Abstract: Around the globe, surges of bacterial diseases are causing serious health threats and related concerns. Recently, the metal ion release and photodynamic and photothermal effects of nanomaterials were demonstrated to have substantial efficiency in eliminating resistance and surges of bacteria. Nanomaterials with characteristics such as surface plasmonic resonance, photocatalysis, structural complexities, and optical features have been utilized to control metal ion release, produce reactive oxygen species, and produce heat for antibacterial applications. The superior characteristics of nanomaterials present an opportunity to explore and enhance their antibacterial activities leading to clinical applications. In this review, we comprehensively list three different antibacterial mechanisms of metal ion release, photodynamic therapy, and photothermal therapy based on nanomaterials. These three different antibacterial mechanisms are divided into their respective subgroups in accordance with recent achievements, showcasing prospective challenges and opportunities in clinical, environmental, and related fields.

Keywords: nanomaterials, metal ions, photodynamic, photothermal, antibacterial mechanism, reactive oxygen species

Introduction

Nanotechnology as a tool has rapidly taken over several fields of life including the health sector.¹ Applications of nanotechnology in the health sector are diverse and range from diagnostics to therapies. One of the therapeutic challenges at a global scale remains the treatment of bacterial infections. Indeed, the long-term use and misuse of antibiotics have led to antibiotic resistance, which threatens public health through different pathways like livestock, food, and water.²⁻⁴ Metal ion release, photodynamic therapy (PDT), and photothermal therapy (PTT) are important methods for different biological applications. Multiple metal and carbon-based complexes (both organic and inorganic) such as copper, bismuth, silver, iron, gallium, gold, titanium, molybdenum, selenium, chitosan, polyvinylpyrrolidone, polyvinylidene fluoride, polyvinyl chloride, carboxymethyl cellulose, graphene etc, have been investigated in clinical studies for antibacterial applications. The superior characteristics of nanomaterials present an opportunity to explore and enhance their antibacterial activities leading to clinical applications. In this review, we comprehensively list three different antibacterial mechanisms of metal ion release, photodynamic therapy, and photothermal therapy based on nanomaterials. These three different antibacterial mechanisms are divided into their respective subgroups in accordance with recent achievements, showcasing prospective challenges and opportunities in clinical, environmental, and related fields.

The variety of metals, their diverse physicochemical properties, their inherited photochemical properties, their shapes, and ligand types make them suitable for widespread use in new antimicrobial designs.⁵⁻³⁵

Moreover, metal atoms easily become positively charged ions through the loss of electrons, and they can then dissolve in biological fluids. Because of their electron deficiency, metal ions have a high affinity for electron-rich biomolecules,
such as DNA and proteins, with which they form complexes. The formation of complexes leads to the inactivation of proteins, DNA damage, membrane impairment, and ultimately bacterial death. Furthermore, PDT and PTT use light to trigger a cascade of events leading to bacterial death. Different antibacterial phototherapy modalities exist based on how light-responsive nanomaterials act. The PDT employs photosensitizers or their precursors which can absorb visible light and produce reactive oxygen species (ROS) that are toxic to cells due to stress oxidation. Nanomaterials for PDT applications include metals, upconversion nanoparticles, carbon-based nanomaterials, two-dimensional (2D) nanomaterials, quantum dots (QDs), etc. PDT can be used to treat infectious diseases without the specter of drug resistance like with antibiotic treatment. In this way, PDT can be applied to all types of microorganisms including bacteria. PTT uses photothermal nanomaterials which can absorb light followed by its conversion into heat leading to hyperthermia which kills cells. With this therapy, a near-infrared (NIR) laser is preferable as a light source due to its advantages in clinical applications such as deeper tissue penetration, safety, and high absorption by photothermal agents (PTAs). In this literature review, we summarize three ways of fighting bacterial infections using materials or composites at the nanometer scale: metal ion release, PDT, and PTT. Thereafter, a brief overview of trends with new approaches for antibacterial drugs is provided.

**Metal Ion Release**

**Overview of Metal Ion Release in Antibacterial Applications**

The ability of metal/metal oxide nanoparticles (NPs) to release metal ions in aqueous media has recently been
extensively explored especially the aspect of their biomedical application and particularly focusing on the antibacterial properties of these metal/metal oxide NPs. The bactericidal properties of these NPs and their resulting metal ions have been extensively reported in recent years, and it was observed that metal ions are to a large extent implicated when describing the toxic mechanisms of these metal/metal oxide NPs against bacteria. These NPs can be oxidized when in biological media, releasing metal ions which can generate ROS or create oxidative stress that in turn leads to biocidal effects which can range from ribosome destabilization, DNA, protein, mitochondrial, and cell wall damage to electron transport disruption and cell death (Figure 1). Many metal ions were reported to exert toxicity against bacteria, such as Ca$^{2+}$, Zn$^{2+}$, Mg$^{2+}$, Fe$^{2+}$, Fe$^{3+}$, Ni$^{2+}$, and Cu$^{2+}$, which at lower concentrations are very useful in bacterial metabolic processes but at higher concentrations become toxic to bacteria and hence have a bactericidal effect. The effects of these metal ions are primarily attributed to their natural affinity for certain cellular components. This is not the case with other metal ions such as Ag$^{+}$ which exerts a very strong bactericidal effect even at very low concentrations. These metal ions are known to have a great affinity for thiol groups, which for example bind to cysteine and then indirectly trigger disruption of a cell’s enzyme functions, metabolism, or general physiology through their ability to destroy a cell’s disulfide bonds which help to maintain tertiary and quaternary protein structures.

Different modes of bacterial execution mechanisms have been identified for different kinds of metal/metal oxide NPs. Some examples include reorganization of the histone-like nucleoid structuring protein of bacteria, which was observed when Escherichia coli (E. coli) was treated with an Ag$^{+}$ solution and bacterial death by the release of metal ions and generation of ROS via destruction of cell membranes and DNA damage, observed as antibacterial effects of Fe$_3$O$_4@$copper (II) metal-organic framework core-shell magnetic microspheres and Ru$_2$O$_3$ nanocomplexes. Furthermore, it is important to also note that these metal ions possibly trigger these toxic effects on cells via a coordinated Haber-Weiss reaction, Fenton reaction, or Fenton-like reaction in which all three reactions yield hydroxyl radicals that adversely affect bacterial cells. The nanomaterials in these cases serve as powerful catalysts by enhancing ROS production through any of the above-mentioned pathways.

Figure 1 Schematic illustration showing some toxic effects of metal ions from NPs.
Several key factors have been identified that influence the generation of ROS and hence the evident toxicity exhibited by some nanomaterials. These factors include solubility, shape, size, oxidation status, surface area, surface coating, surface species, and the degree of agglomeration and aggregation of a nanomaterial. These chemical and physical factors can to a great extent influence the mode of action of these NPs in terms of how they are able to enhance catalytic properties by converting less-toxic oxidants into more-reactive free radicals, which in turn have destructive effects on bacteria, just as Ag⁺, Cu²⁺, and Zn²⁺ exert bactericidal properties by inducing the generation of ROS. Furthermore, when in aqueous solution, multicomponent metal ions act synergistically to produce increased antibacterial effects than single metal ions in solution. This increased synergistic effect occurs as a result of Fenton reactions and ROS production via electron transfer in enzymes.

Recently, the concept of metal ion release has been incorporated into antimicrobial-based biomedical applications. For example, ionic solutions/colloidal suspensions of metallic NPs of Ag, Cu, and Li were incorporated into some dental materials, and the resulting metal ions had an antibacterial effect on Staphylococcus aureus (S. aureus). Other application include pit and fissure sealants designed with antibacterial properties, wound healing, improved disinfection materials, implant technology, wound healing, improved disinfection materials, implant technology, and antibacterial-Ag/plasma polymer nanocomposites for cotton fabrics, among others. The antibacterial capabilities of Ag ions can be preserved while the harmful effect on biological environment is reduced by synthesizing Ag with hydroxyapatite from phosphorus-deficient precursors using carbonate substitution, Ag containing calcium phosphate, and Ag NPs carriers of hydroxyapatite powder.

In general, the release of metal ions in aqueous solutions has been explored for quite exciting biomedical applications especially in antibacterial-based biodesigns.

NP Dissolution and Metal Ion Release

NP dissolution in either a biological system or in an aqueous medium results in the release of ionic species which can elicit bacteria toxicity via specialized pathways. Horie et al assessed the physicochemical properties of 24 metal oxide NPs and their cellular effects. They discovered that metal oxides which dissolved in media, such as ZnO, CuO, NiO, Sb₂O₃, CoO, MoO₃ and Gd₂O₃, released metal ions which caused detrimental cellular effects. Conversely, other metal oxide NPs which were barely able to dissolve in the media exerted very weak cellular effects. Interestingly, the authors discovered that Y₂O₃, a metal oxide NP which released metal ions in solution and also expressed increased ROS levels, showed no level of toxicity toward cells. Schiavo et al also reported similar findings with zinc oxide (ZnO) NPs toward three marine organisms: Dunaliella tertiolecta, Vibrio fischeri, and Artemia salina. They however discovered that the toxicity of ZnO toward these organisms was a result of Zn²⁺ release and also the ZnO particles themselves, but the toxicity level was dependent on the exposure time. The particular physicochemical properties of NPs must be considered when assessing the exact bactericidal mechanism of a given NP. It is also noteworthy that although metal ion release arising from NP dissolution cannot solely be used to explain bactericidal properties of metal/metal oxide NPs, many NPs’ toxicity is greatly accelerated by dissolution. For example, Xia et al assessed the toxicity mechanism of ZnO and cerium oxide NPs and focused on their dissolution and oxidative stress properties; they clearly described how the key mechanism of ZnO toxicity greatly depended on its excellent dissolution property.

NP dissolution plays a very interesting role in the release of metal ions in biological environments. This concept is instrumental in releasing toxic metal ions to kill bacteria or other pathogens as evidenced by several reported findings (Figure 2). Furthermore, understanding the kinetics of NP dissolution can be very useful in designing safe NPs, and also in describing the etiology of some occupational health-related issues. For example, the dissolution property of ZnO was linked to pulmonary toxicity in zinc fume fever in welders. Similarly, the toxicity and biopersistence of carbon nanotubes can be reduced by improving their solubility through a surface functionalization process with polyethylene glycol. Interestingly, it was observed that the shedding of Zn²⁺, Cu²⁺, Cd²⁺, and Ag⁺ during intracellular dissolution can trigger mitochondrial perturbation, lysosomal damage, calcium flux, cytoskeletal alterations, oxidative stress, and cell death. In general, when released in solution, these ions can either be endocytosed by bacteria, be adsorbed onto the surface of the NPs, or undergo hydrolysis which yields insoluble metal hydroxides. These actions would directly or indirectly result in disruption of bacterial cellular processes through halting cell wall synthesis, disintegrating bacterial membranes, disrupting biofilms, destabilizing ribosomes, degrading DNA, peroxidizing lipids, or by disrupting membrane permeability.
Wang et al reported that NP dissolution, adsorption, and hydrolysis are key factors which are likely to influence how metal ions are released by metal oxide NPs (Figure 3). According to that study, the concentration of NPs in solution is initially correlated with the released metal ion concentrations; however, the free metal ion

**Figure 2** Illustration of possible NP toxicity mechanisms.

**Figure 3** Schematic illustration of NPs dissolution, adsorption and hydrolysis. Reprinted from J Hazard Mater, 308, Wang D, Lin Z, Wang T, et al. Where does the toxicity of metal oxide nanoparticles come from: the nanoparticles, the ions, or a combination of both? 328–334, Copyright (2016), with permission from Elsevier.
concentrations in the media at some point becomes limited via a hydrolysis process by the formation of insoluble metal hydroxides. Furthermore, the study showed that when the concentration of NPs in a medium is low, more metal ions are released, because dissolution is increased, but with a higher NP concentration, NP adsorption tends to occur and metal ions are adsorbed onto the surface of the NPs, thereby leading to a decline in available metal ions in the aqueous medium. It was observed by Wang et al that when the CuO NP concentration exceeded 180 mg/L, there were declines in both free Cu$^{2+}$ in the supernatant and the resultant antibacterial activity. In a related study, Baek et al while studying the effects of free ions released by a group of NPs in liquid media, discovered that the dissolution rate of the NPs in the aqueous medium decreased with an increase in the NP concentration; this they attributed to aggregation of the NPs in the medium. Given that the modes of bactericidal effects of some NPs still remain unclear, any study to assess the bactericidal mechanisms of NP dissolution, adsorption, or aggregation properties must be carefully designed to consider other physicochemical properties which also influence the release of metal ions from NPs in biological media.

NP Size/Surface Morphology and Metal Ion Release

NP surface morphology, size, surface area, surface coatings, and the degree of aggregation and agglomeration were identified as some factors that can determine the rate of ROS generation and toxicity of a nanomaterial (Figure 4). Several studies tried to explain how the size and surface morphology affect particle dissolution. For example, some studies reported that particles of different sizes and shapes of the same material at an equivalent dissolved solute concentration dissolved at different rates. NP dissolution is a dynamic process defined by the migration of dissolving NPs

![Figure 4 Schematic representation of several factors that can influence NPs behavior in solutions. Reprinted from Sci Total Environ, 438, Misra SK, Dybowska A, Berhanu D, et al. The complexity of nanoparticle dissolution and its importance in nanotoxicological studies. 225–233. Copyright 2012, with permission from Elsevier.](https://doi.org/10.2147/IJN.S328767)
The diffusion layer is simply an interface between the NP surface and the aqueous environment. This layer is very important because in addition to the intrinsic solubility of the NPs, dissolution also depends on the concentration gradient that exists across this layer. In other words, as the concentration in the aqueous solution reaches equilibrium, the dissolution process decreases and hence metal ion release declines. The kinetics of NP dissolution in aqueous medium can be described using the Noyes-Whitney equation. This equation shows that the dissolution rate constant is dependent on the surface area of the NP. It was reported that a decreasing particle size is directly proportional to a decrease in the thickness of the diffusion layer, hence solvated molecules move faster throughout the bulk solution. In other words, with a larger surface area morphology, faster dissolution of NPs is expected as a result of a thinner diffusion layer; however, with thicker diffusion layers, dissolution will be slower. This can contextually explain why snowflake ZnO particles seem to be the most active when compared to other ZnO morphologies. ZnO nanocrystals with a hexagonal plate-like morphology showed better activity than those with a rod-shaped morphology. Similarly, Cha et al also reported that when compared to nanoplates and nanospheres, ZnO nanopyramids showed superior antibacterial activity against methicillin-resistant Staphylococcus aureus (MRSA).

Those studies provide clues as to how different NP morphologies can influence antibacterial activity. Dissolution studies alone cannot satisfactorily be used to explain why some morphologies of NPs exert greater antibacterial effects than others or why NPs that are smaller in size have higher antibacterial activity than larger ones. This is because not all NPs show good dissolution characteristics in aqueous media, yet these NPs show bactericidal properties. In other words, for less-soluble NPs, other factors with or without metal ion release can contribute to their toxicity and ability to generate ROS (Figure 5). Other critical factors which were also identified include the presence of

![Figure 5 Schematic illustration of some NP characteristics capable of inducing ROS and subsequent bacteria death.](https://doi.org/10.2147/IJN.S328767)
surface defects on the nanostructure of the NPs and the energy stability of the NP planes. According to those studies, surface defects on the NP nanostructure increases the surface area-to-volume ratio which influences ROS generation, whereas analysis of exposed facets (which explains why less-stable planes require less energy to form oxygen vacancies) was utilized to link the bactericidal effects of some NP to the stability of planes.

NP Charge and Metal Ion Release

It was also observed that the degree of electrostatic interaction between the NP and bacterial surface can also influence the bactericidal effects. It was reported that positively charged NPs can alter the function of the bacterial electron transport chain. In a study where TiO$_2$ and gold (Au) NPs were surface-modified, greater toxicity toward microbial cells was observed. The NPs of Ag and Zn for example are known to exert their bactericidal effects by the respective release of Ag$^+$ and Zn$^{2+}$. These positively charged ions are electrostatically attracted to negatively charged lipopolysaccharide (LPS) in bacterial cell walls causing disruption of the electrochemical gradient across the bacterial membrane leading to cell death. Ag$^+$, for example, can interact with sulfhydryl groups in microbial cells making them dysfunctional, which in turn can lead to cell death. Furthermore, exposure of bacteria to positively charged NPs can generate ROS which induce oxidative stress in bacteria. In order to predict the electrostatic behavior of an NP toward an organism, it is vital to consider the NP’s point of zero charge. This point of zero charge is defined as the pH at which the charge on the surface of the NP becomes neutral. For example, at a pH value which is below the NP’s point of zero charge, a metal oxide NP has a positively charged surface, whereas at a pH value above this point of zero charge, the NP has a negatively charged surface. This is very important when predicting antibacterial effects of an NP, because positively, neutrally, and negatively charged NPs respectively

![Figure 6](https://doi.org/10.2147/IJN.S328767)

**Figure 6** Schematic illustration of point of zero charge/NPs surface charge affects NPs bactericidal effects.
exhibit strong, medium, and low bactericidal effects (Figure 6).

The pH value of the environment in which the NP exists was shown to influence the bactericidal outcome of the NP. Wang et al reported that ZnO NPs exhibited excellent dissolution properties at lower pH values. In other words, Zn$^{2+}$ was rapidly released in aqueous media whose pH was acidic than in neutral and alkaline solutions. Similarily, Bian et al earlier described how a lower pH favors high dissolution and hence metal ion release. However, MgO and CaO were found to exert very strong bactericidal characteristics at very high pH conditions. Dong et al showed that at pH 10, a Mg (OH)$_2$ NP suspension triggered strong bactericidal effects on E. coli, the same was also observed with a Ca(OH)$_2$ suspension. The high alkalinity of MgO and CaO which results in their strong bactericidal properties could be linked to their instability in water, which leads to the formation of the hydroxides, Mg(OH)$_2$ and Ca(OH)$_2$, in the presence of water, hence, reactive oxygen species are easily generated and are toxic to bacteria.

**Metal Ions Release and Infection Sites**

One of the recent bioapplications of metal ion release is in the design of pit and fissure sealants which yielded high fluoride ion release and a strong antimicrobial performance. Fei et al reported a very good antibacterial effect against *Streptococcus mutans* (*S. mutans*) biofilms from a pit and fissure sealant which was designed by combining calcium fluoride NPs and dimethylaminohexadecyl (DMAHDM). This combination yielded more ions, increased biofilm pH, and improved antibacterial action against *S. mutans* biofilms compared to existing commercial units, hence making it a promising dental material for dental caries prevention. Similarly, Zhou et al also reported a multifunctional composite containing DMAHDM and amorphous calcium phosphate NPs as a dental material against recurrent dental caries. This composite inhibited the growth of *S. mutans* biofilms, and yielded less enamel demineralization and good enamel hardness. Furthermore, Rawashdeh et al incorporated an ionic solution/colloidal suspension of metallic NPs of Ag, Cu, and Li with some dental materials and tested the resulting antibacterial effect on *S. aureus*. They reported a dental material-dependent antibacterial outcome. The metal ion-incorporated dental materials showed high antibacterial effects which were attributed to the release of Ag$^+$, Cu$^{2+}$, and Li$^+$ metal ions from the dental materials.

Kumar et al also reported fabrication of polyvinyl alcohol- and CS-loaded AgNP hydrogels with good mechanical strength, antibacterial properties, and biocompatibility for wound dressings. The material showed good inhibition toward *S. aureus* and *E. coli*. Li et al showed that silver NP-loaded collagen chitosan (CS) dressing (AgNP-CCD) can yield excellent antibacterial effects and play a good role in the healing of a second-degree burns. In that study, AgNP-CCD showed an antibacterial rate of >99% against *E. coli*, *Sta. aureus*, and *Pseudomonas aeruginosa* when the concentration of silver NPs exceeded 0.3 mg/cm$^2$. Similarly, Paterson et al reported the use of copper-containing mesoporous glass NPs with antibacterial and proangiogenic effects for chronic wounds. The efficacy of this material was attributed to the release of Cu$^{2+}$ ions which showed both proangiogenic and antibacterial properties.

The concept of metal ion release was incorporated into the design of implants with improved bactericidal properties. Hengel et al explored the synergistic antibacterial capabilities of Ag and Cu NPs by functionalizing TiO$_2$ surfaces with those NPs. They observed a 10-fold reduction in the concentration of silver ions while sustaining the same level of antibacterial activity on MRSA. Their work sheds light on how the synergistic antibacterial properties of some metal ions can be harnessed to design more-biocOMPATIBLE implants with efficient antibacterial effects. It was also observed that reinforcing alloys with silicon carbide (SiC) which is hemocompatible and biocompatible and has good antibacterial qualities, can be very useful in improving the performance of some medical equipment. Javadhesari et al showed that TiCu/SiC nanocomposites showed good bactericidal effects against *E. coli* and *S. aureus*. This observed bactericidal effect was due to the release of Cu$^{2+}$ which was directly proportional to the amount of SiC. At the end of this part, we have collected recent achievements by the uses of metal ion release in antibacterial applications as shown in Table 1.

**Photodynamic Antibacterial Activity**

**Overview of Photodynamic Therapy**

Light-activated materials have long been in use to treat diseases, and for the past 100 years, this has been called photodynamic therapy (PDT). PDT needs two elements to be functional: light and a material or chemical entity that can be sensitized by ultraviolet (UV) or visible regions of the electromagnetic spectrum of light irradiation. The mechanism of action is characterized by two kinds of oxygen molecules: the triplet state of oxygen (type I reaction mechanism) and the singlet state of oxygen (type II
The mechanism of action of Ag/ZnO nanocomposites under visible light irradiation is the creation of oxygen vacancies on ZnO NPs to produce H$_2$O$_2$, and this was enhanced by combining with silver NPs. Oxygen from the atmosphere is absorbed onto the oxygen-vacant surface of the nanocomposite that bears electrons which react to produce superoxide radicals ($O_2^-$). $O_2^-$ undergoes a reaction with water (H$_2$O) to form hydroperoxyl radicals (HO$_2^-$), and two HO$_2^-$ molecules combine again to produce H$_2$O$_2$ in a cyclically repeating process. H$_2$O splits into H$^+$ and OH$^-$ ions, and OH$^-$ ions generate hydroxyl (OH) radicals (Figure 8). Electron paramagnetic resonance (EPR) studies validated the above-proposed mechanism for the efficient photocatalytic antibacterial activity of Ag/ZnO nanocomposites. Furthermore, the rupture of cell membranes of both gram-positive and gram-negative bacteria is due to the destruction of the lipid layer by peroxidation after ROS are generated as determined by lipid peroxidation assays. Ag/ZnO nanocomposites were effective and promising antibacterial agents under visible light irradiation compared to bare ZnO.

Recently, Mutalik et al reported that titanium dioxide-iron disulfide (TiO$_2$-FeS$_2$) nanocomposites are an efficient photocatalyst for antibacterial applications. The

**Table 1 Summary of NPs and Their Reported Mechanisms of Toxicity**

| Nanomaterial | Mechanism of Toxicity | Reference |
|--------------|------------------------|-----------|
| Ag$_2$O     | Metal ion release, direct contact with the bacterial cell envelope, ROS generation | [52] |
| CuO         | Metal ion release, direct contact with the bacterial cell envelope, ROS generation | [52,114] |
| Cu$_2$O     | Metal ion release, direct contact with the bacterial cell envelope, ROS generation | [52,114] |
| Al$_2$O$_3$ | Direct contact with the bacterial cell envelope, ROS generation | [52] |
| NiO         | Metal ion release, ROS generation | [77] |
| MoO$_3$     | Metal ion release, ROS generation | [77] |
| WO$_3$      | Metal ion release, ROS generation | [77] |
| Y$_2$O$_3$  | Protein adsorption ability, ROS generation | [77] |
| Co$_3$O$_4$ | Effect from nanoparticles | [90] |
| Cr$_2$O$_3$ | Effect from nanoparticles | [90] |
| MgO         | Direct contact with the bacterial cell envelope, ROS generation, high alkalinity | [111] |
| CaO         | Direct contact with the bacterial cell envelope, ROS generation, high alkalinity | [112] |
| ZnO         | Metal ion release, direct contact with the bacterial cell envelope, ROS generation | [115–117] |
| Fe$_3$O$_4$ | Metal ion release, ROS generation | [118,119] |

**Abbreviations:** Ag$_2$O, silver oxide; ZnO, zinc oxide; Fe$_3$O$_4$, iron(III) oxide; CuO, copper (II) oxide; Cu$_2$O, copper (I) oxide; Al$_2$O$_3$, aluminum oxide; MgO, magnesium oxide; CaO, calcium oxide; NiO, nickel oxide; MoO$_3$, molybdenum trioxide; WO$_3$, tungsten trioxide; Y$_2$O$_3$, yttrium (III) oxide; Co$_3$O$_4$, cobalt tetraoxide; Cr$_2$O$_3$, chromium (III) oxide.
mechanism of action of the photocatalytic antibacterial activity is based on the conversion of anatase titanium dioxide to rutile titanium dioxide NPs by combining iron sulfide nanocrystals to form TiO$_2$-FeS$_2$ nanocomposites, which also expands the absorption of the nanocomposite from the UV region to the visible-near infrared (NIR) region of the electromagnetic spectrum. The bandgap of FeS$_2$ is 0.95 eV and that of TiO$_2$ is 3.2 eV when combined and irradiated with simulated solar light, and due to the reduction in the bandgap of TiO$_2$, there was a substantial increase in the photocatalytic property which was shown to be effective in bacteriostasis against *E. coli*. The facile transfer of electrons from the valence band to the conduction band in TiO$_2$-FeS$_2$ nanocomposites effortlessly generates ROS to produce an efficient antibacterial effect. The TiO$_2$ in TiO$_2$-FeS$_2$ nanocomposites was observed to intensify the absorption of the visible region of light from the UV region of the electromagnetic spectrum to produce light-prompted ROS radicals like O$_2^-$ and OH (Figure 9). The O$_2^-$ and OH radicals generated from TiO$_2$-FeS$_2$ nanocomposites were effective in inhibiting *E. coli*, compared to their counterparts used in those studies, by causing damage to the microbial cell envelope.$^{133–138}$

Nanocomposites of Ag-ZnO-magnetite (F$_3$O$_4$) showed better photocatalytic abilities for antibacterial applications under light-emitting diode (LED) irradiation.$^{139}$ An Ag-ZnO-F$_3$O$_4$ nanocomposite was synthesized using a green method. The reported mechanisms by which ROS are generated include the effective influence of the Fenton reaction of magnetite and SPR of silver under LED light irradiation, and these ROS substantially damage bacterial cell walls. In Figure 10, the SPR effect of silver and silver combined with ZnO induce the production of superoxide radicals and narrows the bandgap of ZnO for swift and easy electron transfer from the valence band to the conduction band of ZnO. The effortless heterojunction transfer of electrons with magnetite facilitates the easy generation of hydroxyl radicals under LED light illumination. The O$_2^-$ and OH radicals produced by the Ag-ZnO-F$_3$O$_4$ nanocomposite under LED light irradiation were efficient
in inhibiting MRSA and *Sta. epidermidis*. Electrons and hole pairs are enhanced, and $\text{H}_2\text{O}_2$ is the end product of the Ag-ZnO-F$_3$O$_4$ nanocomposite due to the presence of silver, which in turn enhances the antibacterial efficiency. The Fenton reaction generated OH radicals to support and enhance the bacterial inhibition under LED irradiation for 3 h.\textsuperscript{140–145}

Nanocomposites of Ag NPs and bismuth vanadium tetraoxide (BiVO$_4$) nanosheets cultivated on the surface of silver vanadium trioxide (AgVO$_3$)-(Ag@AgVO$_3$/BiVO$_4$) showed elevated photocatalytic efficiency against rhodamine B dye, *E. coli*, and *Sta. aureus* under simulated solar light irradiation.\textsuperscript{146} Figure 11A–C exhibit a general proposal for a mechanism to eliminate bacteria under visible light irradiation. In Figure 11A, the SPR effect of Ag NPs is showcased as a primary cause of the antibacterial effect under visible light irradiation. In Figure 11B, after combining and arranging Ag NPs with BiVO$_4$ and AgVO$_3$, the photocatalytic efficiency improved under visible light irradiation. In Figure 11C, the Z-scheme arrangement of Ag@AgVO$_3$/BiVO$_4$ nanocomposites showed improved light-activated antibacterial activity by generating active $\text{O}_2^-$ and OH radicals under visible light irradiation, that was not possible in the former arrangement of Ag@AgVO$_3$/BiVO$_4$ nanocomposites. An increase in the concentration of Ag@AgVO$_3$/BiVO$_4$ nanocomposites also showed an improvement in the photo-activated antibacterial effect. Under light irradiation, the Ag@AgVO$_3$/BiVO$_4$ nanocomposite (molar ratio=0.2) and z-scheme arrangement produced microbial cell wall destruction of *E. coli* and *Sta. aureus* and dye degradation.\textsuperscript{147–152}

Recently, ZnO-selenium (Se) nanocomposites showed effective photocatalytic activity in antibacterial applications under visible light irradiation.\textsuperscript{153} Figure 12 shows penetration of the cell envelope of the pathogen *Sta. aureus*, the impairing mechanism by ZnO-Se nanocomposites under visible light irradiation due to ROS generation, and a biological pathway. Furthermore, ZnO-Se nanocomposites were found to be more efficient against *Sta. aureus* compared to ZnO NPs alone, as evaluated by the zone of

**Abbreviations:** VB, valence band; CB, conduction band; SPR, surface plasmon resonance.
inhibition which was found to be significantly greater in the case of ZnO-Se nanocomposites under visible light irradiation. Moreover, bacterial cell death by selenium is believed to be internally induced by proteins, and ROS generated by ZnO cause substantial rupture of microbial cell walls under visible light irradiation.\textsuperscript{154–157}

**Carbon-Based Nanocomposites**

In Figure 13, nanocomposites of graphitic carbon nitride/chromium (g-C\textsubscript{3}N\textsubscript{4}/Cr)-ZnO showed exceptional photocatalytic properties in antibacterial applications.\textsuperscript{158} Under simulated solar irradiation, g-C\textsubscript{3}N\textsubscript{4}/Cr-ZnO nanocomposite showed an improved photocatalytic mechanism by reducing the bandgap and improved electron-hole regeneration to generate ROS to eradicate bacteria by substantially damaging bacterial cell walls.\textsuperscript{159–161} g-C\textsubscript{3}N\textsubscript{4}/Cr-ZnO nanocomposites at 60\% resulted in more-efficient inhibition of *E. coli*, *Sta. aureus*, *Bacillus subtilis*, and *Str. salivarius* compared to its 60\% g-C\textsubscript{3}N\textsubscript{4}/ZnO, 5\% Cr-ZnO, g-C\textsubscript{3}N\textsubscript{4}, and ZnO counterparts under visible light irradiation. The photogenerated holes and electrons react with oxygen and water molecules present on the surface of the g-C\textsubscript{3}N\textsubscript{4}/Cr-ZnO nanocomposite to generate $\text{O}_2^-$ and OH radicals. The ideal separation of electron-hole pairs and also less dense g-C\textsubscript{3}N\textsubscript{4} sheets induce effortless electron transfer from the valence band to the conduction band for effective generation of ROS under visible light irradiation.\textsuperscript{160,162} The g-C\textsubscript{3}N\textsubscript{4}/Cr-ZnO nanocomposite exhibited better photocatalytic performance under visible light irradiation, and the increased existence of electron-hole pairs enhanced ROS generation to eliminate bacteria and also degrade organic dyes responsible for pollution.

A recently reported copper sulfide-conjugated protonated C\textsubscript{3}N\textsubscript{4} (CuS/PCN) composite showed enhanced antibacterial activity under the dual effects of visible light irradiation and a photothermal effect.\textsuperscript{163} The antibacterial mechanism of CuS/PCN was observed against both gram-positive and gram-negative bacteria under visible light irradiation. In Figure 14, the mechanism of ROS
generation under visible light irradiation is demonstrated. CuS and PCN form heterojunctions for the effortless transfer of electrons, and this combination reduces the bandgap. Electron transfer from the valence band to the conduction band facilitates charge separation in CuS/PCN composites under visible light irradiation. The adsorbed atmospheric oxygen molecules on both CuS and PCN during electron transfer are changed into $\text{O}_2^-$ and OH radicals under visible light irradiation causing observable destruction of microbial cell membranes. The lower bandgap of CuS influences the higher bandgap of PCN to enhance the photocatalytic properties and production of ROS from CuS/PCN composites under visible light irradiation. Electron spin resonance (ESR) studies confirmed and validated the photodynamic ROS production from CuS/PCN composites. The photoactive CuS/PCN composite had effective bacteriostatic properties against both *Sta. aureus* and *E. coli*.

Figure 15A and B explain the mechanistic pathway for the generation of ROS and components that induce effective ROS generation under visible light irradiation. In Figure 15A, two Ag$_3$PO$_4$ and ZnO nanohybrid composites are involved in generating desired radicals which cause substantial microbial cell wall damage (Figure 15B). ZnO NPs generate electrons and are transferred at heterojunctions with their partner Ag$_3$PO$_4$ NPs that in turn generate $\text{O}_2^-$ radicals under visible light irradiation and adsorb surface atmospheric oxygen. Ag$_3$PO$_4$ NPs in combination with ZnO NPs in FSZA2-10% microspheres generate electron holes to form...
OH radicals under visible light irradiation. In FSZA2-10% microspheres, Ag$_3$PO$_4$ and ZnO nanohybrids showed better electron-hole separation, and there was a narrowing of the valence band and conduction band for easy electron transfer and electron-hole generation at heterojunctions of Ag$_3$PO$_4$/ZnO which effectively produced ROS under visible light irradiation. Overall, FSZA2-10% microspheres were effectively photoactive leading to bacterial cell membrane damage in Sta. aureus and E. coli under visible light irradiation and showed effective bacteriostasis for up to six cycles of reuse.\textsuperscript{169–172}

Nanocomposites of Ag/Ag$_3$PO$_4$ were combined with MOFs (MOF-5 or IRMOF-1), and a zinc-based MOF was synthesized by a hydrothermal process followed by a liquid chemical reduction method for antibacterial application under visible light irradiation.\textsuperscript{173} In Figure 16, the mechanistic pathway is functionalized by three components of Ag, Ag$_3$PO$_4$, and IRMOF-1, and showed enhanced photocatalytic efficiency in producing bactericidal properties against E. coli and S. aureus. Nanocomposites of Ag/Ag$_3$PO$_4$-IRMOF-1 radiated with light for 2 h at a concentration 200 µg showed complete inhibition of gram-positive and gram-negative bacteria. In Ag/Ag$_3$PO$_4$-IRMOF-1 nanocomposites, Ag operates through the SPR effect leading to the formation of synergistic electrons which are directly supplied to the IRMOF-1 surface to activate ROS production to generate O$_2^{-}$ radicals and electron-holes generated by Ag$_3$PO$_4$ under simulated light irradiation. Ag/Ag$_3$PO$_4$-IRMOF-1 showed sustained release of Ag$^+$ and Zn$^{2+}$ ions under light irradiation to eliminate E. coli and Sta. aureus by disrupting their cell walls. To sum up, Ag/Ag$_3$PO$_4$-IRMOF-1 nanocomposites were efficient at photo-actively inhibiting E. coli and S. aureus under visible light irradiation compared to their counterparts.\textsuperscript{174–179} In Table 2, we have summarized several examples according to light-driven nanomaterials for antibacterial applications.
Photothermal Therapy

Overview of Photothermal Therapy

Among multiple methods developed as an alternative way to fight bacterial infections in response to antibiotic resistance, PTT occupies a prominent place. When photo-responsive agents are activated with a convenient NIR laser, the surface plasmon band leads to the conversion of electromagnetic radiation to heat. The resulting heat can reach temperatures able to destroy bacterial cells. The photothermal effect results in membrane damage followed by protein inactivation and/or leakage leading to bacterial death. PTT against bacteria is efficacious on both gram-positive and gram negative types and regardless of antibiotic resistance. In addition to its efficiency, it is fast, noninvasive, and can be modulated by the laser intensity and time of irradiation. More interestingly, PTT can be combined with other therapies such as PDT, chemotherapy, radiotherapy, and so on for better treatment results. Therefore, multiple photothermal NPs or nanostructures are being developed to eradicate bacterial infections. These photothermal NPs are also called PTAs and are grouped into five categories of metals, metal sulfides, oxides, carbon-based nanocomposites, small molecule-based nanomaterials, and polymeric nanomaterials. A set of transition metals and their oxide and sulfide forms can advantageously absorb more laser energy compared to inorganic PTAs. For instance, in our previous investigation of the photothermal effects on E. coli of gold nanorods (AuNRs) and gold nanobipyramids (AuNBPs), 100 µg/mL of AuNRs and 25 µg/mL of AuNBPs were used to kill E. coli with an efficiency of 100% after 808-nm laser illumination for 7 min.

The principle of antibacterial PTT is illustrated in Figure 17. Among the different approaches to reducing the heat effect with good efficiency, targeted delivery of PTAs, controlled release of PTAs, and combined therapy are described below.

Approaches for the Targeted Delivery of PTAs

Molybdenum disulfide (MoS$_2$) nanosheets are one of the nanomaterials with efficient photothermal performance. In addition to the efficiency, this nanomaterial can be stabilized when conjugated with other biomolecules. So, Wenbo Cao and colleagues fabricated molybdenum disulfide coated with polyethylenimine (MoS$_2$-PEI) by means of covalent bonds in order to evaluate their photothermal antibacterial
effect as illustrated in Figure 18. So, *S. aureus* and *E. coli* suspensions were mixed to different concentrations of 20–80 µg/mL of MoS$_2$, PEI, and MoS$_2$-PEI. After 10 min of irradiation under an 808-nm laser (1 W/cm$^2$), the mixture was incubated for 5 h and cultured on LB agar and then incubated at 37 °C overnight. In 10 min, a weight concentration of MoS$_2$-PEI at 80 µg/mL induced the temperature to increase to 67 °C. The intrinsic antibacterial effect of MoS$_2$ was better than that of PEI and reduced bacterial viability to 46.0% for *E. coli* and 45.6% for *S. aureus*. Meanwhile, inhibition rates of the MoS$_2$-PEI nanocomposite were 68.1% and 66.2%, respectively. Under NIR laser irradiation, the antibacterial effects of MoS$_2$ and PEI improved. MoS$_2$ reduced *E. coli* and *S. aureus* viability to 53.8% and 52.3%, respectively. By fluorescence microscopy, the synergistic effect of the MoS$_2$-PEI nanocomposite was proven using the live/dead method. The results revealed that upon NIR irradiation, MoS$_2$-PEI induced severe damage to bacterial membranes. This bactericidal effect could be attributed to the positive charge and the captive agent property of MoS$_2$-PEI.

Huajuan Wang and co-authors designed gold NPs (AuNPs) conjugated with a peptide and dimethylmaleic anhydride (Pep-DA) which they named Pep-DA/Au. Pep-DA/Au has a particular characteristic of being charge-convertible and can target bacteria. This synthesized nanocomposite has negative charges in normal physiological conditions of pH 7.4. But in a bacterial infection environment at pH 6.0, the DA is hydrolyzed by the acidity. In this situation, the amino groups on the peptide are displayed leading to a positive charge. So, the new Pep-DA/Au with positive charges can interact with negative charges of bacterial cell surfaces allowing the nanocomposite to attach to the bacteria. Under NIR laser illumination, the generated heat from the AuNPs will kill the bacteria and precisely minimize damage to surrounding tissues. The principle is shown schematically in Figure 19. In the SEM images of MRSA treated
with a control and Pep-DA/Au under irradiation and the bacteria cultured on agar plates after treatment, the survival rate of bacteria confirmed the efficiency of the anti-MRSA photothermal effect of the investigated nanocomposite. More interesting, in a mouse model, in vivo wound healing was evaluated and has provided consistent results compared to in vitro results.

Polymeric antimicrobials such as guanidine NPs can efficiently adhere to bacteria. This adhesion occurs through electrostatic bonds between the positive charges of polymeric antimicrobials and negative charges of bacterial cell walls.\textsuperscript{203,204} However, the drawback of cationic NPs is their interactions with protein corona once in the peripheral blood.\textsuperscript{205,206} To overcome this disadvantage, Congyu Wang and co-workers used a strategy based on charge reversal to design caged guanidine NPs (CGNs). These CGNs were synthesized through two main steps: first, preparation of amphiphilic diblock copolymers denoted P(GEMADA-co-DMA)-b-PBMA utilizing N,N-dimethylacrylamide (DMA), and 2-aminoethyl methacrylate hydrochloride (AEMA) and second, conjugation of the hydrophilic block (DMA) with dimethylmaleic anhydride (DA) for the final P(GEMADA-co-DMA)-b-PBMA as described in Figure 20.\textsuperscript{207} By means of confocal laser scanning microscopic imaging, CGNs were seen to effectively accumulate in bacterial biofilms. Under NIR irradiation, CGNs revealed about a ~40.9% photothermal conversion efficiency. They were also an efficient treatment in mouse models with catheters infected with \textit{Sta. aureus} biofilm where they exhibited a 99.6% bacteria inhibition ratio. The mechanisms of nanocomposite preparation and bacterial killing are given in Figure 20.

To combat food-borne diseases, Shimayali and colleagues developed a nanocomposite for rapid bacterial detection and NIR laser-reinforced antibacterial activity. Graphene oxide (GO), polyethylene glycol (PEG), gold NPs (AuNPs), and specific bacterial antibodies (Abs) were used to design a composite called Ab-PEG-GO-AuNPs. GO with multiple functional groups on its surface, such as carboxyl, epoxy, and hydroxyl, facilitates diverse functionalization of the surface.\textsuperscript{208,209} Due to the presence of the Abs and AuNPs, the designed nanoprobe was able to combine bacterium-specific targeting and photothermal ablation properties as summarized in Figure 21.\textsuperscript{210} \textit{E. coli} and \textit{S. typhimurium} as food-borne bacteria were used to test the specificity through colorimetric detection. The results confirmed the performance of this investigated nanoprobe in terms of specificity and color change. Using bicinchoninic acid and fluorescence methods, the amount of Ab functionalized with PEG-GO-AuNPs was greater than that on PEG-AuNPs. That is why the limit of
Figure 15 (A) Schematic representation of antibacterial mechanism of Fe$_3$O$_4$@SiO$_2$@Ag$_3$PO$_4$/ZnO-10% (Ag$_3$PO$_4$-10 wt%) (FSZA2-10%) microspheres under visible light irradiation and (B) bacterial cell wall damage by ROS generation. visual detection was ten-fold higher for GO-PEG-GO-AuNPs compared to PEG-AuNPs. The results showed that the GO coating of the AuNPs enhanced the photothermal performance with a rise in temperature of up to 76 °C under 808-nm laser irradiation for 30 s. As to the photothermal ablation of bacteria, results showed effective bacterial killing up to 95% within 15 min.

**Approach of the Controlled Release of PTAs**

One of challenges with antibacterial treatment is the efficient delivery of drugs into sites of infection. Biomimicry, in situ polymerization and porous nanomaterial techniques are some of methods to resolve this issue. The uses of nanomaterials as nanocarriers are rapidly cleared by the immune system, thereby reducing the treatment efficiency. The biomimicking technique uses specific cell membranes such as red blood cells (RBCs), macrophages, and platelets, and stem cells in drug biomimization to bypass the immune system. RBC membranes (RBCMs) possess immunomodulatory markers, and their use as nanomaterial camouflage improves the circulation time of NPs in the body. With this logic Luoxiao Ran and co-authors designed a biomimic nanoantibiotic using gentamicin (GM), gold-silver (AuAg) alloy NPs, polydopamine (PDA), and RBCMs. This nanoantibiotic was named RBCM-NW-G, and a summary of its preparation and treatment under 808-nm NIR laser irradiation is given in Figure 22. The biomimic nanocomposite revealed photothermal performance, effective accumulation in

Abbreviations: CMN, carbon-based metallic nanostructure; Ag/PSCN, silver/phosphorus- and sulfur-doped carbon nitride; B-Bi₂O₃@BiOBr, core/shell- beta-bismuth oxide-doped bismuth oxybromide; Ag-BiFeO₃ nanocomposite, silver-doped spindle-like bismuth ferrite; Ag@AgCl-CA/SF, Ag@AgCl-cellulose acetate-doped silk fibroin composite film; Ag-TiO₂ nanocomposite, silver-doped titanium dioxide; VS₄/Ag₃WO₄ nanocomposite, silver tungstate-doped vanadium tetrasulfide nanoplate nanocomposite; Cd-Gd-doped nickel spinel ferrite nanoparticle, cadmium- and gadolinium-doped nickel spinel ferrite nanoparticle; RGO, reduced graphene oxide; Ag₃P₂O₇-FeTiO₃ heterostructure/glucos chitosan, silver phosphate and iron titanate heterostructure-doped glucos chitosan; I-ZnO-n, Iodine modified zinc oxide-nanomaterial; LED, light-emitting diode.
infected areas, and longer blood circulation times with good biocompatibility. With the synergistic effect of photothermal treatment, silver ions, and gentamicin, the prepared nanoantibiotic showed antibacterial potential highlighted in in vitro and mouse models against \textit{E. coli} and \textit{S. aureus}.

Xueqin Yang and co-workers produced a photothermal nanoantibiotic (PTNA) by means of oxidative polymerization of pyrrole and anionic vesicles formed from sodium bis-(2-ethylhexyl) sulfosuccinate (AOT). They examined the antibacterial and antibiofilm activities on multidrug-resistant (MDR) \textit{S. typhimurium}. The entire process is shown in schematic form in Figure 23. Bacterial death was confirmed in two ways; bacterial growth on agar plates was inhibited and scanning electron microscopy clearly showed bacterial membrane damage. PTNA

revealed an intrinsic antibacterial effect, with a reduction of *S. typhimurium* to $2\log_{10}$ (CFU/mL). However, after laser irradiation (at 1 W/cm$^2$ for 10 min), PTNA reduced the bacterial viability by $6\log_{10}$ (CFU/mL) confirming reinforcement of the antibacterial effect. Both effects were compared to a control and the nanocomposite without irradiation. The in vivo antibacterial potential of PTNA was also assessed in that work by determining the survival rate of mice that orally received 100 μL of $10^9$ CFU of *S. typhimurium*. Twenty-four hours later, the mice received treatment with phosphate-buffered saline (PBS), light irradiation, PTNA, and PTNA with light irradiation. Mice under treatment with light or PBS did not survive beyond day 6 or 5. Those treated with PTNA were alive beyond 6 days but did not reach day 15. However, 50% of mice treated with PTNA followed by irradiation under a 1064-nm laser (1 W/cm$^2$) for 10 min remained alive by day 15.

Patel and co-authors developed a nanocomposite consisting of AuNRs coated with mesoporous silica. This complex played a role of nanocarrier onto which the antituberculotic medicine, bedaquiline (BDQ), was loaded. The entire composite was wrapped in thermo-sensitive liposomes (TSLs) under the name GNR@MSNP@BDQ@TSL@NZX with NZX responsible for the bond between the nanocomposite and mycobacteria. This engineered nanomaterial possessed three interesting features: targeted delivery of a nanoantibiotic to mycobacteria due to the affinity between NZX and the bacterial surface; a synergistic effect from BDQ and PTT; and the remotely triggered release of a synthesized bacterial drug under an NIR laser. The designed nanoantibiotic was shown to be 20-times more efficient than an equivalent amount of the free drug against *M. smegmatis*. It induced 99.9% inhibition of intracellular mycobacteria in lung A549 cells. A schematic illustration is shown in Figure 24.

**Approach to Combinational Therapy**

Due to the heat effect of PTT, several strategies were developed to reduce the heat and also to include targeted synergistic therapies, deliver and control the release of PTAs, and regulate...

Black phosphorus (BP) is one of the attractive photosensitizers (PSs) for phototherapeutic applications. To develop a nanostructure with a synergistic effect, Aksoy and collaborators synthesized BP and AuNPs nano-composites to fight pathogenic bacteria especially E. faecalis in planktonic form and as a biofilm. The principle is summarized in Figure 25. They found that the photothermal antibacterial activity of the nanocomposite was better than those of BP and a nanocomposite without irradiation. By a densitometric method at a weight concentration of 128 μg/mL and under 808-nm NIR laser irradiation, the BP/Au nanocomposite inhibited the growth of E. faecalis. Moreover, the BP/AuNPs composite also inhibited E. faecalis biofilm formation with and without light irradiation to 58% and 33%, respectively. In view of this investigation, the antibacterial activity of nanocomposites was due to membrane damage, and photothermal and photodynamic effects. The membrane damage was due to BP/AuNPs disrupting bacterial membranes due to the sharp edges of the BP nanosheets through simple contact.

Amino-conjugated GO (AGO) nanosheets were fabricated by Bo-Yao Lu and co-authors to simultaneously exploit three properties: the natural power of AGO to cut bacteria, positive charges for bacterium targeting, and effective photothermal performance. With this synthesized nanoantibiotic, the antibacterial effect was investigated on S. mutans, the main cause of dental caries. The positive charge of AGO due to the presence of amino groups favored electrostatic attraction with bacterial cell surfaces possessing negative charges. With 30 min of incubation, 100 µg/mL of AGO killed 27% of the bacteria. Under NIR laser irradiation for 5 min, the synergistic effect from the three properties of AGO caused 98% bacterial death. An illustration of this engineered nanosheet is summarized in Figure 26.

Yingnan Liu and colleagues constructed a nanocomposite with antimonene nanosheets (AMNSs) incorporated in chitosan (CS) and named them CS/AMNSs hydrogels. CS can attach to bacteria via electrostatic forces, van der Waals forces, and hydrophobic interactions with cell membranes, and it also possesses an intrinsic antibacterial effect. Furthermore, the photothermal performance of AMNSs was confirmed under an NIR laser. In this design, the hydrogel acts as a carrier of the nanomaterials. CS-based hydrogels have various advantages such as low cost, biocompatibility, biodegradability, and an intrinsic antibacterial
The principle of this design is shown in Figure 27.231 The photothermal conversion efficiency of AMNSs was evaluated to be 45.2%. The synergistic antibacterial effect including capture, intrinsic antibacterial effect, and photothermal performance killed 97% of *E. coli* and 100% of *S. aureus*. In Table 3, we have collected several important studies based on the applications of nanomaterials for photothermal killing of bacteria.

**Challenges and Opportunities**

Recent advances in photothermal, photodynamic, and ion release antibacterial therapies using nanomaterials were brought together in the present review article. The nanostructures reported in these studies could soon be potential antibacterial candidates in food protection, water purification, and medicine. Metal, metal-polymer nanocomposites, bimetallic nanoparticles and polymer nanoparticles are...

Figure 26 Schematic illustration of natural and photothermal antibacterial effect of AGO based on its positive charge, natural cutting effect, and photothermal property.
promising antibacterial agents that can be harnessed for this purpose. The photothermal effects shown by the nanomaterials were presented by describing the mechanism of action and thermal efficiencies to show microbial inhibition in vitro and in vivo. Through their photothermal effect, the nanostructures affect the biological activities of bacteria to foster bacterial inhibition in addition to their enhanced thermal efficiencies under NIR light irradiation. The photodynamically active nanostructures recently investigated were demonstrated with their antibacterial mechanisms, ROS production abilities, and microbial inhibition under simulated solar light or similar light sources. Metal ion release is similar to photodynamic activity under dark conditions and completely depends on the dissolution and dissociation of metal nanostructures to produce ROS and show potential bacteriostatic and bactericidal effects. One of the crucial unanswered questions is clinical acceptance of these metallic nanostructures and their bacterial inhibition capacity (they are required to exhibit 4-log reduction or about 99.99% efficiency). Another crucial question is the cytotoxicity and biocompatibility of these metallic nanostructures which also remain unanswered. PTT can also be coupled with other therapies such as metal ion release, PDT, chemotherapy, radiation, and so on to improve treatment outcomes. Bacterial pestilences are likely to be the most frequent

International Journal of Nanomedicine

Publish your work in this journal

The International Journal of Nanomedicine is an international, peer-reviewed journal focusing on the application of nanotechnology in diagnostics, therapeutics, and drug delivery systems throughout the biomedical field. This journal is indexed on PubMed Central, MedLine, CAS, SciSearch®, Current Contents®/Clinical Medicine, Journal Citation Reports/Science Edition, EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit http://www.dovepress.com/testimonials.php to read real quotes from published authors.

Submit your manuscript here: https://www.dovepress.com/international-journal-of-nanomedicine-journal
