Abstract. The present study aimed to investigate the clinical relevance of circulating tumor cells (CTCs) in patients with locally advanced head and neck squamous cell carcinoma (LA-HNSCC), particularly in patients with nasopharyngeal and hypopharyngeal squamous cell carcinoma. CTCs were isolated using negative immunomagnetic bead enrichment and were identified by fluorescence in situ hybridization. Youden's index and the receiver operating characteristic (ROC) curve were used to select the optimal CTC baseline value. \( \chi^2 \) test or Fisher's test were used to determine the association between CTC counts and clinical parameters, curative effects and prognosis. The Kaplan-Meier estimator was used to analyze overall survival (OS) and progression-free survival (PFS). In the present study, 356 peripheral blood samples (178 pretreatment samples and 178 post-treatment samples) from 178 patients were examined. The results revealed that the pretreatment CTC detection rate was 73.8%. The minimum, maximum and median CTC counts were 1, 22 and 2/3.2 ml, respectively. The number of polyploid CTCs was associated with distant metastasis (P=0.026). In addition, patients with undetectable CTCs, and decreasing or negative CTCs post-treatment tended to have a good prognosis (P<0.05). For nasopharyngeal squamous cell carcinoma, the PFS of patients with increased CTCs and CTCs ≥2/3.2 ml after treatment was significantly lower (P<0.05). For hypopharyngeal squamous cell carcinoma, it was suggested that CTCs with a cutoff value of 3 may be used to evaluate PFS and OS before and after treatment. In conclusion, CTCs may be used to monitor disease progression and the response to chemoradiotherapy for patients with LA-HNSCC. Furthermore, CTCs are a better predictor of the prognosis of hypopharyngeal squamous cell carcinoma than that of nasopharyngeal squamous cell carcinoma.

Introduction

Globally, head and neck cancers account for 5-10% of all malignancies and >500,000 new cases are diagnosed each year (1,2). Among them, ~95% of head and neck cancers are classified as squamous cell carcinoma. The poor prognosis associated with this type of cancer is related to local recurrence and distant metastasis. It has previously been reported that 50-60% of patients exhibit recurrence and regional lymph node metastasis following treatment, and 20% of patients exhibit distant metastasis (3). Even if the surgical margin appears negative, as determined by histopathology, recurrence still occurs in 20% of patients (4,5).

In the past, the diagnosis of recurrence and metastasis was mainly based on imaging, serum tumor marker levels and histopathology. However, these methods are often limited by tumor size and location, low compliance rate, and the inability to achieve real-time monitoring. Previous studies have revealed that circulating tumor cells (CTCs) are reliable indicators that may be used for the early prediction of tumor recurrence and metastasis, thereby facilitating clinical intervention, and improving patient survival and quality of life (6-10).

Liquid biopsies, specifically for CTC detection, can make up for the deficiencies of tissue biopsy. For example, tissue biopsy specimens must be solid lesions, which are unable to respond to the current state of the disease; however, CTC specimens are obtained from peripheral blood and can reflect the current state of the disease. The advantages of CTC detection are its safety, non-invasiveness and reliability (11). Numerous studies have reported the usefulness of CTCs in the evaluation of recurrence, metastasis and prognosis of breast cancer (12,13), prostate cancer (14), colorectal cancer (15), esophageal cancer (16), etc.; therefore, CTCs may be used as an independent predictor of tumor prognosis (12,17-23). In addition, CTCs were defined as a tumor marker by the American Society of Clinical Oncology in 2007 (24), and in
2010, the American Joint Committee on Cancer designated CTCs as a novel M-segment (remote metastasis) standard, which appeared between M0 and M1 as cM0 (+) (25). In 2017, CTCs were included in the TNM staging system in accordance with the breast cancer guidelines of the National Comprehensive Cancer Network (26).

Tumor recurrence and metastasis are the leading causes of death in patients with head and neck squamous cell carcinoma (HNSCC). To date, only a few studies have focused on the detection of CTCs in this type of cancer (1,2,27-32). Furthermore, these studies have several limitations, including few cases analyzed (1,2,27), low technical detection rate (2,8-21) and difficulty in obtaining specimens (32). To investigate the prognostic effect of CTCs on locally advanced HNSCC (LA-HNSCC), as well as the association between CTCs and clinical tumor features, the CTCs detection rate of patients with LA-HNSCC was studied and changes in CTC detection before and after treatment were analyzed.

Materials and methods

Study population and sample collection. Between October 2015 and September 2018, 264 patients that were admitted to the Chinese PLA General Hospital (Beijing, China), and were histopathologically diagnosed with LA-HNSCC via an endoscopic biopsy, were recruited to the present study. Notably, 86 patients were excluded; therefore, 178 patients were assessed. All patients had an Eastern Cooperative Oncology Group performance status score (33) of 0-1. A complete review of their medical history, as well as a thorough physical examination, was conducted for each patient prior to treatment. CTC counts were determined within 3 days prior to chemoradiotherapy and 1 month after radiotherapy (at first follow-up). All patients were followed prospectively, and all patients read and signed informed consent forms.

Inclusion and exclusion criteria. Initially, 264 patients were recruited and 86 patients were excluded, including patients that had undergone relevant treatment before CTC detection and patients with some types of cancer of which there were few cases (including 5 patients that had undergone chemoradiotherapy, 27 postoperative patients, 12 patients with non-squamous cell carcinoma,6 patients with unknown primary sites, 13 patients with laryngeal squamous cell carcinoma, 12 patients with nasal sinus squamous cell carcinoma and 11 patients with oropharyngeal squamous cell carcinoma). Finally, 178 patients were included in the present analysis. Inclusion criteria were as follows: i) Squamous cell carcinoma; ii) expected survival of >3 months; and iii) no treatment prior to CTC detection. Exclusion criteria were as follows: i) Non-squamous cell carcinoma; ii) cachexia or serious medical disease; and iii) treatments were performed prior to CTC detection.

Treatment protocols. All patients received induction chemotherapy with concurrent chemoradiotherapy. The induction chemotherapy regimen consisted of cisplatin + docetaxel + 5-fluorouracil/cisplatin + docetaxel. The concurrent chemoradiotherapy regimen consisted of cisplatin (nadaplatin) + nimotuzumab (cetuximab)/docetaxel + nimotuzumab. Patients with increased CTCs and patients whose CTCs changed from negative to positive post-treatment, and who did not exhibit disease progression or succumb to the disease were treated with thymopentin (TP5). Subsequently, CTCs were reanalyzed.

Detection of CTCs. The CTCs were enriched and identified as described previously (34). Briefly, a 5.2-ml peripheral blood sample was drawn into an acid citrate dextrose anticoagulant tube (BD Biosciences) and centrifuged (650 x g; 5 min; room temperature) to separate the cells from the plasma. The red blood cells were lysed with CS2 buffer (Cyttel), followed by resuspension of cell particulates in CSI buffer (Cyttel) and incubation with an anti-CD45 antibody conjugated to magnetic beads (Cyttel) for 20 min at 15-30°C. The immunomagnetic beads were collected using a magnetic stand (Promega Corporation) and the resulting CTC sample was applied to a glass microscope slide for observation.

The enriched cells (30-100 CTCs/µl) were then fixed in CFI buffer (Cyttel) for 8 min at 15-30°C. The slides were immersed in saline-sodium citrate buffer for 10 min at 37°C and dehydrated in a gradient series of ethanol baths (75, 85 and 100%) for 2 min each. The slides were then incubated with hybridization solution containing chromosome 8 centromere probe (200-1,000 bp; Abbott Laboratories) at 76°C for 5 min and 37°C for 1.5 h, and placed in a hybridizer (Dako; Agilent Technologies, Inc.) for 1.5 h at 37°C. The CTCs were then immunostained for 1 h at room temperature with an anti-CD45 antibody conjugated to Alexa Fluor® 594 (Invitrogen; Thermo Fisher Scientific, Inc.). After staining the nuclei with 4,6-diamidino-2-phenylindole (DAPI; Invitrogen; Thermo Fisher Scientific, Inc.), the slides were mounted for image analysis under a fluorescence microscope. For image analysis, samples underwent double-probe staining with fluorescence in situ hybridization (FISH)-probe A and FISH-probe B (Abbott Laboratories) at 76°C for 5 min and 37°C for 1.5 h. This protocol was conducted by Cyttel Biosciences, Inc. All assessments were performed by investigators who were blinded to the clinical characteristics of the patients (Fig. 1).

Comparison of the enrichment and identification methods adopted in this study with other methods. The negative immunomagnetic bead enrichment method used in the present study can enrich all CTCs, whereas other enrichment methods, such as positive immunomagnetic bead enrichment and two-dimensional electrophoresis, are unable to capture CTCs that no longer possess epithelial cell adhesion molecules after undergoing epithelial-mesenchymal transition. In addition, centrifugation may result in loss of CTCs that have migrated to the plasma, red cell and granulocyte layers, and filtration is not advisable to detect tumor cells <8 µm.

The FISH identification methods adopted in this study are non-radioactive, safe, fast and sensitive, and can be used for analysis of metaphase chromosomes and interphase cells. In addition, the probes used can be detected simultaneously on the same specimen and stored for a long time. Conversely, other identification methods are radioactive, the probes used must be relabeled for each test and the labeled probe is unstable. In
addition, when observing the results, more cell divisions are required for statistical analysis.

**Follow-up.** Follow-up was conducted through outpatient interviews. In some cases, telephone interviews were conducted. Survival was defined as the interval from the time of diagnosis to the time of death or last follow-up. The last follow-up was conducted in November 2018.

**Classification of changes in CTC counts.** Changes in the CTC counts were classified into three categories: Increasing, stable and decreasing. A positive CTC count (above the threshold) at first follow-up compared with a negative CTC count at baseline was considered an increase in CTCs. A negative CTC count (below the threshold) at first follow-up compared with a positive CTC count at baseline was considered a decrease in CTCs. A negative CTC count at baseline and at first follow-up was considered stable. A positive CTC count at baseline and at first follow-up with an increase in CTC count >2/ml was considered increasing, whereas a decrease in CTC count >2/ml was considered decreasing, and a change in CTC count <2/ml was considered stable (35).

**Statistical analysis.** Statistical analysis was performed using SPSS software (version 22; IBM Corp.). Youden's index and the receiver operating characteristic (ROC) curve were used to determine the best diagnostic cutoff value. The associations between CTC detection rate, CTC ploidy number at different cutoff values (CTCs ≥1, CTCs ≥2, CTCs ≥3, CTCs ≥4 and CTCs ≥5), CTC count (tumor load) and clinical characteristics were evaluated. Progression-free survival (PFS) and overall survival (OS) was assessed in the groups stratified according to selected CTC cutoff values for all patients with different types of cancer, and the association between changes in CTC count and treatment response and prognosis was evaluated. \( \chi^2 \) test or Fisher's exact test was used to analyze associations. The log-rank test and Cox proportional hazards model were used to identify prognostic factors independently associated with survival. Survival rates were assessed using the Kaplan-Meier method. PFS and OS were defined as the time from the collection of blood to the time of confirmed disease progression or last follow-up, respectively. P<0.05 was considered to indicate a statistically significant difference.

**Results**

**Identification of CTCs.** The clinical characteristics of the patients, including cancer type, differentiation and clinical stage are shown in Table I. Abnormally proliferating and CD45-negative CTCs with ≥3 nuclear chromosome enumeration probe signals were identified. The nuclei of CTCs were stained with DAPI (Fig. 2).

**CTC detection rate in patients with LA-HNSCC.** Before treatment, the CTC detection rate was 73.8%. The minimum, maximum and median CTC counts were 1, 22 and 2/3.2 ml, respectively. The overall distribution was skewed.

**Association between CTCs or the CTC detection rate and clinicopathological variables.** No significant associations were observed between CTC count or CTC detection rate...
Association between CTCs and the survival rate of patients with LA-HNSCC. Five patients were lost during follow-up; therefore, a total of 173 patients were followed-up, with a follow-up rate of 97.2%. The median follow-up time was 16 months (range, 2-37 months); over the follow-up period, 30 cases exhibited recurrence or metastasis and 12 patients died. According to Youden’s index and the receiver operating characteristic (ROC) curve, the best diagnostic cutoff value was determined (Figs. S1 and S2; Tables SI and SII). All patients had a cutoff value of 2 before treatment and 3 after treatment. There was no significant difference in the PFS and OS of all patients with CTCs above the cutoff value compared to those with CTCs below the cutoff value (P>0.05; Figs. S3 and S4). For patients with nasopharyngeal squamous cell carcinoma, the PFS was significantly lower for those with ≥2 CTCs than those with <2 CTCs after treatment (P<0.05 for a threshold of 2 CTCs/3.2 ml blood; Fig. 3), but the OS before and after treatment were not statistically significant (P>0.05; Fig. S5). For patients with hypopharyngeal squamous cell carcinoma, the PFS and OS of patients with ≥3 CTCs were significantly lower than those with <3 CTCs before and after treatment (P<0.05 for a threshold of 3 CTCs/3.2 ml blood; Figs. 4 and 5).

Association between CTC changes and the survival rate of patients with LA-HNSCC before and after treatment. Blood samples were obtained from 178 patients following treatment. The CTCs of 140 out of 178 patients decreased or remained unchanged after treatment, whereas the CTCs of 38 out of 178 patients increased. In addition, the CTCs of 90 patients were positive before and after treatment, 46 patients were positive before treatment but negative after treatment, and 42 patients were negative before and after treatment. The results revealed that patients with negative CTCs after treatment lived longer than those with positive CTCs after treatment (P<0.05; Figs. S6 and S7). The PFS of these patients was 1.21-fold higher than that of patients with positive CTCs (93.31% vs. 77.40%). The 3-year OS was also significantly reduced by 1.17 times (95.75% vs. 81.70%). In addition, PFS and OS were shorter in patients whose CTCs increased after treatment compared with those whose CTCs decreased or remained unchanged (P<0.0001 and P=0.0301; Figs. S8 and S9).

Association between CTCs and survival in patients with nasopharyngeal squamous cell carcinoma and hypopharyngeal squamous cell carcinoma. The CTC counts of 114 patients with nasopharyngeal squamous cell carcinoma were decreased or remained unchanged after treatment; of these 114 patients, disease progression occurred in eight patients and three patients died. The CTC counts of 21 patients with nasopharyngeal squamous cell carcinoma were decreased or remained unchanged after treatment; of these 21 patients, disease progression occurred in one patient and one patient died.
were increased; of these 21 patients, disease progression occurred in seven patients and two patients died. Compared with patients with decreased or unchanged CTC counts following treatment, the PFS of patients with increased CTC counts was significantly decreased ($P=0.0043$; Fig. 6), whereas no significant change was observed for OS ($P=0.1951$; Fig. 6). In addition, the CTCs of 67 patients were positive post-treatment; of these 67 patients, disease progression occurred in nine patients and three patients died. The CTCs of 68 patients were negative post-treatment; no disease progression was observed in this group and one patient died. Compared with patients with negative CTCs or whose CTCs changed from positive to negative post-treatment, PFS was significantly decreased ($P=0.0174$) in patients whose CTCs were positive after treatment, whereas OS was not ($P=0.1451$) (Fig. 7).

Multivariate analysis of predictors of overall survival for patients with nasopharyngeal and hypopharyngeal squamous cell carcinoma. Univariate analysis revealed that clinical stage, baseline CTC counts, and CTC count at first follow-up were clinical factors affecting OS. Multivariate analysis revealed all of these factors to be independent prognostic markers of OS in patients with hypopharyngeal squamous cell carcinoma (Table III), but not for patients with nasopharyngeal squamous cell carcinoma (data not shown).
TP5 treatment. TP5 is a synthetic pentapeptide that corresponds to position 32-36 of thymopoietin, and exhibits similar biological activity to thymopoietin, which is responsible for phenotypic differentiation of T cells and regulation of the immune system. TP5 has been clinically used for the treatment of patients with immunodeficiency diseases, including rheumatoid arthritis, cancer, hepatitis B virus infection, and acquired immunodeficiency syndrome (36).

Patients with increased CTCs or patients whose CTCs changed from negative to positive post-treatment, and did not exhibit disease progression or succumb to the disease were treated with TP5. Subsequently, CTCs were measured again and were decreased (data not shown). These findings indicated that increased CTCs or positive CTCs post-treatment, which did not result in disease progression, were caused by low immunity.

Discussion

In the present study, the number of polyploid CTCs was associated with distant metastasis (P=0.026). Furthermore, patients with undetectable CTCs, and decreasing CTCs or negative CTCs after treatment tended to have a good prognosis (P<0.05). For nasopharyngeal squamous cell carcinoma, the PFS of patients with increased CTCs and CTCs ≥2/3.2 ml after treatment was significantly lower (P<0.05).
For hypopharyngeal squamous cell carcinoma, CTCs with a cutoff value of 3 may be used to evaluate PFS and OS before and after treatment. The present findings suggested that CTCs may be used to monitor disease progression and the response to chemoradiotherapy for patients with LA-HNSCC. Notably, the results indicated that CTCs are a better predictor of the prognosis of hypopharyngeal squamous cell carcinoma than nasopharyngeal squamous cell carcinoma.

During tumor metastasis, tumor cells interact with their surrounding microenvironment and undergo epithelial to mesenchymal transition (EMT). EMT causes epithelial cells to lose their epithelial cell phenotype and to acquire a mesenchymal cell phenotype, leading to various morphological and functional changes, thereby promoting the migration and invasion of tumor cells. Tumor cells can leave the primary site, and enter vascular or lymphatic systems as CTCs to induce metastasis (37). CTCs can also return to the bone marrow reserve pool in a resting state; under certain conditions, CTCs can again enter the vascular or lymphatic systems, and travel to other organs to form distant metastases (38,39).

CTCs are tumor cells that can be used to screen and classify high-risk tumors (40). Studies have shown that CTC counts are variable in different subtypes and stages of breast cancer, and that CTCs are more frequently observed in advanced stages compared with in early stages (41,42). In addition, CTC counts in patients with non-small cell lung cancer are significantly increased from stages I-II to III-IV (43). Conversely, this study demonstrated that there was no association between CTC count or CTC detection rate and clinical stage in LA-HNSCC. CTC counts are lower in patients with LA-HNSCC than other types of cancer. Notably, there are few comparative studies on the clinical relevance of CTCs in LA-HNSCC, and these studies have reported different conclusions (1,2,27-32) (Table IV). It may be hypothesized that the relevance of CTCs is associated with cancer type, number of cases and the technology used.

CellSearch is the most common method used to isolate CTCs from the blood samples of patients with epithelial carcinoma, using epithelial cell adhesion molecule (EpCAM) as the target for cell capture. However, this technique cannot capture CTCs that no longer express EpCAM after they undergo EMT, resulting in a reduced CTC detection rate (44). Buglione et al (27) studied 73 patients with oropharyngeal, hypopharyngeal, nasopharyngeal, laryngeal and nasal sinus cancer using the CD45- + CellSearch approach. The results revealed that the CTC detection rate was 15.1%, and more CTCs were detected at stage IV than at stages I-III. The decrease or complete disappearance of CTCs during treatment meant that the progression of the disease was halted. The present results revealed that decreased or unchanged CTC counts after treatment was associated with a good prognosis, which was consistent with the aforementioned study. However, CTC detection rate was not associated with clinical stage, which may due to the fact that only stage III and IV cases were studied; therefore, the difference in detection rate was not apparent.

Jatana et al (1), studied 48 patients with oral, oropharyngeal, laryngeal and hypopharyngeal carcinoma at stages I-IV using the CD45- + DAPI approach with a detection rate of 70.8%. The

*P<0.05. CTC, circulating tumor cell.
results revealed that the CTC detection rate was not associated with clinical stage, tumor site and lymphatic metastasis, which was consistent with this study. Wollenberg et al (32) studied 176 patients with stage I-IV HNSCC using the immunohistochemistry-alkaline phosphatase-anti-alkaline phosphatase + cytokeratin 19 (CK19) method. The results revealed that individual CK19-expressing tumor cells were detected in the bone marrow of 30.7% of patients, and there was an association between occult tumor cells in the bone marrow and recurrence. Univariate and multivariate analyses indicated that metastases in locoregional lymph nodes and disseminated tumor cells in the bone marrow were all important predictors of prognosis. Notably, none of the aforementioned studies investigated the association between CTC counts and prognosis of different HNSCC subtypes. In the present study, polyploid CTCs were associated with distant metastases, indicating that highly proliferating tumor cells may be more likely to metastasize.

In this study, CTC detection rate was increased, compared with in other studies (1,27-32), by increasing the number of cases and improving the detection technology used. The best diagnostic threshold value for the different types of cancer was determined according to the ROC curve. An increase in CTCs post-treatment was associated with a poor prognosis, which often indicates drug resistance and the use of ineffective treatments, whereas a decrease or no change in the CTCs was associated with a better prognosis, which often indicates the use of effective treatments. The 3-year PFS of patients with positive CTCs post-treatment was significantly lower than that of patients with negative CTCs post-treatment. The PFS of patients with negative CTCs was 1.21-fold higher than that of patients with positive CTCs (93.31% vs. 77.40%). The 3-year OS was also significantly reduced by 1.17 times (95.75% vs. 81.70%).

Notably, there were still patients with increased CTCs or patients whose CTCs changed from negative to positive post-treatment that did not exhibit disease progression or succumb to the disease. After TP5 was administered to these patients, CTCs were measured again and were decreased. This finding may be associated with a decline in immunity; after using TP5 to improve immunity, the CTC counts may decrease (45).

For patients with nasopharyngeal carcinoma, CTC counts <2/3.2 ml post-treatment were associated with a significantly higher PFS than in patients with CTC counts ≥2/3.2 ml (P=0.0044). For patients with hypopharyngeal carcinoma, CTC counts ≥3/3.2 ml before and after treatment were associated with a significantly reduced PFS and OS compared with patients with CTC counts <3/3.2 ml (P<0.05). CTCs were related to PFS and OS before and after treatment for hypopharyngeal squamous cell carcinoma; however, CTCs were only associated with PFS after treatment for nasopharyngeal squamous cell carcinoma.

The PFS of patients with nasopharyngeal squamous cell carcinoma and decreased or unchanged CTCs post-treatment was 1.64 times higher than that of patients with increased CTCs (93.62% vs. 87.18%); however, no difference was observed with regards to OS. In addition, PFS and OS were significantly lower in patients with nasopharyngeal squamous cell carcinoma whose CTCs remained positive after treatment than those whose CTCs remained negative. The PFS of patients with hypopharyngeal squamous cell carcinoma and decreased or unchanged CTCs post-treatment was 3.08 times...
higher than that of patients with increased CTCs (100% vs. 32.47%), and the OS was 3.27 times higher (95% vs. 29.07%); these findings were significant. When CTCs changed from positive to negative or remained negative, the PFS of patients with hypopharyngeal squamous cell carcinoma was 2.46 times higher than that of patients whose CTCs changed from negative to positive or remained positive after treatment (100% vs. 40.7%); however, the OS was not significantly decreased. These findings indicated that CTCs may be a better predictor of the prognosis of hypopharyngeal squamous cell carcinoma than nasopharyngeal squamous cell carcinoma.

Notably, the present study had many novel aspects compared with previous studies; in particular: i) This study used negative enrichment of immunomagnetic beads, meaning all CTCs could be enriched, combined with fluorescence in situ hybridization, which is a non-radioactive, safe, fast and sensitive technique, the probe for which can be stored for a long time, to detect CTCs. The detection rate was 73.8%. ii) This study investigated the clinical significance of CTCs in patients with nasopharyngeal squamous cell carcinoma and hypopharyngeal squamous cell carcinoma with different prognoses. iii) Youden's index and the ROC curve were used to select the optimal CTC baseline value. iv) The associations between increased/decreased CTCs, positive/negative CTCs and prognosis before and after treatment were analyzed. v) It was demonstrated that after using TP5 to improve immunity, the CTC counts were decreased; thus, the present study analyzed the relationship between immunity and CTCs. vi) Polyploid CTCs were revealed to be associated with distant metastases, indicating that highly proliferating tumor cells are more likely to metastasize. This study provided an explanation as to why CTCs are associated with metastasis.

Conversely, in previous studies: i) The detection rate was 6.0-89.0% (46,47), and in the majority of studies the detection rate was <40%. ii) Numerous cancer species were studied with no separate subtype analysis (1,2,27-32). iii) Youden's index and the ROC curve were not used to select the optimal CTC baseline value (1,2,27-32). iv) Only the relationship between increased/decreased CTCs and prognosis was analyzed (28). v) The relationship between immunity and CTC was not assessed (1,27-32). vi) The fact that CTCs are related to metastasis was mentioned, but the underlying mechanism was not discussed (34).

In conclusion, this study revealed that the number of polyploid CTCs was associated with distant metastasis (P=0.026). In addition, patients with undetectable CTCs, and decreasing or negative CTCs post-treatment tended to have a good prognosis (P<0.05). For nasopharyngeal squamous cell carcinoma, the PFS of patients with increased CTCs and CTCs ≥2/3.2 ml after treatment was significantly lower (P<0.05). For hypopharyngeal squamous cell carcinoma, it was suggested that CTCs with a cutoff value of 3 may be used to evaluate PFS and OS before and after treatment. These findings indicated that CTCs may be used to monitor disease progression and the response to chemoradiotherapy for patients with LA-HNSCC. Furthermore, CTCs are a better predictor of the prognosis of hypopharyngeal squamous cell carcinoma than that of nasopharyngeal squamous cell carcinoma.

In future research, lymphocyte subsets will be examined and the changes in immune function will be evaluated by changes in CD4, CD8, B cells and T cells prior to chemoradiotherapy and 1 month after radiotherapy. In conclusion, a large prospective multi-institutional validation study is required to confirm these results.

The datasets used and/or analyzed during the present study are available from the corresponding author on reasonable request.

Authors' contributions
KL, SY and XZ contributed to the conception of this study and performed the preliminary documentation. All authors participated in the design of the study and implemented the research. KL, NC, JW and LM examined the archives and identified the cases included in the study, examined the slides and collected the pathological information. KL and JW enrolled patients in the study, performed clinical diagnosis and collected clinical data. All authors participated in the statistical analysis and contributed to the interpretation of the results, as well as the writing of the study. All authors reviewed the data and approved the final manuscript.

Ethics approval and consent to participate
This research abides by international and national regulations in accordance with the Declaration of Helsinki. This study was approved by the Ethics Committee of the Chinese PLA General Hospital. All patients provided written informed consent before being included in this study.

Patient consent for publication
Not applicable.

Competing interests
The authors declare that they have no competing interests.
