Length Dependent Thermal Conductivity Measurements Yield Phonon Mean Free Path Spectra in Nanostructures

Hang Zhang, Chengyun Hua, Ding Ding & Austin J. Minnich

Thermal conductivity measurements over variable lengths on nanostructures such as nanowires provide important information about the mean free paths (MFPs) of the phonons responsible for heat conduction. However, nearly all of these measurements have been interpreted using an average MFP even though phonons in many crystals possess a broad MFP spectrum. Here, we present a reconstruction method to obtain MFP spectra of nanostructures from variable-length thermal conductivity measurements. Using this method, we investigate recently reported length-dependent thermal conductivity measurements on SiGe alloy nanowires and suspended graphene ribbons. We find that the recent measurements on graphene imply that 70% of the heat in graphene is carried by phonons with MFPs longer than 1 micron.
Theory

Our goal is to relate experimentally measured thermal conductivities to the MFP spectrum, or the accumulated thermal conductivity as a function of MFP\(^2\). Following the approach of Ref. 20, we therefore seek an equation of the form:

\[ k = \int_0^\infty S(Kn_{\omega}) f(\Lambda_{\omega}) d\Lambda_{\omega} = \int_0^\infty L^{-1} K(Kn_{\omega}) F(\Lambda_{\omega}) d\Lambda_{\omega} \]  

(1)

where Kn\(_{\omega}\) = \(\Lambda_{\omega}/L\) is the Knudsen Number, \(\Lambda_{\omega}\) is the MFP, L is the sample length along the direction of the temperature gradient, \(k\) denotes thermal conductivity as a function of length L, \(f(\Lambda_{\omega})\) and \(F(\Lambda_{\omega})\) are differential and accumulative MFP spectra related by

\[ F(\Lambda_{\omega}) = \int_0^\Lambda_{\omega} f(\Lambda) d\Lambda, \text{ and } S \text{ is the heat flux suppression function that equals the ratio of actual heat flux to the Fourier’s law prediction.} \]

The kernel \(K\) is defined as \(K(Kn_{\omega}) = -dS/dKn_{\omega}\).

The inputs to this equation are a finite number of measured thermal conductivities \(k\) as a function of lengths \(L\). To close the problem, we must identify the suppression function by solving the BTE, given by\(^22\):

\[ \frac{\partial \epsilon_{\omega}}{\partial t} + v \cdot \nabla_{\epsilon} \epsilon_{\omega} = -\frac{\epsilon_{\omega} - \epsilon^0_{\omega}}{\tau_{\omega}} \]  

(2)

where \(\epsilon_{\omega}\) is the desired distribution function, \(\omega\) is the angular frequency, \(\epsilon^0_{\omega}\) is the distribution function at the equilibrium state, \(v\) is the group velocity of phonons, and \(\tau_{\omega}\) is the relaxation time of phonons at certain frequency.

We obtain this function using two distinct approaches: a semi-analytic method and a numerical Monte Carlo (MC) method. First, we use a recently reported semi-analytical solution for steady heat conduction through a crystal of thickness L with two blackbody boundaries\(^23\). In this solution, the BTE is linearized and solved using a series expansion method. The full details are given in Ref. 24. The final result for the suppression function and kernel are:

\[ S(Kn_{\omega}) = 1 + 3Kn_{\omega} \left[ E_5 \left( Kn_{\omega}^{-1} \right) - \frac{1}{4} \right] \]  

(3)

\[ K(Kn_{\omega}) = -\frac{dS}{dKn_{\omega}} = \frac{3}{4} - 3E_5 \left( Kn_{\omega}^{-1} \right) - \frac{3}{Kn_{\omega}} E_4 \left( Kn_{\omega}^{-1} \right) \]  

(4)

where \(E_n(x)\) is the exponential integral function, given by:

\[ E_n(x) = \int_0^1 \mu^{n-2} \exp \left( -\frac{x}{\mu} \right) d\mu \]  

This equation was derived by neglecting temperature slip between the black walls. Physically, this assumption is similar to the weakly quasiballistic regime described in Ref. 23 and implies that the ballistic phonons are low frequency modes with a small heat capacity. The assumption has been shown to be quite accurate for experimentally accessible length scales\(^24\).

We plot this result in Fig. 1a. For extremely short MFPs compared to the sample length \(L\), the suppression function equals unity, indicating these phonons are diffusive and their heat flux contribution equals the Fourier’s law prediction. As the Knudsen number increases, the suppression function decreases and eventually approaches zero, indicating that phonons contribute a smaller amount to the heat flux than predicted by Fourier’s law. Physically, this suppression occurs because phonons cannot travel a full MFP before being absorbed by the blackbody boundary.

**Figure 1** | (a) Suppression functions obtained from analytical (black solid line) and MC methods (open circles and open squares), and the Kernel (green solid line) from the analytic method. The two suppression functions are in excellent agreement. (b) MFP spectra for pure Si slabs of various thicknesses obtained from MC. Larger suppression for long MFP phonons occurs as the length of the Si slab decreases. (c) Thermal conductivities of pure Si slabs as a function of thickness calculated by MC. (d) Reconstructed (red circles) and the actual (blue solid line) MFP spectrum of bulk Si. All the values are normalized to bulk thermal conductivity of pure Si. The reconstructed result is in excellent agreement with the actual MFP spectrum.
We additionally solve the BTE numerically to validate the calculations above as well as to consider more complex situations such as when boundary scattering occurs. For this calculation, we use a linearized deviational Monte Carlo method to solve the adjoint BTE as described by Péraud et al.\textsuperscript{26} This technique solves BTE by simulating advection and scattering of particles that represent phonons traveling inside the simulation domain. Substantial reductions in computational cost are achieved through a number of simple changes to the original MC algorithm. First, the deviational algorithm simulates only the deviation from a known equilibrium Bose-Einstein distribution, thereby incorporating deterministic information and reducing the variance. Further, for small temperature differences, the collision term in the BTE can be linearized, allowing particles to be simulated completely independently and without spatial and temporal discretization.\textsuperscript{87} Next, we use a variable local equilibrium temperature method that closely matches the steady-state temperature profile.

Finally, we solve the adjoint BTE rather than the traditional BTE.\textsuperscript{88,89} In the original algorithms of Refs. 26, 27, the probability for a certain phonon mode to be sampled is proportional to the density of states. Therefore, low frequency phonons are rarely sampled even though they contribute substantially to thermal conductivity, leading to large stochastic noise. The adjoint method overcomes this limitation by drawing particles with equal probability among all phonon modes and correcting the bias introduced by this sampling when thermal properties are calculated. With these advances in numerical approach, we are able to solve the BTE in a 100 micron long domain in minutes on a desktop computer. Further, this numerical approach can incorporate boundary scattering mechanisms for arbitrary geometries exactly, unlike the analytical treatment.

To validate the code, we calculate the MFP spectrum for an infinite planar slab with two blackbody boundary conditions, the same problem solved by the semi-analytical method. For this calculation, we use an isotropically averaged dispersion for Si. The original dispersion and relaxation times were calculated by density functional theory (DFT) by Jesús Carrete and N. Mingo with Sheng\textsuperscript{30,31} and Phonopy\textsuperscript{32}, from interatomic force constants obtained with VASP\textsuperscript{33–35}. We reduce computational cost by taking advantage of the cubic symmetry of Si and computing an isotropic equivalent dispersion as described in Ref. 37. Using this dispersion, we calculate the MFP spectrum for variable lengths, as in Fig. 1b. We observe that decreasing the length of the domain results in the suppression of long MFP phonons to thermal conductivity compared to the bulk spectrum. The ratio of the differential MFP spectrum for a finite length to that for an infinite length yields the suppression function and is plotted for two lengths in Fig. 1a, demonstrating that the function obtained from our numerical approach exactly agrees with the analytical result.

With these tools, we now demonstrate the principal result of this work by using the suppression function to reconstruct the MFP spectrum from variable-length thermal conductivity measurements on a Si slab. We synthesized thermal conductivities as a function of length as shown in Fig. 1c. With these length dependent thermal conductivities and the suppression function, we used the same convex optimization method introduced in Ref. 20 to reconstruct the MFP spectrum. As in Figure 1d, the reconstructed cumulative MFP distribution is in excellent agreement with the actual cumulative MFP distribution, which is obtained from the DFT calculation, demonstrating that our approach can accurately reconstruct the MFP spectrum from length-dependent thermal conductivities of Si slabs.

We now numerically demonstrate that our approach can be applied to more general problems than Si slabs with a single scattering mechanism. We consider a SiGe nanowire in which point defects and the nanowire boundaries scatter phonons in addition to the intrinsic phonon-phonon scattering mechanism. The phonon-phonon relaxation times are taken to be the same as those of pure Si\textsuperscript{30–36}, while the mass defect scattering rate is given by \( \tau_{x_0}^{-1} = x(1-x)A_0x^4 \), where \( A \) is a constant of 3.01 × 10\textsuperscript{41} s\textsuperscript{-1} for Si\textsubscript{1−x}Ge\textsubscript{x}, which is obtained from Ref. 38. This model predicts a thermal conductivity of 14 W/mK for bulk Si\textsubscript{0.9}Ge\textsubscript{0.1}, which is consistent with other models by DFT calculation and experimental result.\textsuperscript{38,39} These scattering rates are combined using Matthiessen’s rule. We incorporate boundary scattering by explicitly simulating phonon trajectories inside a nanowire with a square cross-section of size 100 nm by 100 nm. We use Ziman’s specularity parameter, \( p = \exp(-16\pi\sigma/3\lambda^2) \), to determine the probability of specular or diffuse scattering, where \( \sigma \) is surface roughness and \( \lambda \) is the phonon wavelength.\textsuperscript{40}

With this framework, we use our MC simulations to calculate the length-dependent thermal conductivities for a Si\textsubscript{0.9}Ge\textsubscript{0.1} nanowire with surface roughness of \( \sigma = 0.1 \) nm, a 100 nm by 100 nm square cross-section, over lengths from \( L = 5 \) nm to 16 mm as would be obtained in an experiment. Then, using only our knowledge of these thermal conductivities and the suppression function, we perform the reconstruction procedure to obtain the MFP spectrum of the nanowire. This result is shown in Fig. 2a. The reconstructed spectrum is in good agreement with the actual one without requiring any knowledge of the scattering mechanisms in the nanowire. Thus, the success of the reconstruction of MFP spectrum of the nanowire demonstrates the self-consistency of our approach.

**Discussion**

We now use our approach to examine two recent reports of length-dependent thermal conductivities in nanostructures. First, we consider SiGe alloy nanowires as investigated by Hsiao et al.\textsuperscript{16} These nanowires were reported to have ballistic heat conduction persisting over approximately 8 microns. To investigate this experimental report, we calculate the length-dependent thermal conductivities of Si\textsubscript{0.9}Ge\textsubscript{0.1} nanowires, which has the approximately the same cross-sectional area, 100 nm by 100 nm cross-section, as that of the nanowires in Ref. 16, whose diameters range from 50 nm to 180 nm. Simulated data are shown in Fig. 2b for nanowires with extremely rough boundaries, \( \sigma \rightarrow \infty \), and smooth boundaries, with \( \sigma = 0.1 \) nm.

![Figure 2](image-url)  
**Figure 2** | (a) The actual (MC data) and reconstructed MFP spectra of a simulated Si\textsubscript{0.9}Ge\textsubscript{0.1} nanowire with surface roughness of RMS = 0.1 nm and the same square cross-section with a side length of 100 nm. The reconstructed distribution is in good agreement with the actual distribution, even though it is extracted from merely a series of discrete thermal conductivities without any boundary scattering information. (b) Thermal conductivities of Si\textsubscript{0.9}Ge\textsubscript{0.1} nanowire from both MC simulations (lines) and experimental measurements (open squares) as a function of nanowire lengths. All simulated nanowires have the same square cross section as that in (a), and were simulated with very smooth surface (\( \sigma = 0.1 \) nm, green dashed line) and extremely rough surface (\( \sigma = \infty \), red solid line), respectively. The experimental data does not follow the trend predicted by the simulations. All the thermal conductivities are normalized to their “bulk” value, which is thermal conductivity of the infinitely long nanowire.
We observe a discrepancy between the trends of experimental data and our simulations. The experimental data suggest that the thermal conductivities of these SiGe nanowires are mainly due to phonons with a narrow MFP spectrum around ~8.3 μm, but our simulations indicate that even for very smooth nanowires (σ = 0.1 nm), phonons within this range only contribute ~15% of the total thermal conductivity (Fig. 2a). Most of the heat is carried by MFPs less than 1 micron, with some heat being carried by longer MFPs in the partially specular case. Additionally, most actual nanowires have surface roughness higher than 0.1 nm\textsuperscript{41,42}, and in this case long MFP phonons contribute only a small amount to heat conduction. Due to the relatively large diameter of the nanowire, changes to the phonon dispersion for thermal phonons due to phonon confinement are unlikely\textsuperscript{43}. The experimental measurements thus do not agree with our self-consistent calculations. Due to the lack of appropriate experimental reports, we are unable to apply our approach to other nanowire data sets. Further experimental investigation is necessary to address this discrepancy.

Next, we consider recent measurements on graphene\textsuperscript{45}. In this work, Xu et al\textsuperscript{15} performed thermal conductivity measurements over variable lengths on suspended single-layer graphene ribbons to infer an average MFP of 240 nm at room temperature. Using our approach, we can use these same measurements to obtain the MFP spectrum of graphene. Due to the difficulty of fabrication for very long suspended graphene devices and vulnerability of these devices during measurement, the authors of Ref. 15 didn’t obtain the saturated thermal conductivity from an extremely long, or “bulk”, graphene sample. Therefore, we evaluated the saturation value as ~2,000 W/mK with the same extrapolating method in Ref. 21, which is in the range of previous reported experimental results\textsuperscript{44–46}.

There are two subtleties that require discussion before applying our reconstruction approach to graphene. First, our derivation is based on the relaxation time approximation (RTA) of the BTE. It is well known that the RTA with the computed relaxation times from DFT underpredicts the thermal conductivity of graphene due to the importance of normal processes\textsuperscript{47}. However, while our derivation is based on the RTA, we do not make any assumption of the values of the relaxation times, but rather only that an effective relaxation time for each phonon mode can be identified. Our approach can be applied to graphene provided that we regard the MFP variable as an effective MFP that represents the average propagation length for a particular phonon frequency as determined by both normal and Umklapp processes.

Second, we have derived our suppression function for an isotropic material with a three-dimensional phase space. While graphene can be reasonably modeled as isotropic for the in-plane directions, the phase space is two-dimensional. This dimensionality change requires a modification of the form of the BTE for 2D materials. Repeating the derivation in Ref. 24 for a 2D phase space yields the suppression function \( S \) and kernel \( K \) as:

\[
S_{2D}(Kn_0) = 1 + \frac{4}{\pi} Kn_0 \left[ \int_0^{\pi/2} \cos^2(\theta) e^{-\frac{Kn_0 h_0}{1 + Kn_0 h_0}} d\theta - \frac{2}{3} \right]
\]

\[
K_{2D}(Kn_0) = -\frac{dS_{2D}}{dKn_0} = \frac{8}{3\pi} - \frac{4}{\pi} \int_0^{\pi/2} \cos^2(\theta) e^{-\frac{Kn_0 h_0}{1 + Kn_0 h_0}} d\theta
\]

Figure 3a plots the 2D and 3D suppression functions and kernels, demonstrating that the two are quite similar. Using the 2D kernel, we apply our method to obtain the MFP spectrum of a graphene ribbon as in Fig. 3b. This result shows that MFPs in graphene span a large range from ~100 nm to ~10 μm. In addition, we observe that a large portion of heat in graphene is carried by long MFP phonons: ~70% of thermal conductivity are from phonons with MFPs greater than 1 μm. Further, as reported in Ref. 15, the widths of these graphene ribbons are only between 2 to 4 microns. From Fig. 3b, phonons with MFPs longer than 4 μm still carry 13% of heat, which means that some of these long MFP phonons must be specularly reflected at the edges of the graphene ribbons. This observation further confirms the report in Ref. 15 of weak width-dependent thermal conductivities of suspended graphene ribbons when widths are larger than 1.5 μm. Our MFP reconstruction approach has thus provided valuable insights into the intrinsic and edge scattering mechanisms in graphene ribbons that are difficult to obtain from knowledge of only the average MFP.

**Summary**

We have presented a reconstruction method that allows MFP spectra of nanostructures to be obtained from length-dependent thermal conductivity measurements. Our approach requires no prior knowledge of the scattering mechanisms in the nanostructure. By applying our approach to recent measurements on graphene ribbons, we find that more than half of the heat in graphene is contributed by phonons with MFPs exceeding 1 micron.
