Abstract

Hierarchical models in Bayesian inverse problems are characterized by an assumed prior probability distribution for the unknown state and measurement error precision, and hyper-priors for the prior parameters. Combining these probability models using Bayes’ law often yields a posterior distribution that cannot be sampled from directly, even for a linear model with Gaussian measurement error and Gaussian prior. Gibbs sampling [3] can be used to sample from the posterior, but problems arise when the dimension of the state is large. This is because the Gaussian sample required for each iteration can be prohibitively expensive to compute, and because the statistical efficiency of the Markov chain degrades as the dimension of the state increases. The latter problem can be mitigated using marginalization-based techniques, such as those found in [13, 20, 25], but these can be computationally prohibitive as well. In this paper, we combine the low-rank techniques of [7] with the marginalization approach of [25]. We consider two variants of this approach: delayed acceptance and pseudo-marginalization. We provide a detailed analysis of the acceptance rates and computational costs associated with our proposed algorithms, and compare their performances on two numerical test cases—image deblurring and inverse heat equation.

1 Introduction

Inverse problems arise in a wide range of applications and typically involve estimating unknown parameters in a physical model from noisy, indirect measurements. In the applications that we are interested in, the unknown parameter vector results from the discretization of a continuous function defined on the computational domain and hence is high-dimensional. Additionally, the inverse problem of recovering the unknown parameters from the data is ill-posed: a solution may not exist, may not be unique, or may be sensitive to the noise in the data.

To set the context of our work and some notation, we consider a discrete measurement error model of the form

\[ b = Ax + \epsilon, \quad \epsilon \sim \mathcal{N}(0, \mu^{-1}I_M), \]  

where \( b \in \mathbb{R}^M \) denotes the measurements, \( A \in \mathbb{R}^{M\times N} \) is the discretized forward model, \( x \in \mathbb{R}^N \) is the unknown estimand, and \( \mu > 0 \) is the error precision. The inverse problem here seeks to recover the unknown \( x \) from the measurement \( b \).

\textsuperscript{§}Department of Mathematics, North Carolina State University, Raleigh, NC alexanderian@ncsu.edu
The statistical model eq. (1) implies that the probability density function for \( b \) is given by

\[
\pi(b \mid x, \mu) \propto \mu^{M/2} \exp \left( -\frac{\mu}{2} \left\| Ax - b \right\|^2 \right),
\]

where ‘\( \propto \)’ denotes proportionality. To address the ill-posedness, we also assume a Gaussian prior probability density function (akin to choosing a quadratic regularization function) of the form

\[
\pi(x \mid \sigma) \propto \sigma^{N/2} \exp \left( -\frac{\sigma}{2} x^\top \Gamma_{\text{prior}}^{-1} x \right).
\]

For convenience, we take the prior to have zero mean, but a nonzero mean can also be easily incorporated into our framework. Then, if we define \( \theta = (\mu, \sigma) \), through Bayes’ law we obtain the posterior density function of \( x \) conditioned on \( b \) and \( \theta \):

\[
\pi(x \mid b, \theta) \propto \pi(b \mid x, \mu) \pi(x \mid \sigma) \\
\propto \mu^{M/2} \sigma^{N/2} \exp \left( -\frac{\mu}{2} \left\| Ax - b \right\|^2 - \frac{\sigma}{2} x^\top \Gamma_{\text{prior}}^{-1} x \right).
\]

The maximizer of \( \pi(x \mid b, \theta) \) is known as the maximum a posteriori (MAP) estimator, which is also the minimizer of \(- \ln \pi(x \mid b, \theta)\). This, in turn, has the form of a Tikhonov regularization, thus establishing a connection between Bayesian and classical inverse problems.

The scaling terms in eq. (4) involving \( \mu \) and \( \sigma \) arise from the normalizing constant of the Gaussian measurement error and prior models. In the hierarchical Bayesian approach we will also treat \( \theta = (\mu, \sigma) \) as unknown. The a priori uncertainty about plausible values of \( \theta \) is quantified in the prior distribution with density \( \pi(\theta) \). For convenience, we assume that the precision parameters \( \mu \) and \( \sigma \) are independent and Gamma-distributed. Specifically, we assume

\[
\pi(\theta) = \pi(\mu) \pi(\sigma) \propto \mu^{\alpha_\mu - 1} \sigma^{\alpha_\sigma - 1} \exp(-\beta_\mu \mu - \beta_\sigma \sigma).
\]

Other choices are also possible and are discussed in [15, 26, 7] and elsewhere. Applying Bayes’ law again yields a posterior density function of \( x \) and \( \theta \) conditioned on \( b \):

\[
\pi(x, \theta \mid b) \propto \pi(x \mid b, \theta) \pi(\theta).
\]

The marginal distribution \( \pi(\theta \mid b) \) can be derived by integrating over \( x \); i.e., \( \pi(\theta \mid b) = \int_{\mathbb{R}^n} \pi(x, \theta \mid b) dx \). Explicit expressions for these distributions are provided in section 2.

The focus of this paper is on the problem of sampling from the posterior distribution \( \pi(x, \theta \mid b) \). In general, the full-posterior is not Gaussian and to explore this distribution the prevalent approach is to use Markov chain Monte Carlo (MCMC) methods [14]. Several MCMC algorithms have been treated in the context of inverse problems in recent literature, which we briefly review. Specifically, in [3], conjugacy relationships are exploited to define a Gibbs sampler, in which samples from the conditional densities \( \pi(\theta \mid b, x) \) and \( \pi(x \mid b, \theta) \) (which are Gamma- and Gaussian-distributed, respectively) are cyclically computed. There are two major drawbacks to this approach as \( N \to \infty \) [1]: first, the MCMC chain becomes increasingly correlated; and second, sampling from the conditional \( \pi(x \mid b, \theta) \) becomes prohibitively expensive. Thus as \( N \) increases, due to the first drawback, longer MCMC chains are needed in order to obtain a sufficient number of samples from \( \pi(x, \theta \mid b) \), and due to the second drawback, each MCMC sample is more expensive to compute.

To address the issue of degeneracy, an alternative to the Gibbs sampler is presented in [25], where a proposed state \( (x_*, \theta_*) \) is computed in two stages by first drawing \( \theta_* \) from a proposal distribution and then drawing \( x_* \sim \pi(x \mid \theta_*, b) \). The proposal \( (x_*, \theta_*) \) is accepted or rejected jointly using a Metropolis-Hastings step to obtain an approximate draw from the posterior \( \pi(x, \theta \mid b) \).
This approach, called the one-block algorithm \[25\], does not have the same degeneracy issues as the Gibbs sampler as \( N \to \infty \). However, it is can be expensive to implement when evaluating \( \pi(\theta \mid b) \) is computationally demanding and one still has to compute a sample from \( \pi(x \mid \theta^*, b) \) at every iteration. An alternative approach based on the Partially-Collapsed Gibbs sampler that was developed in [20] also suffers from high computational cost per iteration.

Several approaches exist for handling the computational cost. The approach taken in [7] is to precompute a low-rank approximation of the so-called prior preconditioned data misfit part of the Hessian. This low-rank representation allows efficient sampling from the conditional distribution, reducing the overall computational cost. When the forward operator \( A \) and the prior covariance matrix are diagonalized by the Fourier transform, algorithms such as the Fast Fourier Transform can be used effectively [5]. Other methods based on Krylov subspace solvers, e.g., Conjugate Gradient, have also been developed [17]. All of these approaches still suffer from the degeneracy issue as \( N \to \infty \).

The contributions of this paper are as follows. To tackle the two drawbacks of the Gibbs sampler, we combine the low-rank approach of [7] with the one-block algorithm of [25]. The use of a low-rank approximation defines an approximate posterior density function \( \hat{\pi}(x, \theta \mid b) \). In our first algorithm, which we call approximate one-block, \( \hat{\pi}(x, \theta \mid b) \) is used as a proposal for Metropolis-Hastings, with the proposal samples computed using the one-block algorithm. We propose two other variants of the one-block algorithm that make use of \( \hat{\pi}(x, \theta \mid b) \) within both the delayed acceptance [8] and pseudo-marginal [2] frameworks to obtain samples from the full posterior \( \pi(x, \theta \mid b) \). The proposed algorithms are fairly general in that any appropriate approximate posterior distribution can be used. We present theoretical results that provide insight into the acceptance rates and the performance of the algorithms. The main take away is that when the low-rank approximation is sufficiently close (in a sense that we make precise in section 4), the algorithms have similar behavior to the one-block algorithm.

The paper is organized as follows. In section 2 we present the hierarchical Gibbs sampler and discuss the infinite dimensional limit, presenting the result of [1] showing the degeneracy of hierarchical Gibbs as \( N \to \infty \). We then present the one-block algorithm of [25], which does not have the same degeneracy issues. In section 3 we present the new algorithms making only limited assumptions regarding the approximate full posterior distribution. In section 4 we provide a theoretical analysis of our proposed algorithms, making explicit use of low rank structure. The numerical experiments in section 5 include a model 1D deblurring problem which allows us to compare and contrast the various algorithms and a PDE-based example of inverse heat equation that demonstrates the computational benefits of our approaches. We summarize our work and discuss future research in section 6.

2 Review of MCMC Algorithms

In this section, we present two MCMC algorithms for background. The first method is known as hierarchical Gibbs and is standard. Its convergence characteristics serve as motivation for the second algorithm, which is known as one-block.

2.1 The Hierarchical Gibbs Sampler

Under our assumed model, we provide explicit expressions for the posterior and the marginal distribution. To obtain the expression for the posterior distribution, combine eq. (4) with eq. (5)
via eq. (6) to obtain
\[
\pi(x, \theta \mid b) \propto \mu^{M/2} \sigma^{N/2} \pi(x \mid b, \theta) \pi(\theta)
\]
\[
\propto \mu^{M/2} \sigma^{N/2} \pi(\theta) \exp \left(-\frac{\mu}{2} \|Ax - b\|^2 - \frac{\sigma}{2} x^\top \Gamma^{-1}_\text{prior} x\right),
\]
\[
\propto \mu^{M/2} \sigma^{N/2} \pi(\theta) \exp \left(-\frac{\mu}{2} b^\top b + \mu b^\top Ax - \frac{1}{2} x^\top \Gamma_{\text{cond}(\theta)} x\right)
\]
\[
= \mu^{M/2} \sigma^{N/2} \pi(\theta) \exp \left(-\frac{\mu}{2} b^\top b + \frac{\mu^2}{2} b^\top A \Gamma_{\text{cond}(\theta)} A^\top b\right) \times \exp \left(-\frac{1}{2} \|x - x_{\text{cond}(\theta)}\|^2 \Gamma_{\text{cond}(\theta)}\right),
\]
where \(x_{\text{cond}(\theta)} = \mu \Gamma_{\text{cond}(\theta)} A^\top b\) and \(\Gamma_{\text{cond}(\theta)} = \mu A^\top A + \sigma \Gamma^{-1}_\text{prior}\). It follows that the marginal distribution, \(\pi(\theta \mid b) = \int_{\mathbb{R}^n} \pi(x, \theta \mid b) dx\), is given by
\[
\pi(\theta \mid b) \propto \frac{\mu^{M/2} \sigma^{N/2} \pi(\theta)}{\sqrt{\det(\Gamma_{\text{cond}(\theta)})}} \exp \left(-\frac{\mu}{2} b^\top b + \frac{\mu^2}{2} b^\top A \Gamma_{\text{cond}(\theta)} A^\top b\right).
\]
Observe that the joint posterior density satisfies \(\pi(x, \theta \mid b) = \pi(\theta \mid b)\pi(x \mid \theta, b)\), where \(x \mid \theta, b \sim \mathcal{N}(x_{\text{cond}(\theta)}, \Gamma_{\text{cond}(\theta)})\).

We begin with the hierarchical Gibbs sampler of [3]. Our choice of prior eq. (3) for \(x\), and the hyper-prior eq. (5) for \(\theta = (\mu, \sigma)\), respectively, were made with conjugacy relationships in mind [16]; i.e., so that the ‘full conditional’ densities have the same form as the corresponding priors:
\[
\pi(\mu \mid x, \sigma, b) \propto \mu^{M/2 + \alpha_\mu - 1} \exp \left(-\frac{1}{2} \|Ax - b\|^2 - \beta_\mu\right) \mu, \tag{9}
\]
\[
\pi(\sigma \mid x, \mu, b) \propto \sigma^{N/2 + \alpha_\sigma - 1} \exp \left(-\frac{1}{2} x^\top \Gamma^{-1}_\text{prior} x - \beta_\sigma\right) \sigma, \tag{10}
\]
\[
\pi(x \mid \mu, \sigma, b) \propto \exp \left(-\frac{\mu}{2} \|Ax - b\|^2 - \frac{\sigma}{2} x^\top \Gamma^{-1}_\text{prior} x\right). \tag{11}
\]
Note that eqs. (9) and (10) are Gamma densities, while eq. (11) is the density of a Gaussian distribution. algorithm [11] follows immediately from eqs. (9) to (11) and is precisely the hierarchical Gibbs sampling algorithm of [3].

**Input:** Set \(x(0) = x_{\text{cond}}(\theta(0))\), and define \(K\) and burn-in period \(K_b\).

**Output:** Approximate samples from the posterior distribution \(\{x(t), \theta(t)\}_{t=K_b+1}^K\).

1. **for** \(t = 1\) to \(K\) **do**
2. \hspace{1em} Compute \(\mu(t) \sim \Gamma \left(\frac{M}{2} + \alpha_\mu, \frac{1}{2} \|Ax(t-1) - b\|^2 + \beta_\mu\right)\).
3. \hspace{1em} Compute \(\sigma(t) \sim \Gamma \left(\frac{N}{2} + \alpha_\sigma, \frac{1}{2} (x(t-1))^\top \Gamma^{-1}_\text{prior} x(t-1) + \beta_\sigma\right)\).
4. \hspace{1em} Compute \(x(t) \sim \mathcal{N}(x_{\text{cond}(\theta(t))}, \Gamma_{\text{cond}(\theta(t))})\), where \(\theta(t) = (\mu(t), \sigma(t))\).
5. **end**

**Algorithm 1:** Hierarchical Gibbs Sampler

The values of \(M\) and \(N\) are determined by the number of measurements and the size of the numerical mesh, respectively, making the problems discrete. Since \(M\) is the dimension of our measurement vector, we assume that it is a fixed value. However, we are free to choose \(N\) as we please,
and the behavior of our approaches as $N \to \infty$ is an important question. In what follows, we briefly discuss the infinite-dimensional limit, pointing the interested reader to the extensive treatments found in [28, 12] for more details.

Consider the linear inverse problem, which typically arises from the discretization of a Fredholm integral equation of the first-kind, for example

$$b(s) = \int_{\Omega} a(s; t)x(t)dt, \quad s \in \Omega,$$

where $b$ is the model output function, $\Omega$ is the computational domain, $a$ is the integral kernel or point spread function, and $x$ is the unknown which we seek to estimate. We define $A_Mx$ to be the forward operator discretized only in its range, so that $A_M : X \to \mathbb{R}^M$, where $X = C(\bar{\Omega})$, and $\Omega$ is the spatial domain. For example, in one-dimensional deconvolution, (with $\Omega = (0, 1)$) one can have

$$[A_Mx]_i = \int_0^1 a(s_i - s')x(s')ds', \quad i = 1, \ldots, M.$$

Discretizing this integral in the $s'$ variable, e.g., using a uniform mesh on $[0, 1]$ with $N$ grid elements and midpoint quadrature, then yields $Ax$. Then we have that

$$\lim_{N \to \infty} \|Ax - b\|_2 = \|A_Mx - b\|_2.$$  

Note that here $x$ denotes the discretized version of $x \in X$. For the prior eq. (3), it is typical to choose $\Gamma_{\text{prior}}$ to be the numerical discretization of the inverse of a differential operator. That is, letting $\Gamma_{\text{prior}}$ denote the infinite dimensional prior covariance operator, we define $\Gamma_{\text{prior}} = \mathcal{L}^{-1}$, where $\mathcal{L}$ is a differential operator. A basic requirement on $\Gamma_{\text{prior}}$ is that it has to be trace-class on $L^2(\Omega)$. That is, for any orthonormal basis $\{\phi_i\}_{i=1}^\infty$ of $L^2(\Omega)$, $\sum_{i=1}^\infty \langle \phi_i, \mathcal{L}^{-1}\phi_i \rangle < \infty$; see [28]. Moreover, if $\langle x, y \rangle$ is the standard $L^2(\Omega)$ inner product, we can use midpoint quadrature to obtain $\langle x, y \rangle = \lim_{N \to \infty} \langle x, y \rangle_N$, where the boldface letters indicate discretized versions of the variables and $\langle x, y \rangle_N := \frac{1}{N} \sum_{i=1}^N x_i y_i$. Using this notation,

$$\lim_{N \to \infty} \langle x, \Gamma_{\text{prior}}^{-1}x \rangle_N = \langle x, \mathcal{L}x \rangle.$$  

Combining eq. (13) and eq. (14) yields

$$\lim_{N \to \infty} \left\{ \frac{\mu}{2} \|Ax - b\|_2^2 + \frac{\sigma}{2} \langle x, \Gamma_{\text{prior}}^{-1}x \rangle_N \right\} = \frac{\mu}{2} \|A_Mx - b\|_2^2 + \frac{\sigma}{2} \langle x, \mathcal{L}x \rangle.$$  

There are two issues that arise when we consider the limit as $N \to \infty$: the first is mathematical, and the second is computational. A question that immediately arises is whether or not one can define an infinite dimensional limit of the posterior density function. We cannot define a probability density function on a function space. The reason for this is that in finite dimensions, the posterior density is none but the Radon–Nikodym derivative of posterior probability law of the inference parameter with respect to Lebesgue measure, but one cannot define a Lebesgue measure on an infinite-dimensional function space. However, as shown in [28], given that the prior covariance operator is trace class and $A_M : X \to \mathbb{R}^M$ is a continuous linear transformation, the posterior law of $x$, which we denote by $\nu^{b, \theta} = \mathcal{N}(x_{\text{post}}, C_{\text{post}})$, is a Gaussian measure on $L^2(\Omega)$, whose mean and covariance are given by the following expressions:

$$\Gamma_{\text{post}}^{-1} = \mu A_M^* A_M + \sigma \Gamma_{\text{prior}}^{-1}, \quad x_{\text{post}} = \Gamma_{\text{post}} A_M^* b.$$

Note that here $x_{\text{post}}$ denotes the discretized version of $x_{\text{post}} \in X$. For the prior eq. (3), it is typical to choose $\Gamma_{\text{prior}}$ to be the numerical discretization of the inverse of a differential operator. That is, letting $\Gamma_{\text{prior}}$ denote the infinite dimensional prior covariance operator, we define $\Gamma_{\text{prior}} = \mathcal{L}^{-1}$, where $\mathcal{L}$ is a differential operator. A basic requirement on $\Gamma_{\text{prior}}$ is that it has to be trace-class on $L^2(\Omega)$. That is, for any orthonormal basis $\{\phi_i\}_{i=1}^\infty$ of $L^2(\Omega)$, $\sum_{i=1}^\infty \langle \phi_i, \mathcal{L}^{-1}\phi_i \rangle < \infty$; see [28]. Moreover, if $\langle x, y \rangle$ is the standard $L^2(\Omega)$ inner product, we can use midpoint quadrature to obtain $\langle x, y \rangle = \lim_{N \to \infty} \langle x, y \rangle_N$, where the boldface letters indicate discretized versions of the variables and $\langle x, y \rangle_N := \frac{1}{N} \sum_{i=1}^N x_i y_i$. Using this notation,

$$\lim_{N \to \infty} \langle x, \Gamma_{\text{prior}}^{-1}x \rangle_N = \langle x, \mathcal{L}x \rangle.$$  

Combining eq. (13) and eq. (14) yields

$$\lim_{N \to \infty} \left\{ \frac{\mu}{2} \|Ax - b\|_2^2 + \frac{\sigma}{2} \langle x, \Gamma_{\text{prior}}^{-1}x \rangle_N \right\} = \frac{\mu}{2} \|A_Mx - b\|_2^2 + \frac{\sigma}{2} \langle x, \mathcal{L}x \rangle.$$  

There are two issues that arise when we consider the limit as $N \to \infty$: the first is mathematical, and the second is computational. A question that immediately arises is whether or not one can define an infinite dimensional limit of the posterior density function. We cannot define a probability density function on a function space. The reason for this is that in finite dimensions, the posterior density is none but the Radon–Nikodym derivative of posterior probability law of the inference parameter with respect to Lebesgue measure, but one cannot define a Lebesgue measure on an infinite-dimensional function space. However, as shown in [28], given that the prior covariance operator is trace class and $A_M : X \to \mathbb{R}^M$ is a continuous linear transformation, the posterior law of $x$, which we denote by $\nu^{b, \theta} = \mathcal{N}(x_{\text{post}}, C_{\text{post}})$, is a Gaussian measure on $L^2(\Omega)$, whose mean and covariance are given by the following expressions:

$$\Gamma_{\text{post}}^{-1} = \mu A_M^* A_M + \sigma \Gamma_{\text{prior}}^{-1}, \quad x_{\text{post}} = \Gamma_{\text{post}} A_M^* b.$$
As for the construction of the prior covariance operator, as mentioned before, a common approach is to define them as inverses of differential operators. For example, we can define

$$\Gamma_{\text{prior}} = L^{-s}, \quad L u = -\nabla \cdot (\kappa \nabla u) + \alpha u, \quad \kappa, \alpha > 0,$$

with Neumann boundary conditions. To ensure that the covariance operator so defined is trace-class, we require $s > d/2$, where $d$ is the spatial dimension of the problem. For the one-dimensional example in eq. (12), $s = 1$ would suffice. For problems with $d = 2$ or $d = 3$, a convenient option is $s = 2$. Note this assumption on $s$ also ensures that the prior draws are almost surely continuous. For further details on the definition of Gaussian measures on infinite-dimensional Hilbert spaces, see [10 11].

A second question that arises is whether or not the performance of the hierarchical Gibbs sampler is dependent upon $N$. For inverse problems in which the infinite dimensional limit is well-defined, MCMC methods whose performance is independent of the discretization ($N$ in this case) are desirable. In line 3 of algorithm [1] we see that $N$ appears in the Gamma conditional density $\pi(\sigma \mid x, \mu, b)$, thus it should not be surprising to find the $N$-chain is dependent on $N$. The exact nature of this dependence is the subject of [1, Theorem 3.4], where under reasonable assumptions it is shown that the expected step in the $\sigma$-chain scales like $2/N$. Specifically, for any $\sigma > 0$,

$$\frac{N}{2} \mathbb{E} \left[ \sigma_{(t+1)} - \sigma_{(t)} \mid \sigma_{(t)} = \sigma \right] = (\alpha + 1)\sigma - f_N(\sigma; b)\sigma^2 + \mathcal{O}(N^{-1/2}),$$

where $\mathbb{E}$ denotes expectation and $f_N(\sigma; b)$ is bounded uniformly in $N$. Moreover, the variance of the step also scales like $2/N$; for any $\sigma > 0$,

$$\frac{N}{2} \text{Var} \left[ \sigma_{(t+1)} - \sigma_{(t)} \mid \sigma_{(t)} = \sigma \right] = 2\sigma^2 + \mathcal{O}(N^{-1/2}).$$

A consequence of these results, as is noted in [1], is that the expected squared jumping distance of the Markov chain for $\sigma$ is $\mathcal{O}(1/N)$. Moreover, it is noted that the lag-1 autocorrelation of the $\sigma$-chain behaves like $1 - c/N$ for some constant, but $\text{Var}(\sigma_{(t)}) = \mathcal{O}(1)$. Hence, the Monte Carlo error associated with $K - K_b$ draws in stationarity is $\mathcal{O}(\sqrt{N/(K - K_b)})$. Thus, the $\sigma$-chain becomes increasing correlated as $N \to \infty$. This phenomenon is illustrated in fig. [1] which displays the empirical autocorrelation functions for the $\mu$- and $\sigma$-chains generated by algorithm [1] for a one-dimensional image deblurring test problem. Note that as $N$ increases by a power of 2, so does the integrated autocorrelation time (IACT).

### 2.2 One-Block MCMC

An alternative algorithm for computing a sample $(x', \theta') \sim \pi(x', \theta' \mid b)$ is to first compute a sample from the marginal density $\theta' \sim \pi(\theta' \mid b)$, defined in eq. (8), and then compute a sample from the conditional density $x' \sim \pi(x' \mid b, \theta')$. In principle, we can use this procedure as an alternative to algorithm [1]. In practice, it is often not possible to sample directly from $\pi(\theta \mid b)$. In the one-block algorithm of [25], a Markov chain is generated in which if $(x, \theta)$ is the current element of the chain, a state $\theta'$ is proposed from some proposal distribution with density $r(\theta' \mid \theta)$, then $x' \sim \pi(x' \mid b, \theta')$ is drawn, and the pair $(x', \theta')$ is accepted with probability

$$\rho_1(\theta' \mid \theta) = \min \left\{ 1, \frac{\pi(x', \theta' \mid b) r(\theta' \mid \theta') \pi(x \mid b, \theta)}{\pi(x, \theta \mid b) r(\theta \mid \theta) \pi(x' \mid b, \theta')} \right\} = \min \left\{ 1, \frac{\pi(\theta' \mid b) r(\theta' \mid \theta')}{\pi(\theta \mid b) r(\theta \mid \theta')} \right\}. \quad (16)$$
Figure 1: Plots of the empirical autocorrelation functions for the $\sigma$ chains in the one-dimensional deblurring example: (left) Block-Gibbs and (right) Approximate One-Block discussed in section 3.1. See section 5.1 for details regarding the experimental setup.

**Algorithm 2: One-Block MCMC**

The resulting MCMC method is given by algorithm 2.

Note that the conditional sample $x' \sim \pi(x' \mid b, \theta')$ effectively marginalizes (i.e., integrates out) $x$ from the posterior, as is illustrated by the acceptance ratio eq. (16), which does not depend upon $x$. If $r(\cdot \mid \cdot)$ is used as a Metropolis-Hastings proposal for sampling from the marginal density $\pi(\theta \mid b)$ alone without going through $\pi(x \mid b, \theta)$—this is the MCMC method proposed in [13]—the acceptance ratio is also given by eq. (16). Thus, the $\theta$-chain generated by algorithm 2 converges in distribution to $\pi(\theta \mid b)$. The marginalization circumvents the degeneracy exhibited by the $\theta$-chain generated by algorithm 1.

3 Algorithms

For some applications, evaluating the marginal density $\pi(\theta \mid b)$ is not computationally tractable, nor is computing exact samples $x' \sim \pi(x' \mid b, \theta')$. In this case, implementation of algorithm 2 is infeasible. However, suppose that we have an approximate posterior density function $\hat{\pi}(x, \theta \mid b)$ for which the marginal density $\hat{\pi}(\theta \mid b)$ can be evaluated, and exact samples $x' \sim \hat{\pi}(x' \mid b, \theta')$ can be drawn efficiently.

In this section, we propose three MCMC algorithms, each of which uses $\hat{\pi}(x, \theta \mid b)$ to approximate algorithm 2. We note that Rue and Held [25] also consider approximate marginalization of $x$ in the one-block algorithm. However, the difference between our approach and that of [25]
is the nature of the approximate posterior distribution. Specifically, motivated by non-Gaussian conditional distributions that arise in, e.g., Poisson counts for disease mapping, \cite{25} use an approximation based on a Taylor expansion of the log-likelihood about the mode of the full conditional distribution, resulting in a Gaussian proposal in the Metropolis-Hastings algorithm. By contrast, we are concerned with cases in which the full conditional is still Gaussian distributed, but drawing realizations from the distribution and evaluating the density are computationally prohibitive because of the dimensionality of the unknown parameters. We discuss in section \ref{sec:discussion} our construction of the approximation \( \hat{\pi}(x, \theta \mid b) \) and its effect on the proposed algorithms.

### 3.1 Approximate One-Block MCMC

Suppose we generate a proposal \((x', \theta')\) by first drawing \(\theta'\) from a proposal distribution with density \(r(\theta' \mid \theta_{(t-1)})\) followed by drawing \(x' \sim \hat{\pi}(x' \mid \theta', b)\). Using this in a Metropolis-Hastings sampler with target distribution \(\pi(x, \theta \mid b)\) is simply the one-block algorithm with \(\hat{\pi}(x \mid \theta, b)\) in place of \(\pi(x \mid \theta, b)\). The proposal density is then given by

\[
q(x', \theta' \mid x, \theta) = \hat{\pi}(x' \mid \theta', b)r(\theta' \mid \theta),
\]

and hence, the acceptance probability is

\[
\rho_2(x', \theta'; x, \theta) = \min \left\{ 1, \frac{\pi(x', \theta' \mid b)\hat{\pi}(x \mid \theta, b)r(\theta' \mid \theta)}{\pi(x, \theta \mid b)\hat{\pi}(x' \mid \theta', b)r(\theta' \mid \theta)} \right\}.
\] (17)

The full procedure is summarized in algorithm 3.

There are two observations to make about algorithm 3 each of which motivates the MCMC methods that follow. First, computing the ratio eq. (17) requires evaluating the true posterior density \(\pi(x, \theta \mid b)\). In cases in which this is computationally burdensome, the MCMC method presented next seeks to avoid extraneous evaluations of \(\pi(x, \theta \mid b)\) using a technique known as delayed acceptance 3. Second, algorithm 3 only approximately integrates \(x\) out of \(\pi(x, \theta \mid b)\), since \(\pi(\theta \mid b) \approx \pi(x, \theta \mid b)/\hat{\pi}(x \mid \theta, b)\), but this is not an exact marginalization and thus some dependence between the \(x\) and \(\theta\) chains may remain, slowing convergence of the algorithm. However, as we discuss below, algorithm 3 is a special case of the so-called pseudo-marginal MCMC algorithm 2. By generalizing the approximate one-block algorithm, we can improve the approximation to \(\pi(\theta \mid b)\) and thus improve the mixing of the Markov chains.

---

**Algorithm 3: Approximate One-Block MCMC.**

\[
\text{Input:} \text{ Initialize } \theta_{(0)} \text{. Define the length of the chain } C \text{ and burn-in period } C_b.
\]

\[
\text{Output:} \text{ Approximate sample from the posterior distribution } \{x_{(t)}, \theta_{(t)}\}_{t=C_b+1}^K.
\]

1. Compute \(x_{(0)} \sim \hat{\pi}(x \mid b, \theta_{(0)})\).
2. for \(t = 1 \text{ to } K\) do
3. \quad Draw \(\theta'\) from distribution with density \(r(\theta' \mid \theta_{(t-1)})\).
4. \quad Draw \(x'\) from distribution with density \(\hat{\pi}(x' \mid \theta', b)\).
5. \quad Set \((x_{(t)}, \theta_{(t)}) = (x', \theta')\) with probability \(\rho_2(x', \theta' \mid x_{(t-1)}, \theta_{(t-1)})\) defined in eq. (17); else set \((x_{(t)}, \theta_{(t)}) = (x_{(t-1)}, \theta_{(t-1)})\).
6. end
Input: Initialize $\theta_{(0)}$. Define the length of the chain $C$ and burn-in period $C_b$.

Output: Approximate sample from the posterior distribution $\{x(t), \theta(t)\}_{t=C_b+1}$.

1 Compute $x_{(0)} \sim \hat{\pi}(x \mid b, \theta_{(0)})$.

2 for $t = 1$ to $K$ do

// Stage 1: apply the one-block algorithm to $\hat{\pi}(x, \theta \mid b)$.

3 Draw $\theta_*$ from the distribution with density $r(\theta_0 \mid \theta_{(t-1)})$.

4 Draw $x_*$ from the distribution with density $\hat{\pi}(x_0 \mid \theta_*, b)$.

5 Compute $\hat{\rho}_1(x_*, \theta_*; \theta_{(t-1)})$ defined in eq. (19).

6 Set $(x', \theta') \leftarrow (x_*, \theta_*)$ and promote to Stage 2 with probability $\hat{\rho}_1(x', \theta'; \theta_{(t-1)})$ else set $(x', \theta') \leftarrow (x_{(t-1)}, \theta_{(t-1)})$ and promote.

// Stage 2: accept/reject $(x', \theta')$ as a proposal for $\pi(x, \theta \mid b)$.

7 Define

$$
\rho_3(x', \theta'; x, \theta) = \min \left\{ 1, \frac{\pi(x', \theta' \mid b)q(x, \theta \mid x', \theta')}{\pi(x, \theta \mid b)q(x', \theta' \mid x, \theta)} \right\},
$$

where $q(x', \theta' \mid x_{(t-1)}, \theta_{(t-1)})$ is defined in eq. (20). Set $(x_{(t)}, \theta_{(t)}) = (x', \theta')$ with probability $\rho_3(x', \theta'; x_{(t-1)}, \theta_{(t-1)})$ else set $(x_{(t)}, \theta_{(t)}) = (x_{(t-1)}, \theta_{(t-1)})$.

8 end

Algorithm 4: Approximate One-Block MCMC with delayed acceptance.

### 3.2 Approximate One-Block MCMC with Delayed Acceptance

It will often be the case that evaluating $\pi(x, \theta \mid b)$ is computationally prohibitive and/or significantly more expensive than evaluating $\hat{\pi}(x, \theta \mid b)$, in which case one would like to generate samples from $\pi(x, \theta \mid b)$ while minimizing the number of times its density is evaluated. This motivates the use of the delayed acceptance framework of [8] to improve the computational efficiency of algorithm [2]. In this approach, one step of algorithm [2] is used with $\pi(x, \theta \mid b)$ taken as the target distribution. Only if $(x', \theta')$ is accepted as a sample from $\hat{\pi}(x, \theta \mid b)$ is it proposed as a sample from $\pi(x, \theta \mid b)$. The idea is to only evaluate $\pi(x', \theta' \mid b)$ for proposed states that have a high probability of being accepted as drawn from the true distribution. This prevents us from wasting computational effort on rejected proposals. The approximate distribution in the first stage is essentially a computationally cheap “filter” that prevents this from occurring. The resulting approximate one-block MCMC with delayed acceptance (ABDA) procedure is given in algorithm [4].

Let $\hat{\rho}_1(\theta' \mid \theta_{(t-1)})$ be given by eq. (16), but with $\pi(x, \theta \mid b)$ replaced by $\hat{\pi}(x, \theta \mid b)$; i.e.,

$$
\hat{\rho}_1(\theta' \mid \theta_{(t-1)}) = \min \left\{ 1, \frac{\hat{\pi}(x', \theta' \mid b)\rho(\theta_{(t-1)} \mid \theta')\hat{\pi}(x_{(t-1)} \mid b, \theta_{(t-1)})}{\rho(\theta' \mid \theta_{(t-1)})\hat{\pi}(x \mid b, \theta')} \right\},
$$

$$
= \min \left\{ 1, \frac{\hat{\pi}(\theta' \mid b)\rho(\theta_{(t-1)} \mid \theta')}{\rho(\theta' \mid \theta_{(t-1)})} \right\}. \tag{19}
$$

Then, Stage 2 of algorithm [4] is a Metropolis-Hastings algorithm with target distribution $\pi(x, \theta \mid b)$ and proposal density given by

$$
q(x', \theta' \mid x_{(t-1)}, \theta_{(t-1)}) = \hat{\rho}_1(\theta' \mid \theta_{(t-1)})\pi(x' \mid \theta', b)r(\theta' \mid \theta_{(t-1)})
$$

$$
+ \delta(x_{(t-1)}, \theta_{(t-1)})q(x', \theta')(1 - \gamma(\theta_{(t-1)})), \tag{20}
$$
where \( y(\theta_{(t-1)}) = \int \int \tilde{\rho}_1(\theta' \mid \theta_{(t-1)}) \tilde{\pi}(x' \mid \theta', b) r(\theta' \mid \theta_{(t-1)}) dx' d\theta' \). Note that there is never a need to evaluate \( y(\theta_{(t-1)}) \), since when the promoted state is \((x_{(t-1)}, \theta_{(t-1)})\),
\[
\rho_3(x', \theta' \mid x_{(t-1)}, \theta_{(t-1)}) = 1,
\]
and the chain remains at the same point. Conversely, when the composite sample \((x', \theta')\) is promoted, \((x', \theta') \neq (x_{(t-1)}, \theta_{(t-1)})\) and
\[
q(x', \theta' \mid x_{(t-1)}, \theta_{(t-1)}) = \tilde{\rho}_1(\theta' \mid \theta_{(t-1)}) \tilde{\pi}(x' \mid \theta', b) r(\theta' \mid \theta_{(t-1)}).
\]
We discuss in section 4 the conditions under which the acceptance rate in the second stage is high, thus preventing wasted computational effort on rejected proposals.

For the ABDA algorithm, suppose that the support of the target density \( (\pi(\cdot, \cdot \mid b)) \) is completely contained in the support of the approximating density \( (\tilde{\pi}(\cdot, \cdot \mid b)) \) and that the support of the Metropolis-Hastings proposal distribution for \( \theta \) completely contains the support of the marginal distribution of \( \theta \), given any current state of the chain. Then the support of \( \pi(\cdot, \theta \mid b) \) is contained in the support of \( q(\cdot, \cdot \mid x, \theta) \), for all \((x, \theta)\) such that \( \pi(x, \theta \mid b) > 0 \). But the approximate distributions we consider are such that \( \tilde{\pi}(x, \theta \mid b) > 0 \) if and only if \( \pi(x, \theta \mid b) > 0 \). Hence, provided that an acceptable proposal distribution \( r(\cdot \mid \theta) \) is used in the first stage (i.e., one that would be used in the ordinary one-block algorithm), the properties of the Metropolis-Hastings algorithm guarantee that the ABDA transition kernel satisfies detailed balance with respect to the target joint distribution of \((x, \theta)\). In other words, \( \pi(x, \theta \mid b) \) is a stationary distribution of the Markov chain produced by ABDA. This can also easily be gleaned by recognizing that the ABDA algorithm is simply a special case of the delayed acceptance algorithm in [8], with first stage proposal given by \( \tilde{\pi}(x \mid \theta', b) r(\theta' \mid \theta) \), the approximating density given by \( \tilde{\pi}(x, \theta \mid b) \), and target density \( \pi(x, \theta \mid y) \). This latter observation allows us to apply Theorem 1 of [8] to establish irreducibility and aperiodicity of the ABDA Markov chain. Standard ergodic theory (e.g., [24]) then provides that \( \pi(x, \theta \mid b) \) is, in fact, the limiting distribution.

### 3.3 Pseudo-Marginal MCMC

As noted at the end of algorithm 2, the \( \theta \)-chain generated by algorithm 2 is independent of the \( x \)-chain. Hence, it does not suffer from the same degeneracy issues as the \( \theta \)-chain generated by algorithm 1. When it is not computationally feasible to implement algorithm 2 and an approximate posterior \( \tilde{\pi}(x, \theta \mid b) \) is used as in algorithms 3 and 4, the marginalization is only approximate so that there still remains some dependence between the \( \theta \) and \( x \) chains. This dependence can be mitigated as the approximation to the marginal distribution of \( \theta \) improves. In particular, we can use importance sampling, with importance density \( \tilde{\pi}(x \mid b, \theta) \), to approximate the integration over \( x \). Specifically, we have that

\[
\pi(\theta' \mid b) = \int_{\mathbb{R}^N} \pi(x, \theta' \mid b) dx = \int_{\mathbb{R}^N} \frac{\pi(x, \theta' \mid b)}{\tilde{\pi}(x \mid b, \theta')} \tilde{\pi}(x \mid b, \theta') dx \cong \frac{1}{K} \sum_{j=1}^{K} \frac{\pi(x_j' \mid b, \theta')}{\tilde{\pi}(x_j' \mid b, \theta')} \overset{\text{def}}{=} \pi^K(\theta' \mid b),
\]

where \( x_j' \sim \tilde{\pi}(x' \mid b, \theta') \). The idea behind pseudo-marginal MCMC [2], in our setting, is to generalize algorithm 3 by using \( \pi^K(\theta \mid b) \) as an approximation to \( \pi(\theta \mid b) \). The resulting algorithm is given in algorithm 5.
Consequently, as $K$ increases, the dependence between the $\theta$-chain and the $x$-chain dissipates as desired. It is shown in [2] that the value of $\pi^K(\theta_{(t-1)} \mid b)$ computed in step $t-1$ can be reused in step $t$ so that a new set of importance samples does not need to be computed in eq. (21). Furthermore, this paper showed that the corresponding Markov chain will converge in distribution to the target density, in our case $\pi(x, \theta \mid b)$.

**4 Analysis**

Algorithms 3 to 5 are all approximations of the one-block algorithm, algorithm 2, and they are meant to be used in cases in which implementing one-block is computationally expensive. All three algorithms require an approximation of the posterior, $\tilde{\pi}(x, \theta \mid b)$, which we assume has the form eq. (7), but with the conditional covariance $\Gamma_{\text{cond}}(\theta)$ replaced by an approximation $\tilde{\Gamma}_{\text{cond}}(\theta)$. We will use the following acronyms in what follows: AOB for Approximate One-Block, algorithm 3, and ABDA for Approximate One-Block with Delayed Acceptance, algorithm 4.

All three algorithms require the computation of samples from the approximate conditional $\tilde{\pi}(x \mid b, \theta)$, which is of the form

$$x \mid b, \theta \sim \mathcal{N}(x_{\text{cond}}(\theta), \tilde{\Gamma}_{\text{cond}}(\theta)),$$

where $x_{\text{cond}}(\theta) \equiv \mu_{\text{cond}}(\theta)A^\top b$. In section 4.4, we tailor these results to a specific choice of $\tilde{\pi}(x \mid b, \theta)$. The following quantity will be important in what follows:

$$w(x, \theta) \equiv \exp \left( -\frac{1}{2} x^\top (\Gamma_{\text{cond}}^{-1}(\theta) - \tilde{\Gamma}_{\text{cond}}^{-1}(\theta))x \right).$$

An expression for the moments of $w(x, \theta)$ can be computed analytically by using properties of Gaussian integrals and was established in [7]. For positive integers $m$,

$$\mathbb{E}_{\tilde{\pi}(x \mid b, \theta)}[w^m(x, \theta)] = \frac{1}{M_m(\theta)},$$

**Algorithm 5: Pseudo-Marginal MCMC.**

Input: Initialize $\theta_{(0)}$. Define the length of the chain $C$ and burn-in period $C_b$.

Output: Approximate samples from the posterior distribution $\{\{x_{(t,i)}\}_{i=1}^K, \theta_{(t)}\}_{t=C_b+1}$.

1. Compute $\pi^K(\theta_{(0)} \mid b)$ with $x'_{j} \sim \tilde{\pi}(x' \mid b, \theta_{(0)})$ as in eq. (21). Define $\{x_{(0,j)}\}_{j=1}^K = \{x'_{j}\}_{j=1}^K$.

2. for $t = 1$ to $C$ do

3. Compute $\theta' \sim \pi(\cdot \mid \theta_{(t-1)})$.

4. Compute $\pi^K(\theta' \mid b)$ using $x'_{j} \sim \tilde{\pi}(x' \mid b, \theta')$ as in eq. (21).

5. Compute

$$\rho_t(\theta', \theta_{(t-1)}) = \min \left\{ 1, \frac{\pi^K(\theta' \mid b)r(\theta_{(t-1)} \mid \theta')}{\pi^K(\theta_{(t-1)} \mid b)r(\theta' \mid \theta_{(t-1)})} \right\}.$$  (22)

6. With probability $\rho_t(\theta', \theta_{(t-1)})$, set $\theta_{(t)} = \theta'$ and $\{x_{(t,j)}\}_{j=1}^K = \{x'_{j}\}_{j=1}^K$, else set $\theta_{(t)} = \theta_{(t-1)}$ and $\{x_{(t,j)}\}_{j=1}^K = \{x_{(t-1,j)}\}_{j=1}^K$.

7. end

When $K = 1$, algorithm 5 simply reduces to algorithm 3. Conversely, as $K \to \infty$, $\pi^K(\theta' \mid b) \to \pi(\theta' \mid b)$, and hence the Markov chains produced by algorithms 2 and 3 become indistinguishable. Furthermore, this paper showed that the corresponding Markov chain will converge in distribution to the target density, in our case $\pi(x, \theta \mid b)$.
where
\[ M_m(\theta) \equiv \frac{\exp\left(\frac{1}{2}b^\top A(M_m^{-1}(\theta) - \hat{\Gamma}_{\text{cond}}(\theta))A^\top b\right)}{(\det \hat{\Gamma}_{\text{cond}}(\theta) \det M_m(\theta))^{1/2}}, \] (25)
with
\[ M_m(\theta) = m(\Gamma_{\text{cond}}^{-1}(\theta) - \hat{\Gamma}_{\text{cond}}^{-1}(\theta)) + \hat{\Gamma}_{\text{cond}}^{-1}(\theta). \]
Further results for \( M_m(\theta) \) can be derived if \( \hat{\Gamma}_{\text{cond}}(\theta) \) is known explicitly. When \( \hat{\Gamma}_{\text{cond}}(\theta) \) is constructed using the low-rank approach outlined in section 4.4 below, we have that \( M_m(\theta) \geq 1 \).

### 4.1 Analysis of the Approximate One Block acceptance ratio

Our first result derives a simplified version of the acceptance ratio of AOB (algorithm 3) that is more amenable to interpretation.

**Proposition 1.** In algorithm 3, let \((x, \theta)\) denote the current state of the AOB chain and let \((x', \theta')\) be the proposed state. Then, the acceptance ratio simplifies to
\[
\rho_2(x', \theta'; x, \theta) = \min\left\{1, \frac{z(x', \theta')\pi(\theta' | b)\Gamma(x | \theta')} {z(x, \theta)\pi(\theta | b)\Gamma(x | \theta)} \right\},
\]
where \(z(x, \theta) \equiv w(x, \theta)/\Gamma_1(\theta)\).

**Proof.** Consider the ratio between the full posterior distribution \(\pi(x, \theta | b)\) and the approximate conditional \(\hat{\pi}(x | \theta, b)\),
\[
\frac{\pi(x, \theta | b)}{\hat{\pi}(x | \theta, b)} = \frac{\pi(x | \theta, b)\pi(\theta | b)}{\hat{\pi}(x | \theta, b)}.
\]
From [7, Proposition 1], the ratio of the exact and the approximate conditional densities simplifies to
\[
\frac{\pi(x | \theta, b)}{\hat{\pi}(x | \theta, b)} = z(x, \theta). \tag{26}
\]
Substituting eq. (26) into eq. (17) yields the desired result. \qed

The meaning of this result is clear if we combine eq. (24) and [7] Proposition 2 to obtain
\[
\mathbb{E}_{\hat{\pi}(x | \theta, b)} [z(x, \theta)] = M_1^{-1}(\theta)\mathbb{E}_{\hat{\pi}(x | \theta, b)} [w(x, \theta)] = 1. \tag{27}
\]
In other words, given the current state \(x\) and a proposed state \(\theta'\), the acceptance rate in algorithm 3, when averaged over \(\hat{\pi}(x' | \theta', b)\), is that of the one-block algorithm. Observe that if one takes \(\hat{\Gamma}_{\text{cond}}(\theta) = \Gamma_{\text{cond}}(\theta)\), so that \(z(x, \theta) = 1\), then
\[
\rho_2(x', \theta'; x, \theta) = \min\left\{1, \frac{\pi(\theta' | b)\Gamma(\theta | \theta')}{\hat{\pi}(\theta | b)\Gamma(\theta' | \theta')} \right\},
\]
which is exactly the one-block acceptance ratio eq. (16). Similarly, if \(\hat{\Gamma}_{\text{cond}}(\theta) \approx \Gamma_{\text{cond}}(\theta)\) is a sufficiently accurate approximation, then \(z(x, \theta) \approx 1\), and AOB will closely approximate the One-Block algorithm.
4.2 Analysis of the ABDA acceptance ratios

Next, we discuss the acceptance ratio of ABDA (algorithm 4). In the first stage, one-block is applied to $\hat{\pi}(x, \theta | b)$, yielding the acceptance ratio eq. (19) and target distribution $\hat{\pi}(\theta | b)$. The analysis for the acceptance rate at the second stage is split into two parts, propositions 2 and 3.

**Proposition 2.** Let $(x, \theta)$ denote the current state of the ABDA chain and let $(x', \theta')$ be the proposed state. Then, the acceptance ratio at the second stage is

$$\rho_3(x', \theta'; x, \theta) = \min \left\{ 1, \frac{\pi(x', \theta' | b)\hat{\pi}(x, \theta | b)}{\pi(x, \theta | b)\hat{\pi}(x', \theta' | b)} \right\}.$$  

(28)

**Proof.** First, note that $\hat{\rho}_1(\theta'; \theta)$, defined in eq. (19), can be expressed as $\min\{1, \gamma\}$, where

$$\gamma = \frac{\hat{\pi}(\theta' | b)r(\theta | \theta')}{\hat{\pi}(\theta | b)r(\theta' | \theta)}.$$  

Similarly, $\hat{\rho}_1(\theta; \theta') = \min\{1, \gamma^{-1}\}$. But if $\gamma \neq 0$ then $\min\{1, \gamma\}/\min\{1, \gamma^{-1}\} = \gamma$. Therefore, the ratio $\hat{\rho}_1(\theta'; \theta)/\hat{\rho}_1(\theta; \theta')$ simplifies to $\gamma$, from which it follows that

$$\frac{q(x, \theta | x', \theta')}{q(x', \theta' | x, \theta)} = \frac{\hat{\pi}(x | \theta, b)\hat{\pi}(\theta' | b)}{\hat{\pi}(x' | \theta', b)\hat{\pi}(\theta | b)},$$

where $q$ is defined by eq. (20). Thus, the ratio appearing in eq. (18) simplifies to

$$\frac{\pi(x', \theta' | b)q(x, \theta | x', \theta')}{\pi(x, \theta | b)q(x', \theta' | x, \theta)} = \frac{\pi(x', \theta' | b)\hat{\pi}(x | \theta, b)\hat{\pi}(\theta | b)}{\pi(x, \theta | b)\hat{\pi}(x' | \theta', b)\hat{\pi}(\theta | b)} = \frac{\pi(x, \theta | b)\hat{\pi}(x, \theta | b)}{\pi(x', \theta' | b)\hat{\pi}(x', \theta' | b)}.$$  

This result shows that algorithm 4 amounts to generating a proposal from the approximate posterior distribution $\hat{\pi}(x, \theta | b)$ in a Metropolis-Hastings independence sampler. Compared to algorithm 3, we expect algorithm 4 to have lower statistical efficiency but with much improved computational efficiency, since the posterior distribution $\pi(x, \theta | b)$ is only evaluated when a “good” sample has been drawn.

**Proposition 3.** Let $(x, \theta)$ denote the current state of the ABDA chain and let $(x', \theta')$ be the proposed step. With $w(x, \theta)$ defined in eq. (23), the acceptance ratio at the second stage is

$$\rho_3(x', \theta'; x, \theta) = \min \left\{ 1, \frac{w(x', \theta')}{w(x, \theta)} \right\}.$$  

(29)

**Proof.** From proposition 2, it is clear that we only need to focus on the ratio of the exact to approximate posterior densities $\pi(x, \theta | b)/\hat{\pi}(x, \theta | b)$ which simplifies according to eq. (26). Moreover, it is straightforward to verify that $M_1(\theta) = \hat{\pi}(\theta | b)/\pi(\theta | b)$, where $M_1(\theta)$ is defined in eq. (25). Substituting these two results into eq. (28) and recalling that $z(x, \theta) = w(x, \theta)/M_1(\theta)$, we obtained the desired result.
This result states that the acceptance ratio at the second stage is close to 1 if \( \hat{\pi}(x, \theta | b) \) is a good approximation to \( \pi(x, \theta | b) \). The value of the ABDA algorithm is seen by observing that regardless of the choice of proposal distribution for \( \theta \), the acceptance rate at the second stage will be high when \( \hat{\pi}(x, \theta | b) \) closely approximates the true target density \( \pi(x, \theta | b) \). For instance, if a poor proposal density is used for \( \theta \), then many bad states \( \theta' \) will likely be proposed, but they will be discarded without wasting the computational effort to evaluate \( \pi(x', \theta' | b) \). Provided we construct \( \hat{\pi}(x, \theta | b) \) to closely approximate \( \pi(x, \theta | b) \) for all \((x, \theta) \in \text{supp } \pi\), we can be confident that the true density will only be evaluated for states that have a high chance of being accepted. Further, using the approximate density in the second stage reduces the problem of tuning a Metropolis(-Hastings) algorithm to one of tuning the proposal \( r(\theta' | \theta) \), which is easier to do when \( \theta \) is low-dimensional.

### 4.3 Analysis of the Pseudo-marginal acceptance ratio

We turn to the analysis of the Pseudo-marginal algorithm (algorithm 5). It is worth recalling that for \( K = 1 \), the Pseudo-marginal algorithm reduces to AOB.

**Proposition 4.** The acceptance ratio is

\[
\rho_A(\theta'; \theta) = \min \left\{ 1, \frac{z_K(\theta') \pi(\theta' | b) r(\theta | \theta')}{z_K(\theta) \pi(\theta | b) r(\theta | \theta)} \right\},
\]

where \( z_K(\theta) \equiv \frac{1}{R} \sum_{j=1}^{K} z(x^j, \theta) \).

**Proof.** The proof is similar to proposition 1 and is omitted.

More insight can be obtained by considering the asymptotic behavior of \( z_K(\theta) \). By eq. (27) and the strong law of large numbers, it follows that, for fixed \( \theta \), \( z_K(\theta) \overset{a.s.}{\to} 1 \) as \( K \to \infty \). The interpretation is that the Pseudo-marginal algorithm exhibits similar behavior as AOB with respect to one block. The difference is that, by taking \( K \to \infty \), we attain almost sure convergence to the one block acceptance ratio, as opposed to an average behavior. Further, by the Central Limit Theorem and the fact that \( x^1, \ldots, x^K \) are independent for fixed \( \theta \), we have that \( \sqrt{K}(z_K(\theta) - 1) \overset{d}{\to} \mathcal{N}(0, \sigma^2_z(\theta)) \), where

\[
\sigma^2_z(\theta) \equiv \text{Var}_{\hat{\pi}(x|\theta, b)}[z(x, \theta)] = \frac{1}{M^2(\theta)} \left( \frac{1}{M_2(\theta)} - \frac{1}{M^1(\theta)} \right) < \infty, \quad \forall \theta \text{ (a.e.)}
\]

It follows from the Central Limit Theorem that \( z_K(\theta) \) is \( \sqrt{K} \)-consistent for 1 \(\overset{[23]}{\leq} 1 \) i.e.,

\[
z_K(\theta) - 1 = O_p(K^{-1/2}) \quad (29)
\]

as \( K \to \infty \). However, it is important to observe that \( \sigma_z(\theta) \) will be close to zero when the approximate distribution is close to the true distribution, in which case \( z_K(\theta) \) will be close to one with high probability even for small \( K \).

This analysis shows the advantage of the Pseudo-marginal approach, namely that we can still achieve desirable marginalization behavior in the presence of a poor approximation to the full conditional distribution of \( \pi(x, \theta | b) \). If the approximation \( \hat{\pi}(x, \theta | b) \) is not very good, one can set \( K \) to be large to guarantee \( z_K(\theta) \approx 1 \), at the expense of drawing repeated realizations from the approximating distribution. Otherwise, if the approximation \( \hat{\pi}(x, \theta | b) \) is good, \( z_K(\theta) \approx 1 \) even for small \( K \). The trade-off is thus a large number of realizations from a poor approximation, or few (one in the case of AOB) realizations from a quality approximation. Regardless, if \( z_K(\theta) \approx 1 \), algorithm 5 will closely approximate the one-block algorithm.
4.4 Approximate posterior distribution using low-rank approximation

We briefly review the low-rank approach for sampling from the conditional distribution \( \pi(x \mid \theta, b) \), originally proposed in [7]. First, recall that \( \Gamma_{\text{cond}}^{-1}(\theta) = \mu A^\top A + \sigma \Gamma_{\text{prior}}^{-1} \) and assume \( \Gamma_{\text{prior}}^{-1} = LL^\top \), so that

\[
\Gamma_{\text{cond}}^{-1}(\theta) = L^\top \left( \mu L^{-\top} A^\top A L^{-1} + \sigma I \right) L.
\]

Next, define a rank-\( k \) approximation as

\[
L^{-\top} A^\top A L^{-1} \approx V_k \Lambda_k V_k^\top,
\]

where \( \Lambda_k \) is diagonal with the \( k \) largest eigenvalues of \( L^{-\top} A^\top A L^{-1} \) and \( V_k \) contains orthonormal columns. Combining the previous two equations, we obtain the approximate covariance

\[
\hat{\Gamma}_{\text{cond}}^{-1}(\theta) \equiv (\mu L^\top V_k \Lambda_k V_k^\top L + \sigma \Gamma_{\text{prior}}^{-1}) = L^\top (\mu V_k \Lambda_k V_k^\top + \sigma I) L.
\]

Defining \( \hat{x}_{\text{cond}}(\theta) = \mu \hat{\Gamma}_{\text{cond}}(\theta) A^\top b \), the approximate posterior distribution is obtained as

\[
\hat{\pi}(x, \theta \mid b) \propto f(\theta) \exp \left( -\frac{\mu}{2} b^\top b + \frac{\mu^2}{2} b^\top A \hat{\Gamma}_{\text{cond}}(\theta) A^\top b - \frac{1}{2} \|x - \hat{x}_{\text{cond}}(\theta)\|^2_{\hat{\Gamma}_{\text{cond}}^{-1}(\theta)} \right),
\]

where, \( f(\theta) = \mu^{M/2} \sigma^{N/2} \pi(\theta) \). The marginal density is

\[
\hat{\pi}(\theta \mid b) \propto \frac{f(\theta)}{\sqrt{\det(\hat{\Gamma}_{\text{cond}}(\theta))}} \exp \left( -\frac{\mu}{2} b^\top b + \frac{\mu^2}{2} b^\top A \hat{\Gamma}_{\text{cond}}(\theta) A^\top b \right).
\]

To sample from the approximate conditional distribution, \( \hat{\pi}(\theta \mid b) \) we compute

\[
x = \hat{x}_{\text{cond}}(\theta) + G \varepsilon \quad \varepsilon \sim \mathcal{N}(0, I),
\]

where \( G := \sigma^{-1/2} L^{-1}(I - V_k \hat{D}_k V_k^\top) \) and \( \hat{D}_k = I \pm (I - D_k)^{1/2} \). It is shown in [7] that \( \hat{\Gamma}_{\text{cond}} = GG^\top \). Since \( \hat{D}_k \) is diagonal and \( k \ll n \), eq. (33) provides a computationally cheap way of generating draws from \( \hat{\pi}(x \mid b, \theta) \).

**Acceptance ratio analysis** From [7, Proposition 2], the expression for \( w(x, \theta) \) simplifies considerably. First,

\[
\Gamma_{\text{cond}}^{-1}(\theta) - \hat{\Gamma}_{\text{cond}}^{-1}(\theta) = \mu L^\top \left( \sum_{j=k+1}^N \lambda_j v_j v_j^\top \right) L,
\]

implying \( w(x, \theta) = \exp \left( -\frac{1}{2} \sum_{j=k+1}^N \lambda_j (v_j^\top Lx)^2 \right) \), which in turn implies [7, Theorem 1]

\[
M_n(\theta) = \exp \left( \frac{\mu^2}{2\sigma^2} \sum_{j=k+1}^n \frac{m\mu\lambda_j}{m\mu\lambda_j + \sigma} (b^\top A L^{-1} v_j)^2 \right) \prod_{j=k+1}^n \left( 1 + \frac{m\mu}{\sigma} \lambda_j \right)^{1/2}.
\]

The key insight from this calculation is that \( z(x, \theta) = w(x, \theta) / M_1(\theta) \) only contains eigenvalues that are discarded in the low-rank approximation. This means if the discarded eigenvalues are very small, AOB is very close to the one-block algorithm. Similarly, for the ABDA algorithm, this implies the acceptance ratio of the second stage is very high and for the Pseudo-marginal MCMC, the variance \( \sigma_z(\theta) \) is close to zero.
Table 1: Summary of various computational costs in the Approximate One-Block Algorithm

| Component       | Dominant Cost               | Additional Cost |
|-----------------|-----------------------------|-----------------|
| Pre-computation | $2k(T_A + T_{L^{-1}})$      | $O(nk^2)$       |
| Sample          | $T_{L^{-1}}$                | $O(nk)$         |
| Acceptance ratio| $T_A + T_L$                 | $O(nk)$         |

In practice, computing the truncated SVD can be computationally expensive. However, the low-rank decomposition can be approximately computed using a Krylov subspace approach [27], or using a randomized approach [19]. These approximate factorizations can be used instead to construct the approximating distribution, such as the conditional $\tilde{\pi}(x \mid b, \theta)$, the marginal $\tilde{\pi}(\theta \mid b)$, and the full posterior distribution $\tilde{\pi}(x, b \mid \theta)$. The details are given in [7].

4.5 Computational cost

We briefly review the computational cost of the three algorithms proposed in this paper. Denote the computational cost of forming the matrix-vector product (henceforth, referred to as matvec) with $A$ by $T_A$. Similarly denote the cost of a matvec with $L$ and $L^{-1}$ as $T_L$ and $T_{L^{-1}}$, respectively. To simplify the analysis, we make two assumptions: first, the cost of the matvecs dominates the computational cost, and second, the cost of the transpose operations of the respective matrices is the same as that of the original matrix.

**AOB algorithm** We first analyze the computational cost associated with AOB (algorithm 3). There are three major sources of computational cost. In the offline stage, we pre-compute a low-rank approximation as in eq. (30). By using a Krylov subspace solver or randomized SVD algorithm, the dominant cost is in computing the matvecs, i.e., $2k(T_A + T_{L^{-1}})$ floating point operations (flops), with an additional cost of $O(nk^2)$ flops. In the online stage, to generate a composite sample $(x', \theta')$, the major cost that depends on the dimension of the problem is due to eq. (33) and can be quantified as $T_{L^{-1}}$ flops, with an additional $O(nk)$ cost. Finally, computing the acceptance ratio requires one evaluation of the full posterior distribution, and one evaluation of the approximate posterior distribution. Evaluating the full posterior using eq. (7) requires $T_A + T_L$ flops, with an additional cost $O(nk)$ flops, whereas evaluating the approximate posterior distribution using eq. (31) only requires $O(nk)$ flops.

**ABDA algorithm** The cost of ABDA, algorithm 4, is the same as that of AOB, algorithm 3, with only one notable exception. The extra step of evaluating the approximate marginal distribution eq. (32) requires an additional $2T_{L^{-1}} + O(nk)$ flops. However, while the per-iteration cost of ABDA is comparable to that of AOB, the overall cost of ABDA can be lower. The reason is that the acceptance ratio involving the full posterior distribution is only evaluated in the second stage, unlike AOB in which the posterior distribution is evaluated at every iteration. The computational speedup has been demonstrated in numerical experiments, see section 5. Estimates of the computational speedup can be obtained by following the approach in [9], but we omit this discussion.

**Pseudo-marginal algorithm** The cost of the Pseudomarginal approach (algorithm 5) is the same as algorithm 3 with two exceptions: $K$ samples need to be generated which costs $K[T_{L^{-1}} + O(nk)]$ flops, and to evaluate the acceptance ratio, we need $K[T_A + T_L + O(nk)]$ flops. The benefits
of the Pseudo-marginal algorithm, i.e., more effective marginalization, has to be weighed against the additional cost of generating the samples and evaluating the acceptance ratio.

5 Numerical Experiments

Throughout this section, the proposal distribution for $\theta$ is taken to be the Adaptive Metropolis proposal [18] using a lognormal proposal for $\theta$. For the prior and noise precision parameters, we assign a Gamma prior, Gamma($1, 10^{-4}$), based on the recommendation of [5]. If a priori knowledge is available regarding the distribution of $\theta$, this can be incorporated into the hyperpriors. It is also worth mentioning that besides the Gamma priors, other choices for the hyper-priors can also be made, e.g., proper Jeffreys. See [7] for a detailed discussion. Besides these parameters, no other tuning parameters were necessary.

5.1 1D Deblurring

We take a simple 1D deblurring example to illustrate our algorithms. This application arises from the discretization of a Fredholm integral equation of the first kind as in eq. (12). The details of this application are given elsewhere and we refer the reader to them [3]. For the problem size we choose $N = 128$ and add Gaussian noise with variance $0.01^2 \|Ax_{\text{true}}\|^2$ to simulate measurement error, where $x_{\text{true}}$ is the true vector which is assumed to be known. We model smoothness on $x$ a priori by taking $\Gamma_{\text{prior}}^{-1} = -\Delta$, where $-\Delta$ is the discrete Laplacian with Dirichlet boundary conditions [21].

A low-rank approximation with $k = 35$ computed using the “exact” SVD was used to define the approximate posterior distribution. We run 20,000 iterations of the AOB algorithm. The first 10,000 samples were considered to be the burn-in period and were discarded. The left panel of fig. 2 shows the true vector $x_{\text{true}}$ and the blurred vector $b$ with the simulated measurement noise. The right panel of the same figure shows the approximate posterior mean superimposed on the true vector $x_{\text{true}}$; also plotted are the curves corresponding to the pointwise 95% credible bounds. The plots show that the true image is mostly contained within the credible intervals, thereby providing a measure of confidence in the reconstruction process.

Diagnostics for convergence We now provide some limited diagnostics to assess the convergence of the algorithm. In the upper left panel of fig. 3 we display the trace plots of the precision parameters $\mu$ and $\sigma$ for three different chains with different initializations. It is seen that the chains appear to converge. Furthermore, the Multivariate Potential Scale Reduction Factor (MSPRF) [6]
Figure 3: The (top left) trace plots and (top right) histograms of the $\mu$ and $\sigma$ chains for the 1-D deblurring example using the AOB algorithm. (Bottom) Cumulative averages of the $\mu$ and $\sigma$ chains against the number of iterations. The target rank is $k = 50$.

for the $x$ chain is 1.06, which is within the recommend rule-of-thumb range (less than 1.1). The top right panel of the same figure shows the histograms of the precision parameters. The (two-sided) Geweke test [4] applied to the resulting $\mu$- and $\sigma$-chains yield $p$-values both greater than 0.98, meaning that there is no reason to believe the chains are out of equilibrium. Further support for convergence is obtained by monitoring the cumulative averages of the $\mu$ and $\sigma$-chains plotted in the bottom panel of fig. 3, from which it is readily seen that the cumulative averages converge.

In the right panel of fig. 1 (in section 2), we show the empirical autocorrelation function of one of the $\sigma$ chains. As mentioned earlier, the autocorrelation decays rapidly. While we do not plot the autocorrelation of the $\mu$ chain, we observed that it had similar behavior. The integrated autocorrelation time (IACT) was 6.97 for the $\sigma$-chain. The acceptance rate was 33.8% and the effective sample size (ESS) was 1434.61. Here, the ESS [22] is defined as $\text{ESS} = N_s / \tau_\sigma$, where $N_s$ is the Monte Carlo sample size and $\tau_\sigma$ denotes IACT of the Markov chain.

Comparing different methods We now compare all three algorithms proposed in section 3. The setup of the problem is the same as the previous experiment. The previous analysis shows that the AOB algorithm does a good job decorrelating the $\sigma$-chain from the $x$ chain. We repeat this experiment for the other two methods as well. fig. 4 plots the autocorrelation functions of the $\sigma$-chains produced by the other two methods, ABDA and PM with $K = 5$. As is readily seen, both methods successfully reduce the autocorrelation in the $\sigma$-chains. Although we do not plot the $\mu$-chains, they behave similarly to the $\sigma$-chains.

In table 2 we compare the various methods proposed here. The ESS of the PM algorithm
Figure 4: Plots of the empirical autocorrelation functions for the $\sigma$ chains in the 1-D deblurring example: (left) ABDA and (right) PM with $K = 5$.

|       | IACT $\sigma$ | ESS   |
|-------|---------------|-------|
| AOB   | 6.97          | 1434.61 |
| ABDA  | 7.14          | 1400.90 |
| PM $K = 5$ | 6.90 | 1448.38 |

Table 2: Integrated autocorrelation times (IACT) and effective sample sizes (ESS) for the $\sigma$ chains produced by the proposed algorithms for the 1-D deblurring example.

is marginally better than ABDA or AOB. This is because PM has a lower IACT. This is not surprising since the PM uses additional samples to marginalize the posterior distribution. More details regarding the PM method are given in the next experiment. Between the AOB and ABDA algorithms, AOB has a higher ESS and is more statistically efficient. In principle, though, ABDA is much less computationally expensive since the forward operator $A$ is evaluated less frequently. The difference is more pronounced in the inverse heat equation example in which the forward model is more expensive to evaluate.

**Effect of target rank** Here we investigate the effect of the target rank on the acceptance rate and the statistical efficiencies of the samplers. The model is identical to that in the first experiment with the exception that we change the target rank $k$ that controls the accuracy of the approximate posterior distribution. We vary the target rank $k$ from 20 to 40 in increments of 5. The results are displayed in table 3. When the target rank $k$ is below 25, we find that the acceptance rate is very close to zero, indicating that the low-rank approximation is not sufficiently accurate. On the other hand, when the target rank $k$ is 25 and above, the acceptance rate is close to 33%. It is also seen that the increasing the target rank does not substantially increase the acceptance rate. This suggests that we have successfully approximated the posterior distribution to the point that the only limitation is the proposal distribution for $\theta$; effectively, the dimensionality has been reduced from 128 to 25 which is roughly a factor of 5. Similar results are observed for the ABDA algorithm as well, shown in the right panel of table 3.

**Effect of increased importance sample size** In this experiment, we explore the effect of the importance sample size $K$ on the statistical efficiency in the PM algorithm. In addition to the ESS
Table 3: Summary of the effect of increasing rank for the 1-D deblurring example. ‘A.R.’ refers to acceptance rate; the number as a suffix refers to the stage. In general, an increase in the target rank increases the acceptance ratio and the ESS.

Table 4: Effect of the importance sample size \( K \) on the \( \sigma \)-chains produced by the Pseudo-marginal approach in the 1-D deblurring example. The target rank is fixed to be \( k = 20 \).

and the IACT of the \( \sigma \)-chain, we report the CPU time in seconds, and the Computational cost per Effective Sample (CES), which is the ratio of the CPU time to the ESS. proposition \( 4 \) shows that there are two ways to make the PM algorithm closer to one-block: by increasing the target rank that defines the approximate distribution, or by increasing the number of samples \( K \). We take the target rank to be \( k = 20 \). From the previous experiment it is seen that the samples have high autocorrelation and the resulting ESS is poor. table \( 4 \) shows that by increasing the number of samples \( K \), the PM approach seems to be performing better as evident in the increase in the ESS. However, the CPU time also increases considerably since each step in the algorithm is more expensive, with increasing \( K \). Indeed, when \( K \) increases by a factor of 10, the ESS merely doubles. On the other hand, from table \( 3 \) (corresponding to PM with \( K = 1 \)), increasing the target rank \( k \) by 10 substantially increases the ESS, but is far less expensive. However, when the spectrum of the prior-preconditioned Hessian is flat, increasing the target rank may not improve the ESS. On the other hand, proposition \( 4 \) shows that increasing the sample size \( K \) will have the desired effect.

5.2 A PDE-based example

In this application, we consider the inversion of the two-dimensional initial state in the heat equation. Given the initial state \( u_0 \), we solve

\[
\begin{align*}
  u_t - \kappa \Delta u &= 0, \quad \text{in } \mathcal{D} \times [0, T], \\
  u(x, t) &= 0, \quad \text{on } \partial \mathcal{D} \times [0, T], \\
  u(x, 0) &= u_0, \quad \text{in } \mathcal{D}.
\end{align*}
\]

The domain is taken to be \( \mathcal{D} = [0, 2] \times [0, 1] \). In the present experiment the diffusion coefficient was set to \( \kappa = .001 \) and we used a final simulation time of \( T = 5 \). The inverse problem seeks to use point measurements of \( u(\cdot, T) \) to reconstruct the initial state. The assumed true initial state used to simulate the data is shown in fig. 5 (left). We suppose that measurements are taken at an array of 512 observation points depicted in fig. 5 (right).
We used a Gaussian prior with covariance operator \( A^{-2} \), where \( A \) is the Laplacian with zero Dirichlet boundary condition. The data were generated by adding 10% Gaussian noise to the measurements. The problem is discretized with a \( 64 \times 32 \) grid. In the inverse problems, we seek to reconstruct a discretized initial state in \( \mathbb{R}^n \) with \( n = 63 \times 31 = 1953 \).

![Figure 5: True initial-state (left) and observation points (right).](image)

Let \( A \) denote the discretized forward operator that is obtained by composing the PDE solution operator and the observation operator that extracts solution values at the measurement points. Owing to the fast decay of singular values of \( A \), we can use a low-rank approximation. In the present example, a rank-70 approximation was found to provide sufficient accuracy.

**Performance of AOB and ABDA** As a first experiment, we apply the AOB method to the present inverse problem. Our MCMC implementation is run for \( 2 \times 10^4 \) iterations; we retain \( 10^4 \) samples, and discard the rest as part of the burn-in period. In fig. 6, we provide the trace plots of the \( \mu \) and \( \sigma \) chains (left), along with approximate posterior mean estimate of the initial state (right). We also report the empirical autocorrelation functions for the \( \mu \) and \( \sigma \) chains in fig. 7. The acceptance rate for the algorithm was approximately 30%.

![Figure 6: AOB results for the inverse heat equation example. Left: \( \mu \) and \( \sigma \) trace plots; right: Posterior mean estimate of the initial state. The Monte Carlo sample size was \( 10^4 \).](image)

Next, we compare the performance of AOB with that of ABDA. The results of our numerical experiments are summarized in fig. 8. We note that both methods produce essentially the same results. However, table 5 illustrates the reduction in computation time facilitated by ABDA. This
ACFs for $\mu$ and $\sigma$, $N=1953$

Figure 7: The empirical autocorrelation function computed using AOB in the inverse heat equation example.

Application suggests that ABDA may be preferable to AOB when the forward problem is computationally expensive.

Figure 8: Statistical inversion results for the heat equation example, using AOB and ABDA methods.
| metric  | AOB    | ABDA   |
|---------|--------|--------|
| time (sec) | 819.89 | 622.19 |
| ESS     | 1096.46| 933.37 |
| IACT    | 9.12   | 10.71  |

Table 5: Sampling metrics for AOB and ABDA methods for the inverse heat equation example.

6 Conclusions

This paper focuses on the problem of sampling from a posterior distribution that arises in hierarchical Bayesian inverse problems. We restrict ourselves to linear inverse problems with Gaussian measurement error, and we assume a Gaussian prior on the unknown quantity of interest. The hierarchical model arises when the precision parameters for both the measurement error and prior are assigned prior distributions. Gibbs sampling [3] and low-rank independence sampling [7] have been proposed for this type of problem, but the statistical efficiency of the resulting MCMC chains produced by either approach decreases as the dimension of the state increases. We discuss this phenomenon in detail and consider a solution using marginalization-based methods [13, 20, 25]. Marginalization can be just as computationally prohibitive for sufficiently large-scale problems. Thus, we combine the low-rank techniques with the marginalization-based approaches to propose three MCMC algorithms that are computationally feasible for larger-scaled problems. The first of these new MCMC methods is a direct extension of the one-block algorithm [25]; the second is an extension of the delayed acceptance algorithm [8]; and the last is an extension of the pseudo-marginal algorithm [2]. We test and compare the performances of these three methods on two test cases, demonstrating that they all work reasonably well. We also offer suggestions on when one algorithm might be preferable over another based on, e.g., the spectrum of the prior-preconditioned Hessian matrix. Future work will consider extensions to nonlinear forward models and non-Gaussian priors on the unknown quantity of interest.
