Objectives: Reliable evidence is the keystone for any noncommunicable disease (NCD) prevention plan to be initiated. In this study we carried out a risk factor investigation based on the WHO Stepwise approach to Surveillance (STEPS).

Methods: The study was conducted on 1000 adults between 15 and 64 years of age living in Ardabil province, north-west Iran during 2006, based on the WHO STEPS approach to surveillance of risk factors for NCD. At this stage only the first and second steps were carried out. Data were collected through standard questionnaires and methods analyzed using STATA version 8 statistical software package.

Results: 29.0% of men and 2.6% of women were current daily tobacco smokers. The mean number of manufactured cigarettes smoked per day was 18.9 among current daily smokers. Smoking was most prevalent among men of low-income families and those of lower education. The mean body mass index (BMI) was 26.6 kg/m², and was significantly correlated with systolic blood pressure. 58.9% were overweight or obese; 18.0% had raised blood pressure and 3.7% had isolated systolic hypertension. The mean number of servings of fruit consumed per day was 1.1; 33.1% had low levels of activity. Combined risk factor analysis showed that 4.1% of participants were in the low-risk group (up to 5.1% among men and 3.2% among women). Those in the high-risk group comprised 25.6% in the 25- to 44-year age group and 49.7% in the 45- to 64-year age group. Mean BMI increased by age in both sexes at least at the first three decades of adult life.

Conclusion: Based on observed status of risk for cardiovascular health, burden of cardiovascular diseases is expected to increase if an effective prevention strategy is not undertaken.

Keywords: cardiovascular health, noncommunicable diseases, WHO STEPS, smoking, obesity, physical activity

Introduction

Life expectancy at birth has increased from a global average of 46 years in 1950 to 66 years in 1998.1 Along with lifestyle changes and environmental hazards, this life expectancy increase has caused an elevated rate of noncommunicable diseases (NCDs) globally but with delay in developing countries. “Of 57 million global deaths in 2008, 36 million, or 63% were due to noncommunicable diseases. In 2008, nearly 80% of noncommunicable disease deaths (29 million), occurred in low- and middle-income countries with about 29% of deaths occurring before the age of 60 in these countries”.2 NCDs are predicted to account for approximately three-quarters of all deaths in the developing world by the year 2020.3

Developing countries shared 72% of 33.4 million deaths caused by NCDs during the year 2002.4 Nearly 90% of the world’s total disease burden occurs in developing
countries, while only 10% of global health expenditure is allocated in these countries. The NCD condition is the same for many of the WHO Eastern Mediterranean Region countries, and considering the pre-existing heavy load of infectious diseases in these countries, they are tolerating a double burden of both infectious diseases and NCDs.

Iran is known to have a good national health network. Since 1984, the primary health care system in Iran has become highly organized and efficient, resulting in a dramatic decrease in infant, maternal, and neonatal mortality rates, with an increase in population growth and life span, and a marked shift towards NCDs. Some success in controlling nutritional diseases and injuries has also been reported but there is no documentation of national success in combating major NCDs.

Most NCDs have common preventable risk factors such as smoking, poor diet, high alcohol consumption, hypertension, sedentary lifestyle, and obesity, and for cardiovascular diseases (CVD), morbidity and mortality increase when these risk factors cluster. Reliable evidence is the keystone for any NCD prevention plan to be initiated. In this study we carried out a risk factor investigation based on the World Health Organization (WHO) STEPwise approach to Surveillance (STEPS).

Methods

This study was carried out in Ardabil in 2006. The study population comprised people aged 15 to 64 years old living in rural and urban areas of Ardabil province. Ardabil province is located in north-west Iran with a population about 1.2 million. The study was conducted based on the WHO STEPS of risk factors for NCDs. This approach uses different levels of risk factor assessment including collecting information using questionnaires (step 1), physical measurements (step 2), and taking blood samples for biomedical assessment, (step 3). Each step can include core, expanded core, and optional items. Further details can be found in Table 1 or the source reference.

At this stage only the first and second steps were carried out. This study was conducted by probability proportional to size (PPS) multistage stratified cluster sampling through which 50 clusters were selected. In PPS sampling, the selection probability for each element is set to be proportional to its size measure. The sampling frame of this study was based on the postal code frame of the national post office, which is 10-digit postal code number. In urban areas clusters comprise one to several blocks or parts of blocks. Blocks are usually attached buildings. In rural areas a cluster may comprise one to several villages or part of a village. After determining the cluster start point, enrollment and data collection started. In each cluster ten females and ten males were enrolled. These included two eligible persons in each sex and age group. This began from the household at the cluster start point and continued toward the other households until the required number of participants was enrolled. Consecutive households were selected based on geographical location of buildings to the right-hand side of each building. Data were collected based on interviews, physical examinations, and anthropometric measurements carried out by a team of trained nurses and health professionals. Research survey and examination teams visited households according to previously arranged appointments. Before the interviews or examinations by the survey teams, appointments were made by pioneer teams visiting households at least 1 day before and preferably during evenings when most people are at home. Measurements were done using calibrated and standard instruments. Height was measured with participants standing without shoes using a standard metal ruler. Weight was measured also by calibrated digital scales while light clothes were worn, in consideration of cultural principles. Waist circumference was measured at a level midway between the lower rib margin and iliac crest to the nearest 0.5 cm. Blood pressure (BP) was measured based on WHO recommendations used in the research protocol.

Five age groups were considered for sampling: five equally distributed groups between age 15 and 64 years. This method of sampling enabled 100 participants to be included in each age and sex group, thus enrolling 1000 participants. The large sample size, the 99.5% response rate, and the sampling design and framework meant that the sample was representative of the study population. Completed questionnaires were evaluated daily, once by district supervisors and again at the provincial health center. Questionnaires with any problems or deficiencies were sent back to be rechecked and completed.

All the data were entered into the computer by one operator at a provincial health center. Data were analyzed using Stata statistical software package (v 8; Stata Corp, College Station, TX). Simple bivariate as well as multiple regression analysis was used to analyze data. Statistical significance was set at 0.05. Priority was given to practical benefit and clinical significance in interpreting statistically
significant data. Specific definitions in categorizing data are provided in the relevant tables. Physical activity was measured using questions on four different aspects: physical activity at the workplace, physical activity during recreation time, physical activity while traveling, and physical resting time. To define a combined risk factor index, five components were considered: (1) being a current daily smoker; (2) < five servings of fruits and vegetables per day; (3) low level of activity (<600 MET–minutes); (4) body mass index $\geq 25$ kg/m$^2$; (5) raised BP (SBP $\geq$ 140 and/or DBP $\geq$ 90 mmHg). Participants lacking any of these were classified as low risk and those having at least three of the above-mentioned risk factors were considered as high risk of NCDs. For the definition of abdominal obesity the cut-off points of 102 cm in men and 88 cm in women were used according to the WHO.

The study was approved by the committee of ethics of the Iranian Ministry of Health and Medical Education.

### Results

Participants had a nearly uniform cultural structure, comprising 98% Turks. Most participants were housekeepers (42.4%), 29.2% were self-employed, 10.1% were students, and 6% were government employees. Of these participants, 68.9% had a monthly income <2 million Rials (US$218), 29.5% had a monthly income of 2–7 million Rials (US$218–763), and 1.6% had a monthly income of $7 million Rials.

A summary of results from step 1 are given in Table 2 and results from step 2 are given in Table 3.

Combined risk factor analysis showed that 4.1% of participants were in the low-risk group (up to 5.1% among men and 3.2% among women). Of those in the high-risk group, 25.6% were in the 25- to 44-year age group and 49.7% in the 45- to 64-year age group. Percentages of females were higher in both age groups.

Mean body mass index (BMI) increased with age in both sexes, at least at the first three decades of adult life (Figure 1).

### Table 1

| Measures | Step 1 (Self report) | Step 2 (Physical examination) | Step 3 (Biochemical assessment) |
|----------|----------------------|-----------------------------|---------------------------------|
| Core     | Socioeconomic and demographic variables including years of education, tobacco and alcohol use, physical inactivity, intake of fruit and vegetables | Measurement of weight, height, waist circumference, blood pressure | Measurement of fasting blood sugar, total cholesterol |
| Expanded core | Ethnicity, educational attainment, occupation, income, use of smoke less tobacco, fat consumption, types of physical activity, history of high blood pressure, history of diabetes, treatment for diabetes, treatment for high blood pressure | Hip circumference, pulse rate | Fasting high-density lipoprotein, cholesterol, and triglycerides |
| Optional | Other health-related behaviors, mental health status, disability, injury | Objective measurement of physical activity, measurement of skin-fold thickness | Oral glucose tolerance test, urine examination |

### Table 2

| Results for adults aged 15–64 years (95% CI) | Males | Females | Both sexes |
|-------------------------------------------|-------|---------|------------|
| **Step 1 Tobacco use**                   |       |         |            |
| Percentage who currently smoke tobacco daily | 29.0% | 2.6%    | 15.7%      |
| For those who smoke tobacco daily         |       |         |            |
| Average age started smoking (years)       | 20.5 (19.3–21.8) | 23.4 (16.8–30.1) | 20.8 (19.5–22.0) |
| Percentage smoking manufactured cigarettes | 97.2% | 99.8%   | 98.5%      |
| For smokers of manufactured cigarettes   |       |         |            |
| Mean number of manufactured cigarettes smoked per day | 19.8 (19.1–20.6) | 9.0 (7.4–10.8) | 18.9 (18.2–19.6) |
| **Step 1 Fruit and vegetable consumption (in a typical week)** |       |         |            |
| Mean number of servings of fruit consumed per day | 1.0 (0.9–1.1) | 1.1 (1.0–1.2) | 1.1 (1.0–1.1) |
| Mean number of servings of vegetables consumed per day | 1.1 (1.0–1.2) | 1.2 (1.1–1.3) | 1.1 (1.0–1.2) |
| Percentage who ate $\geq$5 combined servings of fruit and vegetables per day | 4.2    | 4.1     | 4.1        |
| **Step 1 Physical activity**              |       |         |            |
| Percentage with low levels of activity (defined as $<600$ MET-minutes/week) | 24.9 | 41.2 | 33.1 |
| Median time spent in physical activity per day (hours) | 2.9 (1.2–6.9) | 1.4 (0.6–3.5) | 2.1 (0.9–5.0) |

**Abbreviation:** MET, metabolic energy.
BMI was significantly correlated with both SBP \( (r = 0.33, \ P < 0.01) \) and DBP \( (r = 0.28, \ P < 0.01) \). Abdominal obesity was observed in 14.8\% of men vs 56.9\% of women \( (P < 0.001) \). A comparison of waist circumference among age groups and between genders is shown in Figure 2.

The mean age of starting smoking was 20.5 years (95\% confidence interval [CI]: 19.3–21.8) among men and 23.4 years (95\% CI: 16.8–30.1) among women. Smoking was most prevalent among men of low-income families and those of lower education.

Figure 3 shows the percentage of participants classified into a low level of total physical activity compared with different age groups and sexes.

Mean BP, hypertension, and abdominal obesity increased with age in both groups \( (P < 0.01) \). The change was larger among women.

Regression analysis results showed that mean units of fruit eaten per day did not differ between sexes or among age groups (women ate only 0.12 more units of fruit per day than men \( [P = 0.046] \); with each 1-year increase in age [regression coefficient: 0.002] units of fruit eaten per day decreased by only 0.006), although these differences were statistically significant. Mean units of vegetables eaten per day did not differ between sexes or among age groups (women ate only 0.1 units more vegetables per day than men \( [P = 0.58] \); with each 1-year increase in age units, fruit and vegetables eaten per day decreased by only 0.002 \( [P = 0.19] \)).

Some eating habits were correlated with mean BP. Among women, the correlation between mean BP and average days of eating fruit per week was 0.15 \( (P < 0.05) \) and the correlation between mean BP and average days of eating vegetables was 0.1 \( (P < 0.05) \). Among men only the correlation between mean BP and average days of eating vegetables was statistically significant \( (r = 0.1, \ P < 0.05) \). Fruit and vegetable eating habits were not associated with abdominal obesity. Moderate activity during recreational time was negatively associated with abdominal obesity \( (P < 0.001) \). However, such an association was not explored for work time physical activity and abdominal obesity.

Figure 4 shows the distribution among different age groups of eating fruit or vegetables <4 days a week.

No sex difference was shown for consumption of fish; comparison among age groups showed that fish consumption decreased after age 35 years. Solid vegetable oil was used for cooking most often by 83.45\% of people while only 14.24\% used liquid oil (not significantly different between sexes or among age groups).

**Discussion**

In the past it was thought that CVD was confined primarily to industrialized nations, but now CVD has emerged as a major health threat in developing countries. CVD currently accounts for 30\% of mortality in low- and middle-income
countries each year, with significant economic effects. Nevertheless, many governments and global health institutions have largely overlooked CVD.8

Nearly one-third of the men in Ardabil province were daily smokers. We found that smoking was most prevalent among men of the low-income families and those of lower education. This may indicate that, like some other developing countries, our population is in the second stage of a smoking epidemic and we may expect even higher mortality and morbidity during the coming decades.9,10

Considering the governing role of men at Iranian households especially in rural areas, this result should also raise concerns about the effect of passive smoking on others, particularly children. This problem is exacerbated by the fact that it occurs mostly among people of lower education and income, who live in low-roofed houses and are unaware of the risks of passive smoking.

The overall prevalence of current smokers was 15.7%, higher than studies conducted with a similar methodology in neighboring provinces as well as the country as a whole.11,12 But it was much lower than in a study carried out using WHO STEPS in Indonesia, in which 54% of men and 27.6% of the total population were current daily smokers. The main difference in methodology was that the Indonesian study enrolled an age range of 15–74 years, but this may not adequately explain the different results. Another study in 1998 in Turkey,

Figure 2 Box plots of waist circumference compared among age groups according to sex.

Figure 3 Percentage of participants classified into low level of total physical activity compared between sexes and among age groups.
which is a northern neighbor of Iran and has an approximately equal population, showed that 49.7% of men and 11.8% of women were daily smokers.\textsuperscript{10,13}

Nearly one-third of the population in our study had a low level of physical activity, which was higher among women and higher age groups. Similar results were found in a nearby study, in east Azerbaijan.\textsuperscript{11} Those having higher activity also had lower BMI. Such an association is in line with previous studies.\textsuperscript{14–18}

The obesity prevalence was 25.5%. Although the figure is a little higher than in neighboring provinces and than national figures, it lies in a range reported by other Iranian studies and in some developing countries. Similar to our findings, other studies have also shown that obesity is less common in early adulthood and advances faster among women.\textsuperscript{11,12,19–22}

Mean BMI (Figure 1) increased with age in the first three decades of age among men, then, after a plateau, it continued to increase at a slower rate. For women the increase continued for a little longer, but then declined after 54 years of age. The trend in women may be explained by the effects of aging, such as lower intake of food, or declining uptake of nutrients due to gastrointestinal dysfunction or even changed metabolism. Another plausible mechanism may be the lower life span of obese people, reducing their chance of being included in the sample. But in men the late BMI increase, which is contrary to expectations, can be explained by the fact that men stay at home more when they get old. Here they have easier access to food and compensate for lack of the distraction of work by wandering around the house eating and/or drinking. Some similar results have been published previously.\textsuperscript{14,16,20,23}

In this study 18% of people had at least mild hypertension, lower than a study conducted in east Azerbaijan.\textsuperscript{11} In a national study in Iran the overall prevalence of systolic, diastolic as well as systolic or diastolic hypertension were 4.2%, 5.4%, and 7.7%, respectively, with no significant sex difference.\textsuperscript{24} Mean SBP and DBP in our study were 118.5 and 73.5 mmHg, respectively. In a study with similar methodology based on WHO STEPS conducted in three Asian and African countries, mean SBP varied from 117 to 127 mmHg.\textsuperscript{25}

BMI in our study was significantly correlated with SBP and DBP, which was consistent with the WHO STEPS study in Asian and African countries.\textsuperscript{25}

Americans are known for their bad eating habits. American adults are 24% more likely to be overweight/obese and 59% more likely to be inactive in leisure time than Canadians.\textsuperscript{26} Interestingly, one study has found that obesity, overweight, and hypertension in Iran is as prevalent as in the US, but Iranian women are more obese than American women while a reverse pattern was found in males. This is also in line with our study, indicating that health policy makers should consider this gender discrepancy as a major issue to be addressed.\textsuperscript{27}

Mean daily servings of both fruit and vegetables were both 1.1 in this study, which is reasonable compared with those in some other countries. Fruit and vegetable consumption has always been an important scientific health recommendation.\textsuperscript{28} Gaskin’s study showed that 62% ate two or fewer servings of fruits or vegetables daily.\textsuperscript{29} By secondary exploratory analysis we also found inter-correlations among the studied risk factors; for example, some eating habits and
physical activities were correlated with BP. Although these were in line with results of other studies, such associations need to be more specific, and detailed methodology need to be addressed. Newly developed statistical models that have been suggested for use in public health research could enable such complex associations of large numbers of variables to be explored.33–35

One methodological issue we encountered during the data collection phase was that in the WHO-based questionnaire assessing the number of days people eat vegetables and fruits, 5 and 6 days seemed to be underestimated and 7 days seemed to be overestimated. We think this may not reflect reality, possibly because people may prefer to choose the highest score of a bounded scale if they feel their score is close to the upper boundary. This may affect the distribution of the scale of interest. However, to prevent biased test results we used nonparametric methods in such cases.

Our findings provide evidence for health policy-makers as well as municipalities about lifestyle problems in a studied population. A burden of more diseases is expected if an effective prevention strategy is not undertaken. Although even short-term educational programs have been shown to be effective in improving lifestyle, a durable education strategy and cost-saving policies supported by sustained mass media education and school-based educational programs can be the starting point for a possible national program on controlling NCDs.
