A scheme to execute an $n$-bit Deutsch-Jozsa (D-J) algorithm using $n$ qubits has been implemented for up to three qubits on an NMR quantum computer. For the one and two bit Deutsch problem, the qubits do not get entangled, hence the NMR implementation is achieved without using spin-spin interactions. It is for the three bit case, that the manipulation of entangled states becomes essential. The interactions through scalar J-couplings in NMR spin systems have been exploited to implement entangling transformations required for the three bit D-J algorithm.

The utilization of the intrinsically quantum mechanical nature of the physical world to widen the scope of computational algorithms is one of the important discoveries of this decade [1-3]. It was shown recently that quantum computers can perform certain computational tasks exponentially faster than classical computers [4-6].

The Cleve version of the D-J algorithm [7], which requires $n + 1$ qubits to solve the $n$-bit Deutsch problem, has been implemented by several research groups using NMR [8-10]. It has been shown recently that the $n$-bit Deutsch problem can be solved using $n$ qubits alone [11].

In this paper, we experimentally demonstrate that the $n$-bit D-J algorithm does not require $n + 1$ qubits for its implementation. By doing away with the extra qubit, the algorithm can be more easily accessed for a greater number of qubits. Furthermore, the one-bit and two-bit implementations of the modified version do not involve quantum entanglement [12,13]. In these cases, only the concept of coherent superposition is exploited, to prepare “in parallel” an input state which is a superposition of all possible classical inputs, and the experiment has been performed without using spin-spin interactions. It is only in the implementation for three or more qubits does quantum entanglement play a vital role. A judicious combination of rf pulses and free evolution intervals (under the interaction Hamiltonian), has been employed to construct the required entangling transformations.

Consider an $n$-bit binary string $x$; a function $f$ can be defined on this $n$-bit domain space to a 1-bit range space, with the restriction that either the output is the same for all inputs (the function is constant) or the output is 0 for half the inputs and 1 for the other half (the function is balanced). All the $2^n$ possible input strings are valid inputs for the function ($f(x) = \{0, 1\}$). In quantum computation, these $n$-bit logical strings are in one-to-one correspondence with the eigenstates of $n$-qubits, and one can hence label the logical string $x$ by the eigenstate $|x\rangle$. Classically, for an $n$-bit domain space, one needs to compute the function at least $2^{n/2} + 1$ times in order to determine whether it is constant or balanced. The D-J algorithm achieves this on a quantum computer using only a single function call [14].

The usual implementation of the D-J algorithm for $n$ bits requires $n + 1$ qubits, the function $f$ being encoded through an $f$-dependent unitary transformation,

$$|x\rangle_{w-bit} |y\rangle_{1-bit} \xrightarrow{U_f} |x\rangle_{w-bit} |y \oplus f(x)\rangle_{1-bit}$$

(1)

where $\oplus$ denotes addition modulo 2. The implementation of the unitary transformation $U_f$, along with the Hadamard transformation, then suffices to distinguish the function as constant or balanced [15]. A Hadamard transformation on one qubit mixes the eigenstates maximally,

$$|0\rangle \xrightarrow{H} \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$$

$$|1\rangle \xrightarrow{H} \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)$$

$$H = H^{-1} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$$

(2)

The Hadamard transformation for $n$-qubits is the tensor product of the one-qubit transformation ($H^n = H \otimes H \otimes H \cdots \otimes H$), its action on the $n$-qubit eigen states being

$$H^n |x\rangle = \sum_{y=0}^{2^n-1} (-1)^{\sum_j x_j y_j} |y\rangle$$

(3)

where $x_j$ and $y_j$ are the $j$th entries of the $n$-bit strings $x$ and $y$.

A modified scheme can be designed to solve the $n$-bit Deutsch problem, using $n$ qubits alone [16]. Here, for every function $f$ a unitary transformation is constructed, such that its action on the eigenstates of $n$-qubits is

$$|x\rangle_{w-bit} \xrightarrow{U_f} (-1)^{f(x)} |x\rangle_{w-bit}$$

(4)

Consider $n$ qubits, all in the state $|0\rangle$; a Hadamard transformation $H^n$ converts this state to a linear superposition of all $2^n$ eigenstates with equal amplitudes and no phase differences. The unitary transformation $U_f$ (defined in Eqn. 3) acting on this state, introduces an $f$-dependent phase factor in each eigenstate in the superposition. At this juncture, all information about $f$ is encoded in the quantum state of the $n$ qubits. A Hadamard transformation $H^n$ is once again applied in order to extract the function’s constant or balanced nature:

$$|0\rangle \xrightarrow{H^n} \sum_{x=0}^{2^n-1} |x\rangle \xrightarrow{U_f} \sum_{x=0}^{2^n-1} (-1)^{f(x)} |x\rangle \xrightarrow{H^n} \sum_{x=0}^{2^n-1} \sum_{y=0}^{2^n-1} (-1)^{f(x) - \sum_j x_j y_j} |y\rangle$$

(5)
The final expression for the output state in Eqn. 5 has an amplitude 1 for the state \( |0\rangle_{\text{n-bit}} \) for a constant function and an amplitude 0 for a balanced function. The categorisation of the function as constant or balanced through a single function call using \( n \) qubits, is shown pictorially in Fig. 1.

![FIG. 1. The block diagram for the modified D-J algorithm.](image)

The number of functions for the \( n \)-bit Deutsch problem is \( ^N\!C_{N/2} + 2 \) (where \( N = 2^n \)). The experimental implementation of the modified D-J algorithm for \( n \) bits requires the realisation of the unitary transformation corresponding to each of these functions, and the \( n \)-bit Hadamard transformation, on a physical system. We now proceed towards the NMR implementation of the modified D-J algorithm for one, two and three qubits, where the number of functions are 4, 8, and 72 respectively.

The pseudo-Hadamard transformation \([14]\) (practically equivalent to the Hadamard operator described in Eqn. 3) achieved by a \((90^\circ)_y\) pulse on a spin, has been utilised in our experiments. For the case of two and three qubits, the same has been achieved by a \((90^\circ)_y\) pulse applied non-selectively on all the spins.

The \( n \)-bit unitary transformations \( U_f \) corresponding to the functions \( f \), are diagonal in the eigenbasis and find a natural description in terms of the single-spin operators,

\[
I^{(j)} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad \sigma_z^{(j)} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}
\]

where \( j \) labels the qubit involved. The action of \( U_f \) on an eigenstate (as described in Eqn. 3), can be used to calculate the explicit matrix forms of \( U_f \), for every function \( f \).

The operator representations of the four unitary transformations for the one-bit modified D-J algorithm are

\[
\begin{align*}
U_1^{(1-\text{bit})} &= I^{(1)} \quad \text{(Const.)} \\
U_2^{(1-\text{bit})} &= -I^{(1)} \quad \text{(Const.)} \\
U_3^{(1-\text{bit})} &= \sigma_z^{(1)} \quad \text{(Bal.)} \\
U_4^{(1-\text{bit})} &= -\sigma_z^{(1)} \quad \text{(Bal.)}
\end{align*}
\]

A pseudo-Hadamard operation achieved by a \((90^\circ)_y\) pulse is applied on a thermal initial state, in order to create a coherent superposition prior to applying the desired unitary transformations \( U_f \). The constant functions correspond to a “do-nothing” operation, while the balanced functions are achieved by a rotation by the angle \( \pi \) about the z-axis of the spin, up to a global phase factor. These \( z \)-rotations have been implemented using composite-\( z \) pulses, whereby a rotation by an arbitrary angle \( \theta \) about the \( z \)-axis, can be decomposed as a set of rotations about the \( x \) and \( y \) axes \([13]\):

\[
(\theta)_z \equiv (\pi/2)_x (\theta)_y (\pi/2)_x - x
\]

Global phase changes are not detectable in NMR and are hence ignored. The spectrum reflects the constant or balanced nature of the function implemented (Fig. 2). After the implementation of a balanced function, the qubit is in a state out-of-phase with the rest of the spectrum. The modified D-J algorithm for one qubit demonstrates the power inherent in even a single bit of quantum information.

![FIG. 2. The modified D-J algorithm for one qubit implemented on 5-nitro-2-furaldehyde, the proton resonating at 9.2 ppm being chosen as the single qubit.](image)

All the 8 unitary transformations corresponding to the functions for the two-qubit case are given in terms of \( I^{(j)} \) and \( \sigma_z^{(j)} \) as

\[
\begin{align*}
U_1^{(2-\text{bit})} &= I^{(1)} \otimes I^{(2)} \quad \text{(Const.)} \\
U_2^{(2-\text{bit})} &= \sigma_z^{(1)} \otimes I^{(2)} \quad \text{(Bal.)} \\
U_3^{(2-\text{bit})} &= I^{(1)} \otimes \sigma_z^{(2)} \quad \text{(Bal.)} \\
U_4^{(2-\text{bit})} &= \sigma_z^{(1)} \otimes \sigma_z^{(2)} \quad \text{(Bal.)} \\
U_5^{(2-\text{bit})} &= -U_{i-4} \quad (i=5,6,7,8)
\end{align*}
\]

All these operators are direct products of single spin operators. They are thus incapable of generating entangled states and can be implemented by operations on individual spins. A pseudo-Hadamard transformation was performed on all the spins (initially in thermal equilibrium) prior to the execution of the desired \( U_i \) transformations. The two constant functions correspond to the “do-nothing” operation, experimentally. The NMR implementation of the balanced functions \( U_2^{(2-\text{bit})} \) and \( U_3^{(2-\text{bit})} \) involves rotations by \( \pi \) about the \( z \)-axis in the single-spin subspaces of spins 1 and 2 respectively, and have
been achieved using composite-z pulses (Eqn. 8). The $U^{(3{\text{-hit})}_4}$ transformation too, does not require the scalar J spin interaction and is implemented as successive π rotations about the z-axes of spins 1 and 2 respectively. The balanced functions are distinguished by one (or both) the spins being out-of-phase with the rest of the NMR spectrum (Fig. 3). Only half the total number of functions have been shown in the one and two-qubit cases, as the others are merely negatives of these, and lead to the same spectral patterns (spectra not shown).

![Diagram](image)

FIG. 3. The modified D-J algorithm for two qubits, implemented on 5-nitro-2-furaldehyde with the two qubits resonating at 6.47 ppm and 6.29 ppm respectively.

The three-qubit D-J algorithm affords the simplest example where quantum entanglement plays a definitive role in the computation. The task here is to implement 72 unitary transformations, the explicit operator forms for 9 of which are

\[
\begin{align*}
U^{(3{\text{-hit})}_1} &= I(1) \otimes I(2) \otimes I(3) \quad (\text{Const.}) \\
U^{(3{\text{-hit})}_2} &= \sigma_z(1) \otimes I(2) \otimes I(3) \quad (\text{Bal.}) \\
U^{(3{\text{-hit})}_3} &= I(1) \otimes I(2) \otimes \sigma_z(3) \quad (\text{Bal.}) \\
U^{(3{\text{-hit})}_4} &= \sigma_z(1) \otimes \sigma_z(2) \otimes I(3) \quad (\text{Bal.}) \\
U^{(3{\text{-hit})}_5} &= \sigma_z(1) \otimes \sigma(2) \otimes \sigma_z(3) \quad (\text{Bal.}) \\
U^{(3{\text{-hit})}_6} &= \frac{1}{2}\sigma_z(1) \otimes (I(2) \otimes I(3) + \sigma_z(2) \otimes I(3)) + \\
&\quad \quad I(2) \otimes \sigma_z(3) - \sigma_z(2) \otimes \sigma_z(3) \quad (\text{Bal.}) \\
U^{(3{\text{-hit})}_7} &= \frac{1}{2}\sigma_z(2) \otimes (I(1) \otimes I(3) + \sigma_z(1) \otimes I(3)) + \\
&\quad \quad \sigma_z(1) \otimes I(3) - \sigma_z(1) \otimes \sigma_z(3) \quad (\text{Bal.}) \\
U^{(3{\text{-hit})}_8} &= \frac{1}{2}\sigma_z(3) \otimes (I(1) \otimes I(2) + \sigma_z(1) \otimes I(2)) + \\
&\quad \quad I(1) \otimes \sigma_z(3) - \sigma_z(1) \otimes \sigma_z(2) \quad (\text{Bal.}) \\
U^{(3{\text{-hit})}_9} &= \frac{1}{2}(\sigma_z(1) \otimes I(2) \otimes I(3) + I(1) \otimes I(2) \otimes \sigma_z(3)) - \\
&\quad \quad \sigma_z(1) \otimes \sigma_z(2) \otimes \sigma_z(3) + I(1) \otimes \sigma_z(2) \otimes \sigma_z(3) \quad (\text{Bal.}) \\
\end{align*}
\]

The operators $U^{(3{\text{-hit})}_4} - U^{(3{\text{-hit})}_9}$ cannot be decomposed as direct products of single-spin operators and are hence capable of generating entangled states from non-entangled ones. The operators $U^{(3{\text{-hit})}_6}_6$, $U^{(3{\text{-hit})}_8}_7$, and $U^{(3{\text{-hit})}_8}_9$, are entangling in different two-spin subspaces and can be factored as direct products of a single-spin operator and a two-particle entangling transformation. They can thus generate states in which two qubits are entangled, with the third qubit remaining non-entangled with either of them. On the other hand, the transformation $U^{(3{\text{-hit})}_9}$ does not allow any such simplifications. It is maximally entangling and leads to states that are three-qubit entangled. These 9 functions are thus divided into three categories namely, non-entangling, two-qubit entangling, and maximally (three-qubit) entangling. The remaining functions are similar in form, and can be classed into one or the other of these categories.

The result of experimentally applying the non-entangling transformations $U^{(3{\text{-hit})}_1}_1 - U^{(3{\text{-hit})}_5}_5$ after a pseudo-Hadamard transformation on a thermal equilibrium state, is shown in Figure 3. The constant function $U^{(3{\text{-hit})}_1}_1$ is the unit operator, and corresponds to the “no pulse” or the “do-nothing” operation. The balanced functions $U^{(3{\text{-hit})}_2}_2$ and $U^{(3{\text{-hit})}_3}_3$ correspond to a rotation by the angle π about the z-axis of the first and the third spins respectively, without perturbing the other spins. This has been achieved by a spin-selective $[\pi]_z$ pulse in each case, using composite z-pulses (Eqn. 8). The spectrum is categorised by the spin in question being out-of-phase with the rest of the spectrum. The transformation $U^{(3{\text{-hit})}_4}_4$ has been implemented by two spin-selective $[\pi]_z$ pulses applied consecutively on the first and the second spins respectively, and leads to a spectrum with both these spins being out-of-phase with the third. The non-entangling balanced function $U^{(3{\text{-hit})}_5}_5$ has been implemented by successive spin-selective $[\pi]_z$ pulses on all the three spins.

The two-qubit entangling transformation $U^{(3{\text{-hit})}_6}_6$, is achieved by the pulse sequence

\[
[p/2]_z^2 \frac{\pi}{2} \frac{\tau_{23}/2}{z} \frac{\pi}{2} \frac{\tau_{23}/2}{z} \frac{\pi}{2} \frac{\tau_{23}/2}{z} \frac{\pi}{2} \frac{\tau_{23}/2}{z}
\]

where $\tau_{23} = 1/J_{23}$ and 1, 2 and 3 are qubit labels. The operators $U^{(3{\text{-hit})}_6}_6$ and $U^{(3{\text{-hit})}_8}_8$ correspond to cyclic permutations of the qubits. The spin-selective π pulses in the middle of the free evolution period $\tau_{23}$ refocus the chemical shift evolution. The pulse sequence (applied after a pseudo-Hadamard transformation on all three qubits in a thermal initial state) results in a density matrix with the product operator form $-I_z^3 + 2I_x^2I_z^3 + 2I_x^3I_z^3$, leading to a spectrum with the multiplet of the first qubit inverted, and an antiphase doublet of doublet pattern for the other two qubits (Fig. 3). The three-qubit entangling function $U^{(3{\text{-hit})}_9}_9$ is implemented by the pulse sequence

\[
[p/2]_z^3 \frac{\pi}{2} \frac{\tau_{23}/2}{z} \frac{\pi}{2} \frac{\tau_{23}/2}{z} \frac{\pi}{2} \frac{\tau_{23}/2}{z} \frac{\pi}{2} \frac{\tau_{23}/2}{z}
\]
leading to an antiphase spectral pattern for all three qubits, corresponding to the product operators $2I_1^x I_2^z + 2I_2^z I_3^x + 4I_1^x I_2^z I_3^z$ (Fig. 3). The spectra in Figure 3 suffer from phase distortions arising from the inaccurate refocusing of the chemical shifts during the $\tau$ periods, and $J$-evolution during long spin-selective composite-$z$ pulses ($[\pi/2]_y [\pi/2]_x = 42$ msec).

This implementation of the D-J algorithm does not require the initial preparation of the spins in a pseudo-pure state, since the thermal equilibrium state serves equally well as a good initial state. The observable spectral result is the same in both cases, though beginning with a pseudo-pure state creates some (undetectable) multiple-quantum coherences. The final pseudo-Hadamard transformation to extract the constant or balanced nature of the function (Fig. 1) is canceled by the $(90)^0$ read-out pulse usually used in NMR experiments, and the computation essentially culminates in the application of the desired $U_f$ function after the first pseudo-Hadamard transformation.

A modification to the usual D-J algorithm enabled an $n$-bit implementation using $n$ qubits. The required unitary transformations were tailored to eliminate the need for the extra qubit, and the modified D-J algorithm was tested experimentally for one, two and three qubits. While the one and two qubit cases use non-entangling unitary transformations, it was noted that for three (or more) qubits, multi-particle entangling transformations are required.
