Chest pain in emergency department: A diagnosis of diabetic ketoacidosis must be ruled out

Nasir Mohamad, Rashidi Ahmad, PK Cheah

ABSTRACT

Introduction: Diabetic ketoacidosis (DKA) is a common diabetic complication presenting to the Emergency Department (ED). Early recognition and initial aggressive treatment of DKA decreases morbidity and mortality. Clinical presentations of DKA are non specific such as nausea, vomiting, dehydration and abdominal pain. Chest pain is unusual presentation of DKA, however, acute coronary syndrome and pericarditis that manifest with chest pain are known precipitating factors of DKA. Case Report: We report a case of a middle aged diabetic patient who was presented with severe chest pain and elevated creatine kinase that might have thrown us off the correct diagnosis of DKA. Conclusion: A description of his presentations and acute management, along with review of literatures, is presented.

Keywords: Chest pain, Elevated creatine kinase, Diabetic ketoacidosis

INTRODUCTION

Acute coronary syndrome (ACS) and DKA are common medical emergencies. They have different clinical manifestations. The main symptom of ACS is chest pain. However, patients may present with atypical chest pain or angina equivalent such as exertion dyspnoea. In contrast, DKA has varied clinical symptoms. The typical symptoms include nausea and vomiting, abdominal pain, weight loss, dehydration, hypotension, tachycardia, Kausmahl’s respiration and odour of acetone on the breath [1]. The non-typical symptoms have been reported such as DKA associated with pericarditis and myocardial . However, the mechanism in the development of myocardial necrosis remains unclear [2-4].

Many patients presenting with severe chest pain in Emergency Department (ED) initially believed to be cardiac in aetiology may, in fact, have diabetic ketoacidosis (DKA) as an alternative or additional cause of their complaints. We describe a known diabetic patient who is presented to ED with severe chest pain and elevated creatine kinase might have thrown us off the correct diagnosis of DKA.
CASE REPORT

A 44-year-old man arrived at the Emergency Department (ED) triage counter screaming in pain and holding his chest. He was immediately sent to the red zone. We were unable to get a proper history as he repeatedly complained of severe central chest pain and shortness of breath. Initial focused examination revealed he was in severe chest pain, restless, moderately dehydrated, dyspneic and tachypneic. His BMI was 26.2. His initial blood pressure, heart rate, respiratory rate, oxygen saturation and temperature were 129/62 mmHg, 98 beats per minute, 28 per minute, 100% under room air and 37°C respectively. Electrocardiogram (ECG) revealed sinus tachycardia rhythm. All peripheral pulses were palpable and equal on both sides. Abdominal examination revealed soft abdomen with mild tenderness over the epigastric area. Bowel sounds were normal (10/min). Examinations of the cardiovascular and respiratory system were unremarkable.

High flow oxygen via non rebreathing mask was instituted and an intravenous drip of normal saline according to the protocol was initiated. Soluble aspirin 300 mg, sublingual glyceryl trinitrate (GTN) 0.5mg and isosorbide dinitrate infusion 10 mcg/min were administered. The chest pain was persistent despite the initial treatment. The pain was controlled after 10 mg of intravenous morphine (titrating dose every 5 minutes). Intravenous midazolam of 2.5mg was also administered to make him more calm and comfortable. He was treated as acute coronary syndrome (ACS). Intravenous heparin according to the protocol was instituted and an intravenous drip of normal saline administered. The chest pain was persistent despite controlled; it was sudden in onset, about one hour prior to admission. The patient claimed that he had intermittent, sudden central chest pain, radiating to the neck and epigastric area, lasting for a few minutes, and sweating. The pain was not precipitated by exercise and food intake. He had a few occasions of vomiting and low-grade fever for the last 3 days. He did not seek any treatment from a general practitioner. He has been suffering from Type II diabetes mellitus since 5 years and is currently on subcutaneous Actrapid insulin (18 IU/18U/10U). For the past 2 weeks of fasting month-Ramadhan, he did not take his daylight insulin injections since he was fasting and he was afraid that insulin might cause him hypoglycemia. He is a non-smoker and has no history of ischemic heart disease or hypertension. However, he had family history of heart ailments and hypertension in his first degree relative.

Serial electrocardiograms showed a normal sinus tachycardia and absence of ST-T changes. Bedside laboratory tests demonstrated hyperglycemia (capillary blood glucose 17.1 mmol/L) and wide anion gap metabolic acidosis (arterial blood gases pH, 7.24; bicarbonate, 13.1 mmol/L; paCO2, 25.1 mmHg; pO2, 315 mmHg; BE, -10 and sodium, 133 mmol/L; potassium, 4.7 mmol/L; urea 4.7 mmol/L; chloride, 93 mmol/L; anion gap, 27 mmol/L). Urine analysis demonstrated heavy ketonuria dipstick urine ketone, 4+, glycosuria (urine sugar ++++) and absence of urinary tract infection (urine nitrite and leukocyte – nil) and rhabdomyolysis (haemoglobinuria or tea coloured urine). His full blood counts showed haemoglobin, 13.6g/dL; total white cell count, 17,400/uL (72.3% neutrophils and 22.2% lymphocytes); platelet count, 280,000/uL. His creatine kinase (CK) during admission was 879 U/L. Troponin T during admission was normal (T<0.01 µg/L). Chest radiograph showed normal lung field and no cardiomegaly. Supine plain abdominal radiograph showed normal distribution of gases and no calcification seen.

A differential diagnosis of Diabetic Ketoacidosis (DKA) precipitated by acute coronary syndrome was made based on the clinical findings (chest pain) and laboratory results (hyperglycemia, heavy ketonuria, wide anion gap metabolic acidosis and elevated CK). Rehydration therapy and subcutaneous injections of soluble insulin (Actrapid 6 IU/hour) were started. His condition was getting better after 2.5 L of normal saline infusion. His blood glucose, blood pressure and heart rate after two hours in ED were 13.2 mmol/L, 110/80 mmHg and 80 beats per minute respectively. His arterial blood gases showed some improvement (pH: 7.31; bicarbonate, 20.3 mmol/L; paCO2, 38.5 mmHg; pO2, 125 mmHg; BE, -5.7). The patient was transferred to the medical ward for further management and observation.

Serial electrocardiogram (ECG) showed no evidence of ischemic heart disease (ST-T changes). Serial creatine kinase (CK) (normal value: < 190 U/L) on day 1, day 2 and day 3 were 879 U/L, 751 U/L and 579 U/L respectively. Serial CK-MB (normal value: < 25 U/L) on day 1, day 2 and day 3 were 46 U/L, 39 U/L and 28 U/L respectively. Qualitative Troponin T six hours apart was less than 0.01 µg/L. The chest pain improved after intensive fluid therapy and insulin infusion. His glucose level and metabolic acidosis returned to normal. Insulin infusion was tapered off 4 days later. He started ambulating without any further complaints of chest pain. According to the Cardiologist, there was no objective evidence to suggest his current illness was due to acute coronary syndrome. Hence, stress test and coronary angiography were not required at that point in time. Counselling on compliance to medication was given prior to discharge on day 10 of admission. He was given an outpatient appointment in the physician clinic for follow-up treatment. During recent follow-up, he denied chest pain and shortness of breath. His blood glucose was fairly controlled (FBS: 8.6 mmol/L, HbA1c: 6.8%).
DISCUSSION

Management of patients with severe chest pain is a great challenge to the emergency residents. Adequate history related to the symptom may be difficult to obtain from such patients on presentation. We strongly suggest an administration of titrated dose of intravenous narcotic to relief pain suffering once primary survey is completed and vital signs have been recorded and evaluated. Adequate pain relief facilitates history taking and improves patient satisfaction to hospital management.

The patient presented to us with a severe chest pain made the ACS the most likely diagnosis despite a normal ECG. Elevated creatine kinase made our suspicion of ACS greater and he was managed accordingly. It is known that diabetes is an important risk factor for coronary artery disease and it is associated with a worsened prognosis for patients with acute myocardial infarction. Therefore, diabetic patients who have chest pain either typical or atypical angina is considered to have high or moderate probability of ACS. Meanwhile, it has been reported that DKA and ACS may be presented together [5]. Routine practice of blood sugar checking and arterial blood gases by the medical personnel’s for tachypneic marked elevation of CK with acute renal failure, possibly requiring hemodialysis [7]. Rhabdomyolysis occurs commonly in patients with DKA but is usually subclinical. Rhabdomyolysis associated with DKA may be overlooked, resulting in renal failure that may be averted with appropriate therapy. The mechanism of DKA-mediated muscle injury is uncertain. Theories include insufficient energy delivery to muscles, hyperosmolar effects and underlying metabolic defects such as McArdle’s [7].

According to the WHO expert committee, a diagnosis of non-ST elevation acute coronary syndromes is made when patients have symptoms of ischemic chest pain and elevated cardiac enzymes [8]. Current consensus guidelines of the Joint European Society of Cardiology and American College of Cardiology state that troponins are the preferred biomarkers of myocardial necrosis; this is because of their improved sensitivity and specificity compared with the conventional biomarkers creatine kinase and its isoenzyme MB (CK-MB) [9]. In fact, in the setting of cardiac ischaemia or coronary, myocardial infarction (MI) is defined as a typical rise and fall of troponin; the alternative CK-MB is used only when Tn assays are not available.

DKA does cause acute myocardial necrosis [3]. However, the mechanism is unclear. Theories include severe acid-base and electrolyte disturbances triggered coronary spasms and dehydration, low cardiac output, increased blood viscosity, impaired blood flow, increased platelet aggregation, increased red blood cell rigidity and hemostatic changes triggering the development of thrombosis [10]. DKA results in a prothrombotic state and activation of the vascular endothelium, which in turn predispose to cerebrovascular accidents or myocardial necrosis [3].

CONCLUSION

Many patients presenting with severe chest pain in Emergency Department (ED) initially believed to be cardiac in aetiology may, in fact, have diabetic ketoacidosis (DKA) as an alternative or additional cause of their complaints. The prompt recognition of DKA and simple institution of rapid rehydration have continued to reduce the mortality and complications. It is advisable to perform random blood glucose and urine ketone in diabetic patients as the investigations are affordable and non invasive. As ACS is very difficult to rule out, in fact, it may be associated with carditis or myocarditis, we should consider cardiac enzymes including troponin T and creatine kinase, serial ECG, and echocardiography during acute phase. Perhaps in the future, Echocardiography Stress Test, Technetium Scan or Coronary Angiography should be done in high-risk patients to rule out coronary artery disease.
