurs when viruses and bacteria released by pneumonia’s infected person during coughs or sneezes are accidentally inhaled by a non-infected person (Mathew, 2018; Nathan et al., 2020). The transmission may escalate when the suitable environment met (Putra and Wulandari, 2019; WHO, 2014). Two environmental factors affecting the survival of pneumonia pathogens are weather conditions, (Chowdhury et al., 2018) and air quality (Particulate Matters) (Vodonos et al., 2016).

Previous studies revealed that the presence of PM$_{2.5}$ and PM$_{10}$ in the atmosphere could aggravate the air quality (Turyanti and Chaeurnisa, 2017), and further increased the number of people with ARI’s symptoms (Turyanti, 2011) including pneumonia, which had been registered in health services. Other studies confirmed the relation between PM$_{2.5}$ to the incidence rate (Mehta et al., 2013). One study also reported that PM$_{10}$ concentration in the atmosphere was correlated to the incidence of upper respiratory tract infections in Hong Kong (Tam et al., 2014). The number of pneumonia cases in children under five registered in 41 metropolitan Atlanta hospitals and Georgia hospitals was also associated with an increasing concentration of pollutants from motor vehicles, including PM$_{2.5}$ (Darrow et al., 2014). Based on this information, identification of the relationship between air quality and climatic variables with the incidence rate of pneumonia cases is important, especially in urban areas such as Bogor.

Based on INRIX 2019 Global Traffic Scorecard (a research institution and transportation agency), Bogor is in the 5th position as the most congested city in Indonesia. Congestion is closely related to increasing concentrations of pollutants in the atmosphere, including PM$_{2.5}$ and PM$_{10}$ (Aida et al., 2019; Turyanti and Santikayasa, 2006), which can also lead to increasing ARI potential incidence (Pedde et al., 2017) including pneumonia (Chang et al., 2018). The climatic conditions in Bogor can either support or limit the potential of the disease. Bogor, which is located near the hillside of Mt. Gede Pangrango and Mt. Salak, has a fairly high annual rainfall and quite warm air temperatures (Hidayat and Farihah, 2020). These climatic conditions can support the survival of pneumonia pathogens (Sohn et al., 2019), thus potentially increase the pneumonia incidence. However, the concentration of pollutants in the atmosphere from traffic density and other activities will be decreased due to the deposition by rain (Kwak et al., 2017), which otherwise lowers the potential for pneumonia incidence.

Based on these environmental elements, this study examines the relationship between climatic variables, PM concentration in the atmosphere, and the number of pneumonia incidence in Bogor. More specifically, this study aims to: (1) identify the relationship between environmental factor (climatic variables) and PM concentrations in the atmosphere, and (2) analyze the influence of climatic variables and PM concentrations on pneumonia incidence. As a case study, the analysis was performed using the data period of 2017-2019.

**RESEARCH METHODS**

**Data Sources**

This study required daily data of pneumonia incidence under 5-year old children in Bogor for the 2017-2019 period. The data was obtained from ten public health centers spread across Bogor. Other data were needed especially daily PM$_{2.5}$ and PM$_{10}$ concentration data, and daily meteorological data including air temperature, humidity (RH), and rainfall for the 2017-2019 period in Bogor. The latter data were obtained from the Centre for Climate Risk and Opportunity Management in Southeast Asia and Pacific (CCROM-SEAP) IPB, which was collaborated with National Institute for Environmental Studies (NIES) Japan. Each analysis process was executed using data processing software namely Minitab 18 and Microsoft Excel.

**Analysis of the Climatic Variables Influence on PM Concentrations**

The relationship between PM and climatic variables was analyzed using correlation analysis with a confidence level of 95% or a p-test result value of <0.05. Correlation analysis was conducted to determine the degree of association and direction of the relationship between the X (independent) variable and the Y (dependent) variable. The correlation analysis was calculated based on the Pearson correlation coefficient in Equation (1).

$$r = \frac{\Sigma(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\Sigma(x_i - \bar{x})^2}(y_i - \bar{y})^2}$$ (1)

where $r$ pearson correlation coefficient, $x_i$ climatic variables (rainfall, temperature, and relative humidity), $\bar{x}$ average of climatic elements, $y_i$ pollutants concentration (PM$_{2.5}$ and PM$_{10}$), $\bar{y}$ average of pollutants concentration.
Analysis of the Relationship between Pneumonia Incidence, Climatic Variables, and PM Concentration

We assumed that the number of pneumonia infection cases represented the ratio of all pneumonia-infected children over time. The relationship between climatic variables and PM concentration on pneumonia incidence was analyzed using Principal Component Analysis (PCA) and visualized in a 3D-surface plot using Minitab 18 software. PCA eliminated the multicollinearity between climatic variables and PM concentration which occurred because both variables were not linearly independent. The climatic variables and the PM concentration data were first standardized to be on the same scale. PCA was then performed on the standardized data in Minitab 18 using the covariance matrix type (considering both variables were already in the same size). The proportion results described each principal component (PC), which represented the data diversity. The number of principal components used subjectively depends on the proportion that was considered sufficient to capture the data structure. The equation of the relationship between pneumonia incidence and the PCs was expressed in linear regression, where the outcoming PCs were a combination of climatic and PM data which also weighted following the values in the Eigenvector table. PCs in the regression equation result was then transformed back into the anomalies data of climatic and PM variables which resulted in linearly independent regression form of the relationship between the pneumonia incidence to standardized climatic and PM data. The anomalies data of climatic and PM variables in the equation was also transformed back into the previous climatic and PM data form by substituting the average of the climatic and PM variables in the anomaly (Equation 2).

\[ d = d_{an} + \bar{d} \]  

(2)
where $d$ is the variable, $d_{an}$ is the variable anomalies in the regression equation, and $\bar{d}$ is the average value of the variable.

RESULTS AND DISCUSSIONS

**PM$_{2.5}$ and PM$_{10}$ Concentration in Bogor**

Exposure to pollutants, such as Particulate Matter (PM) can aggravate respiratory infections. PM is a mixture of solid particles and droplets that come from emissions from various sources with varying sizes, mass, and chemical compositions. PM consists of various pollutants such as sulfate, nitrate, ammonia, sulfur, chloride, black carbon, and mineral dust. PMs with different sizes will also react differently in the atmosphere. The aerodynamic differences in PM will also differentiate its transmission and elimination processes in the atmosphere (McLoughlin et al., 2019; Satsangi and Agarwal, 2019).

The monthly concentrations of PM$_{2.5}$ and PM$_{10}$ in Bogor from 2017 to 2019 had a similar pattern. The average concentration of PM$_{2.5}$ and PM$_{10}$ in the wet season which represented by DJF (December-January-February) months were 14 µg/m$^3$ and 38 µg/m$^3$ with a smaller concentration range, while the average concentrations in the dry season which represented by the JJA (June-July-August) months were 35 µg/m$^3$ and 71 µg/m$^3$ with a wider concentration range (Figure 2).

The wide range and extreme values of PM concentration in the dry season were the results of the inconsistent daily amount of rainfall which at some point was high but occasionally there was none (Figure 2-rainfall). PM concentration during the dry season in Bogor reached up to twice as high as the average PM concentration during the wet season, which correspondence with Nishihashi et al. (2019) research.

According to the monthly average data presented in the scatter plot (Figure 3), relative humidity and PM concentration were significantly correlated with a 95% confidence level, namely -0.76 for PM$_{2.5}$ and -0.71 for PM$_{10}$. Rainfall and PM concentration was also significantly correlated, namely -0.44 for PM$_{2.5}$ and -0.38 for PM$_{10}$. Air temperature and PM concentration were significantly correlated with a positive correlation namely 0.43 for PM$_{2.5}$ and 0.37 for PM$_{10}$. These values indicated that the concentrations of PM$_{2.5}$ and PM$_{10}$ will be low if the rainfall and humidity were relatively high but tend to be high if the air temperature was also high.

PM concentration was high during the dry season due to the low amount of rainfall and humidity and vice versa. A high amount of rainfall and high humidity will escalate the wet deposition process which is the most effective mechanism for cleaning the atmosphere (Ruchiraset and Tantrakarnapa, 2020).

![Figure 2. Boxplot of monthly concentrations of PM$_{2.5}$, PM$_{10}$, and rainfall in Bogor for 2017-2019.](image-url)
Another factor that can increase the concentration of PM during the dry season is high surface temperature and high air temperature which results in lower air density thus PM is more easily lifted from the surface and floats in the air and accumulates due to atmospheric circulation (Zalakeviciute et al., 2020).

Pneumonia Incidence, Climatic Variables, and PM Concentration

The total number of pneumonia incidence in children under five registered in ten health centers for the 2017-2019 period in Bogor was 2,380 from a total population of 94,902 in 2018 (around ±2.5% of the total toddler’s population in three years). Pneumonia incidence in Bogor showed an increasing trend from 2017 to 2019, with the highest rate arisen in 2019 (Figure 4e). The highest incidence of pneumonia occurred from wet season to transitional season from wet season to dry season which was in February and March. The peak incidence of pneumonia occurred during the dry season in July 2017 and 2019, also during the transitional season from dry to wet season which was in October 2018 with a lower peak compared to those in the wet season. This case will then become the basis for analysis of the pneumonia incidence categorized by season, which divided into the wet season in December-January-February (DJF), the transition from the wet to the dry season in March-April-May (MAM), the dry season in June-July-August (JJA), and the transition from the dry to the wet season in September-October-November (SON).

The pneumonia incidence in December to May had the same pattern as rainfall and relative humidity but had the opposite/inverse pattern to PM and air temperature. The pneumonia incidence from December to May occurred when rainfall and humidity increased (Figures 4a and 4d), which was in line with Ike and Mbonu’s (2019) research, and when PM concentration and air temperature decrease (Figures 4b and 4c). On the contrary, the incidence of pneumonia in June to November has the same pattern as PM concentration and air temperature but has the opposite/inverse pattern to rainfall and air humidity. The incidence of pneumonia from June to November occurred when PM concentration and air temperature increases, while rainfall and humidity decreases, which was in line with Cahyadi et al. (2016) research.

The correlation between pneumonia incidence with climatic variables and PM concentration had the most statistically significant value in the transitional season. The correlation coefficient showed that pneumonia incidence in the MAM months was not only had a statistically significant negative correlation with air temperature, PM$_{2.5}$, and PM$_{10}$ but also had a significantly positive correlation with rainfall. At SON months, the pneumonia incidence was not only had a significantly positive correlation with PM$_{2.5}$ and PM$_{10}$ but also had a significant negative correlation with relative humidity (Table 1). The correlation value was calculated in a weekly period assuming that pneumonia symptoms became visible and hospital visits were carried out within a week. The correlation value obtained was low, arguably because there was a possible lag/gap between climatic variables and PM with the time the patient visits the hospital. Either climatic variables and PM can be combined and lead to cause pneumonia, but the mechanism will be vary depending on which was the most dominant.
According to the overall correlation coefficient, the weekly pneumonia incidence in 2017-2019 had a significantly positive correlation with climatic variables (actual vapor pressure and relative humidity) and a significantly negative correlation with PM concentrations (PM$_{2.5}$ and PM$_{10}$). The variable used for PCA in 2017-2019 was relative humidity (RH) to represent the humid condition in the wet season and PM$_{2.5}$ which had a greater correlation with pneumonia compared to PM$_{10}$.

PCA was performed to eliminate multicollinearity between RH and PM$_{2.5}$ which had a significant negative correlation of -0.629. The component used was only PC1 which represented 81% of the total pneumonia incidence. PC2 had an insignificant correlation with the incidence of pneumonia. The equation obtained is: Pneumonia = 17.046 + 1.990 PC1, which then transformed back in the form of pneumonia regression equation with RH and PM$_{2.5}$ as follows: Pneumonia = -43.967 + 1.4 RH – 1.413 PM$_{2.5}$ and then plotted into a 3D-surface plot (Figure 5a). The results of the 3D-surface plot showed that if humidity reached 80% and the PM$_{2.5}$ concentration was relatively low (<15 µg/m$^3$), the highest incidence of pneumonia was around 40 cases. This showed that humidity was mainly influenced pneumonia incidence in Bogor.

Figure 4. Monthly pattern of: (a) rainfall, (b) PM2.5 and PM10 concentration, (c) near-surface air temperature, (d) relative humidity, and (e) pneumonia incidence in Bogor in 2017-2019 period.
Table 1. Correlation coefficient (r) of pneumonia incidence with climate factors and PM concentration.

|          | RH  | Rainfall | T    | ea  | PM$_{2.5}$ | PM$_{10}$ |
|----------|-----|----------|------|-----|------------|-----------|
| MAM      | 0.18| 0.40     | -0.43| 0.01| -0.44      | -0.42     |
| p_value  | 0.237| 0.009    | 0.005| 0.945| 0.003      | 0.005     |
| SON      | -0.54| -0.14    | 0.35 | -0.51| 0.58       | 0.59      |
| p_value  | 0.003| 0.488    | 0.072| 0.007| 0.001      | 0.001     |

Note: correlation was performed in a weekly period

The effect of PM on pneumonia was analyzed in SON months using PCA on the actual vapor pressure (ea) and PM$_{2.5}$ concentration. PCA was performed to eliminate multicollinearity between ea and PM$_{2.5}$ which had a significantly negative correlation of -0.508. The component used was only PC1 which represented 78% of the total pneumonia incidence. PC2 had an insignificant correlation with the incidence of pneumonia. The equation obtained is: Pneumonia = 13.583 – 2.584PC1, which then transformed back in the form of pneumonia regression equation with ea and PM$_{2.5}$ as follows: Pneumonia = 6.993 – 1.827ea + 1.827PM$_{2.5}$ and then plotted into a 3D-surface plot (Figure 5b). The results of the 3D-surface plot showed that if the actual vapor pressure was low and about <19 hPa and the PM$_{2.5}$ concentration reached 40µg/m$^3$, the highest incidence of pneumonia occurred which was around 40 cases. This showed that PM$_{2.5}$ had a more dominant influence during the dry period, especially in SON months (the transition season from the dry to the wet season).

According to Griffiths et al. (2017), the response of a toddler’s body to pneumonia infection can be influenced by climatic variables through the respiratory tract sensor’s sensitivity to weather changes. The incidence of pneumonia in the wet season is not directly affected by rainfall but influenced by the consequences of humid conditions, namely the increase of viruses growth and development, bacteria, and fungi which are dangerous when being inhaled (Ike and Mbonu, 2019; Jati and Ginandjar, 2017). The spores of atmospheric fungi and bacteria are varied in size, ranging from 1-10 µm (Gonzalez-Martin, 2019) which allows them to enter the respiratory tract. According to Adaji et al. (2019), indoor pollution during the wet season can also affect pneumonia incidence in children under five. The effect of indoor pollution including microorganisms is unidentifiable because it is unable to be measured by a standard PM gauge placed in an outdoor measuring station.

The result showed that pneumonia incidence may also occur in the dry season was in line with Cahyadi et al. (2016) and Hidayati et al. (2017). According to Tam et al. (2014) and Sahuquillo-Arce et al. (2017), in the dry season, the population of microorganisms causing respiratory infections did not grow rapidly due to dry conditions caused by lower humidity. However, when the humidity is low, the infection can also easily occur because mucosal fluids as a PM filter will be easier to dry so that more PM can be inhaled. High PM concentrations in the respiratory tract will lead to oxidative stress (when the number of free radicals in the body exceeds the body’s capacity to neutralize them) resulting in tissue destruction. The damaged tissue will be more easily infected by the disease-causing viruses and bacteria combined with PM.

![Figure 5](image-url). The 3D-Surface plot of (a) the Pneumonia incidence, RH, and PM$_{2.5}$ in 2017-2019, and (b) Pneumonia incidence, RH, and PM$_{2.5}$ in transition season (SON).
The main factor causing pneumonia is the infection of microorganisms (bacteria and viruses) on the respiratory tract and organs, but the presence of microorganisms is not always related to pneumonia (Quinton et al., 2018; Sun et al., 2019; Suprobowati and Kurniati, 2018). Nevertheless, the infection also depends on the body conditions and its response to these microorganisms. Pneumonia microorganisms can spread through droplets from an infected person which are then inhaled or attached to another person's mucosal tissue. When microorganisms have entered and attached to the respiratory tract, these microorganisms will break into cells to multiply themselves using existing facilities in the cell then destroy the cell and move to another cell. The epithelial cells will then detect this activity and instruct the body's defense system (alveolar macrophages) to eat these microorganisms so that their proliferation and damage to cells can be immediately stopped. Pneumonia occurs when inflammation due to the inability of the body's defense system to fight microorganisms does not recover for a long time.

CONCLUSIONS

PM concentration in the atmosphere was mainly influenced by relative humidity with a correlation coefficient of -0.76 for PM$_{2.5}$ and -0.71 for PM$_{10}$ (with a 95% confidence level). High rainfall and relative humidity during the wet season reduce PM$_{2.5}$ and PM$_{10}$. The trend of pneumonia incidence under 5-year children in Bogor in 2017-2019 had increased. The incidence of pneumonia reached 40 cases when the humidity was around 80% and the PM$_{2.5}$ concentration was relatively low (<15 µg/m$^3$). The PM$_{2.5}$ concentration significantly affected the incidence of pneumonia in the transition season from the dry season to the wet season (September-October-November). The PCA results showed that the incidence of pneumonia in the dry season was also quite high, reached 40 cases when the actual vapor pressure (ea) was low (<19 hPa) and the PM$_{2.5}$ concentration reached 40µg/m$^3$.

ACKNOWLEDGEMENT

The authors would like to thank the CCROM-SEAP IPB for their strong support and assistance by providing PM concentration data, climate data, and pneumonia data. This research had been presented in the 5th Annual Meeting on GHGs and AQ Joint Monitoring in Indonesia on February 16th, 2021.
