Abstract

Background: Congenital heart defects (CHDs) are a significant cause of death in infancy. Although contemporary management ensures that 80% of affected children reach adulthood, post-infant mortality and factors associated with death during childhood are not well-characterised. Using data from a UK-wide multicentre birth cohort of children with serious CHDs, we observed survival and investigated independent predictors of mortality up to age 15 years.

Methods: Data were extracted retrospectively from hospital records and death certificates of 3,897 children (57% boys) in a prospectively identified cohort, born 1992–1995 with CHDs requiring intervention or resulting in death before age one year. A discrete-time survival model accounted for time-varying predictors; hazards ratios were estimated for mortality. Incomplete data were addressed through multilevel multiple imputation.

Findings: By age 15 years, 932 children had died; 144 died without any procedure. Survival to one year was 79.8% (95% confidence intervals [CI] 78.5, 81.1%) and to 15 years was 71.7% (63.9, 73.4%), with variation by cardiac diagnosis. Importantly, 20% of cohort deaths occurred after age one year. Models using imputed data (including all children from birth) demonstrated higher mortality risk as independently associated with cardiac diagnosis, female sex, preterm birth, having additional cardiac defects or non-cardiac malformations. In models excluding children who had no procedure, additional predictors of higher mortality were younger age at first procedure, lower weight or height, longer cardiopulmonary bypass or circulatory arrest duration, and peri-procedural complications; non-cardiac malformations were no longer significant.

Interpretation: We confirm the high mortality risk associated with CHDs in the first year of life and demonstrate an important persisting risk of death throughout childhood. Late mortality may be underestimated by procedure-based audit focusing on shorter-term surgical outcomes. National monitoring systems should emphasise the importance of routinely capturing longer-term survival and exploring the mechanisms of mortality risk in children with serious CHDs.

Introduction

Serious congenital heart defects (CHDs), requiring surgery in the first year of life, affect around 1% of births each year in the UK [1–3] and include a broad spectrum of complexity and severity. Without intervention in early life, serious CHDs are often incompatible with long-term survival. Continuous improvement in medical, intensive care and surgical technologies have significantly reduced infant mortality and around 90% of affected babies now survive the first year of life [4–7]. Despite the rising number of paediatric cardiac procedures being undertaken [8], surgical mortality is decreasing and the number of UK adults with CHDs is steadily growing [9]. Nevertheless, long-term survival for individuals within most CHD subgroups remains below that of the unaffected population [10].

Recognising the growing population of adolescents and adults with CHDs, recent research has focused on the epidemiology and health experience of adult survivors. It is generally assumed that
additional mortality between infancy and 15 years of age is extremely low and likely to be related to further surgery, yet observational studies with prospective long-term follow-up of the transition of children with CHDs from infancy through school, adolescence and into adulthood are lacking. While short-term surgical outcome studies provide extensive detail about postoperative survival and mortality, particularly within specific CHD subgroups, the factors associated with mortality risk that are common to all diagnostic subgroups and their significance at different ages are poorly defined [11]. Developing a life course approach [12] to children and adults surviving with CHDs is a vital step in recognising that they experience complex interactions between intrinsic early life factors, cardiac diagnosis and the pressures of the external environment, which have a significant impact on their growth, development and late outcomes. There remains a crucial lack in our understanding of the relevance of different risk factors and exposures at each stage of the lifecourse and how these may modify long-term outcomes, not only when they occur in relation to critical periods but also when experienced as repeated exposures such as multiple surgical interventions. Such information is key to future interventions to improve survival and health outcomes and ensure a smooth transition to adult life for affected children.

The UK Collaborative Study of Congenital Heart Defects (UKCSCHD) was established as a UK-wide multi-centre cohort involving almost 4000 children, diagnosed with serious CHDs during their first year of life, to determine prospectively survival, health, educational and quality of life outcomes. In this paper we examine survival from birth to 15 years of age, characterise the timing and causes of death during childhood and investigate the relative importance of patient-specific and early life factors to mortality risk during childhood for this national cohort that is largely representative of contemporary surgical and medical management.

**Materials and Methods**

**Ethics statement**

Ethics approval was granted by Trent Multicentre Research Ethics Committee (MREC 04/4/017). Case notes review was undertaken within collaborating centres under the supervision of the local responsible cardiologist; the names and addresses of the children were not provided to the central study team who carried out analyses on de-identified data.

**Methods**

The UKCSCHD includes children with serious CHDs born between 1992 and 1995 and prospectively notified to a UK-wide study evaluating fetal diagnosis by paediatric cardiologists (British Congenital Cardiac Association [BCCA] members) in all 17 UK paediatric cardiac surgical centres [13]. Serious CHDs were defined as structural heart malformations requiring intervention or resulting in death during the first year of life [13].

A retrospective hospital records review of 3897 children was coordinated by the central research team; 268 children from the original register were excluded as there were insufficient details in the case notes to confirm that all inclusion criteria (Table 1) for the UKCSCHD were met. Local clinicians extracted data and completed a standardised proforma for 3698 (95%) of 3897 children. Record retrieval varied by centre, reflecting local record-keeping, and retrieval was less successful for children who were reported by local clinicians to have died (difference 6% [95% CI 4%, 8%]).

Deaths were traced within hospital systems then validated through the Office for National Statistics (England and Wales) and General Register Office (Scotland). A primary cardiac diagnosis (Table 2) was assigned to every child using a hierarchical classification prioritising the most severe structural defect adapted from Wren et al. [14]; three clinical raters (CB, CW, RK) independently assigned diagnoses (generalised kappa (ƙ) for rater agreement = 0.83) and the final diagnosis was agreed by consensus. Two cardiologists (CB, CW) designated one procedure for each child as ‘definitive’, defined as the procedure which would approximate normal anatomy and restore biventricular function or provide long-term palliation without expectation of further surgery during childhood, thus the final stage of a multi-stage repair was considered definitive. The definitive procedure may have taken place at any time during follow-up. Children were assigned to a cardiac prognostic severity (CPS) group, adapted from Lane [15], based on primary diagnosis and whether their definitive procedure was presumed curative, corrective or palliative (Table 2).

**Statistical analysis**

Descriptive statistics are presented as numbers and percentages, or median and interquartile ranges (IQR), and 95% confidence intervals (CI) were estimated for the difference between two proportions. Table 3 provides information about the numbers of children who died or were censored alive (last seen) during each

---

**Table 1. Inclusion and exclusion criteria for the UKCSCHD cohort.**

| Inclusion criteria (for the UKCSCHD and original register). Live born infants: |
|---|
| 1) born between 1st January 1992 and 31st December 1995 |
| 2) resident in the United Kingdom (UK) at birth |
| 3) with a serious congenital heart defect, defined as a structural malformation of the heart or great vessels, requiring an intervention or resulting in death during the first year of life. |

| Exclusion criteria (for the UKCSCHD and original register). Live born infants with: |
|---|
| 1) isolated cardiovascular defects such as persistent ductus arteriosus, vascular ring or anomalous coronary arteries |
| 2) myocardial dysfunction, arrhythmia or tumours in a structurally normal heart |
| 3) a congenital heart defect that did not require an intervention or result in death during the first year of life. |

| Excluded from the UKCSCHD but included in the original register: |
|---|
| Babies with a fetal diagnosis of serious congenital heart defect made at prenatal ultrasound but not subsequently live born. |

Notes:
*adapted from Wren [14]; **adapted from Lane [15].

Assignment of primary CHD diagnosis: The methodology for assigning primary diagnoses to 1,768 children with multiple defects was validated independently by three raters (RK, CB, CW). Based on cardiac diagnoses in medical records, children assigned a primary diagnosis were 1,738 (98%), 1,610 (91%) and 1,146 (65%) for each rater; this increased to 1,761 (99.7%), 1,689 (95.5%) and 1,658 (93.8%) respectively using records of surgical procedures (Interrater agreement: k = 0.83). A 'miscellaneous' category included defects found in fewer than 40 children: congenitally corrected transposition of the great arteries (n = 24), partial atrioventricular septal defect (n = 20), aortopulmonary window (n = 26), atrial septal defect (n = 36) and rarer diagnoses (n = 83).

CPS groups were: no intervention—children who received no surgical intervention prior to death during first year of life; curative—children who had successful repair of atrial or ventricular septal defect, pulmonary stenosis or total anomalous pulmonary veins and had no additional cardiac defects; corrective—children who had a procedure which approximated normal anatomy and restored biventricular function, with no expectation of future surgery during childhood; palliative—children whose surgery did not restore biventricular function, including children for whom all stages of multi-stage repair were not achieved, who had a valve replacement which would require later revision, or for whom only a single functional ventricle circulation was possible.

doi:10.1371/journal.pone.0106806.t002
A multilevel discrete time event history model was developed to investigate the factors influencing survival; this was a binomial logit model with the response variable, death or censoring, coded as a binary variable. The discrete time hazard function represented the conditional probability of an event in each interval given that the event had not occurred in a previous interval: \( h(t) = \Pr(T = t | T \geq t) \).

The period of observation was divided into 24 discrete intervals; 12 intervals of one month duration for the first year of life when the majority of events occurred, then 11 intervals of one year from one to 12 years of age and a final interval of three years duration representing the interval 12 to 15 years of age, in which events were rare. In the final model including multiple predictors, three ‘smoothed’ categories (representing the first year of life, one to 12 years, and 12 to 15 years of age) were developed by estimating the log-transformed midpoint of each variable and dividing by the number of months within each category. Although the 24 category model had marginally better fit than the ‘smoothed’ category model (DIC 8887.9 and 8946.8 respectively), the smoothed category model improved model convergence and was therefore used.

Within each interval, it was assumed that the hazards were constant and the binary response variable indicated whether death occurred during the final interval. Covariates specific to the child, such as sex or preterm birth, remained constant whilst factors recorded at each procedure, such as cardiopulmonary bypass duration, were permitted to vary between intervals. Weight and height were converted to age- and sex-standardised z-scores (British 1990 growth reference) [16]. Each predictor was explored in univariable analyses then multivariable models were constructed to determine joint associations.

Missing data were imputed using a hierarchical imputation model developed with MLwiN 2.18–2.20 [17] and Realcom-Impute [18]. The imputation procedure used Markov-chain Monte Carlo (MCMC) procedure to generate 20 imputed datasets during 2500 iterations. Imputation was conditioned on centre availability of records, as this significantly influenced missingness. Imputation excluded 28 children whose date of death or censoring was unknown, and variables with more than 50% missing data; the included variable with the most missing data was clinical status on admission (46%; Table 4). Distributions of continuous variables before and after imputation were compared using density plots (data not shown).

Hierarchical models of mortality risk were developed to take account of the grouping of individual children within cardiac centres and the correlation of procedure-related data within the individual child. For each imputed dataset multilevel discrete-time event models [19,20] were constructed to predict mortality risk from birth to follow-up in 2007, when all surviving children were aged 12 to 15 years. The final results reported are those averaged over these datasets according to ‘Rubin’s rules’. The results from these analyses using imputed datasets were compared with those using the ‘complete case’ datasets (including only those children with complete data).

Analyses were undertaken using Stata SE 11 (Timberlake Consulting) and MLwiN 2.18–2.20 [17].

**Results**

Almost one-quarter of the cohort died (n = 932 deaths) and, of these, 727 (78%) deaths occurred within the first year and 323 (35%) within the first month of life. Although the risk of death was lower after the first year of life, 20% of all cohort deaths occurred after one year of age. Death occurred before intervention, or parents chose palliative care, for 144 (4%) children who died without any procedure; most (n = 63; 44%) of these children had hypoplastic left heart and/or mitral atresia (HLH/MA). The median age at death for children who died without undergoing an

| Year of follow-up | Number at risk | Deaths | Censored (last seen) |

| 7–8 years        | 1950          | 8      | 64                  |
| 8–9 years        | 1878          | 3      | 106                 |
| 9–10 years       | 1769          | 5      | 168                 |
| 10–11 years      | 1596          | 4      | 405                 |
| 11–12 years*     | 1187          | 4      | 520                 |
| 12–13 years*     | 663           | 4      | 424                 |
| 13–14 years*     | 235           | 1      | 214                 |
| 14–15 years*     | 20            | 0      | 20                  |

*All children in the cohort were aged 12 years or older at the time of ascertainment of deaths in 2007, thus losses from follow-up at younger ages were due to death or censoring alive on the date last seen (as recorded in hospital case notes). Between 12 and 15 years there are fewer children under follow-up (at risk) in the older age groups as many children had not reached these ages and this reduced the precision of survival estimates after 12 years.

Notes:
*excludes 144 children who did not have an intervention;
1 Number (%) of children with missing data: Sex n = 129(3%); Unstable clinical status n = 1784(46%); age at first procedure n = 50(1% of 3753 children who had an intervention); Preterm birth/Down’s syndrome (DS)/Non-DS non-cardiac malformations/Additional cardiac defects: no missing data.

Key: IQR interquartile range; preterm <37 completed weeks gestation at birth; Add. cardiac defects - in addition to primary CHD diagnosis; unstable clinical status on first admission was defined as unstable if one or more of the following symptoms/signs were present: unwell = significant pallor, breathlessness or sweating, intubated, mechanically ventilated, hypotension = systolic blood pressure [SBP] <50 mmHg, hypertensive = SBP >100 mmHg, cardiac or respiratory arrest, metabolic acidosis, requiring adrenaline or high dose inotropic support; HLH/MA hypoplastic left heart and/or mitral atresia; TA tricuspid atresia; DIV double inlet ventricle; PA+IVS pulmonary atresia with intact ventricular septum; PA+VSD pulmonary atresia with ventricular septal defect; CAT common arterial trunk; CAVSD complete atrioventricular septal defect; TGA transposition of the great arteries; TOF tetralogy of Fallot; TAPVC total anomalous pulmonary venous connection; VSD ventricular septal defect; AS aortic stenosis; PS pulmonary stenosis; COA coarctation of the aorta; Misc miscellaneous cardiac defects (not included within other categories).

doi:10.1371/journal.pone.0106806.t004
The intervention was 8.5 days (IQR 3, 7.5 days) and only one-third survived beyond the first month of life. Of 723 children who survived to one year without having undergone a definitive corrective or palliative procedure, 578 (80%) died between age one and 15 years. There was no significant difference in the proportion of girls and boys who died without a procedure. Characteristics of the cohort children and procedure-related factors are presented in Table 5 and Table 6 respectively.

Overall 80% (95% CI 78%–81%) of children were alive at one year and 72% (70%, 73%) at 15 years of age. Survival varied by primary cardiac diagnosis (Figure 1; Table 7). For 2,489 children remaining under follow-up after one year of age, survival between one and 15 years was 90% (95% CI 88%, 91%) overall, however for children within six diagnostic subgroups (HLH/MA, tricuspid atresia [TA], double inlet ventricle [DIV], pulmonary atresia with intact ventricular septum [PA+IVS], PA+VSD and CAVSD), survival post-infancy was lower than 90%.

In univariable models involving all children followed from birth, preterm birth (hazard ratio [HR] 1.43 [95% CI: 1.16, 1.77]), non-Down’s syndrome non-cardiac malformations (HR 1.56 [1.27, 1.93]), cardiac defects additional to the primary diagnosis (HR 1.24 [1.09, 1.41]) and unstable clinical status on first admission (HR 1.43 [1.07, 1.90]) were statistically significant predictors of higher mortality. Relative to the largest subgroup (ventricular septal defect [VSD]), all primary diagnostic subgroups except pulmonary stenosis (PS) and aortic coarctation (COA) were associated with increased mortality.

In the multivariable model including all children and adjusted for centre effects, higher mortality up to age 15 years was associated with female sex (HR 1.25 [1.06, 1.47]), preterm birth (HR 1.44 [1.15, 1.79]), non-Down’s syndrome non-cardiac malformations (HR 1.49 [1.20, 1.86]), additional cardiac defects (HR 1.23 [1.07, 1.42]) and, relative to VSD, all primary diagnoses except for PS and COA (data not shown). When procedure-related risk factors were included in the multivariable model, thus excluding children who died without a procedure, independent predictors of higher mortality risk were female sex, preterm birth, additional cardiac defects, pre-procedure sepsis or hypertension, post-procedure seizures, cardiac arrest, renal failure, stroke, sepsis or disseminated intravascular coagulopathy (DIC), lower weight or

### Table 5. Characteristics of individuals in the cohort (n = 3897).

| Patient-specific factors                      | N (% of 3897) | Missing N (% of 3897) |
|----------------------------------------------|---------------|-----------------------|
| Sex                                          |               |                       |
| Boys                                         | 2147 (55%)    | 129 (3%)              |
| Girls                                        | 1621 (42%)    |                       |

Table 6. Characteristics of procedure-related factors (6351 procedures in 3753 individuals).

| Procedure-related factors | Details of procedures |
|---------------------------|-----------------------|
| **Pre-procedure variables:** |                       |
| Any pre-procedure complications/support | 786 (12%)*               |
| Intubated | 590                             |
| Inotropic support | 252                             |
| Acidosis | 159                             |
| Hypotensive (systolic BP <50 mmHg) | 111                             |
| Sepsis | 93                             |
| Hypertensive (systolic BP >100 mmHg) | 51                             |
| Seizures | 46                           |
| **Intra-procedure variables:** |                       |
| Procedures not requiring bypass² | 2486 (39%)           |
| Cardiopulmonary bypass (CPB) time² | 2346 (median = 87(IQR 60,129) minutes) |
| Circulatory arrest (CA) time² | 1059 (median = 30 (IQR 14,49) minutes) |
| Aortic cross-clamp (XC) time² | 1980 (median = 52 (IQR 32,75) minutes) |
| **Post-procedure variables:** |                       |
| Any post-procedure complications | 816 (13%)*               |
| Sepsis | 356                             |
| Re-intubated (after 24 hrs extubation) | 224                         |
| Renal failure | 202                         |
| Cardiac arrest | 169                        |
| Seizures | 113                             |
| ECMO (extracorporeal membrane oxygenation) | 47                             |
| DIC (disseminated intravascular coagulopathy) | 31                             |
| Stroke | 22                             |

**Notes:**
- IQR interquartile range; BP blood pressure; hrs hours.
- *Procedures at which there was more than one pre-procedure (or post-procedure) complication are only counted once in the totals so the sum of individual complications is greater.
- ²Procedures for which cardiopulmonary bypass would not be required, e.g. catheter intervention.
- Excludes procedures in which duration is recorded as 0 minutes.

Discussion

In this UK-wide cohort involving 3897 children with serious CHDs, mortality was 20% in the first year of life. An additional 8% of the cohort died between one and 15 years of age, thus 20% of all deaths within the cohort occurred after the first year of life. There were 144 children in the cohort who died without any intervention during the first year of life. Overall survival was 79.8% at one year and 71.7% at 15 years of age with variation by primary cardiac diagnosis, thus for children who survived the first year survival into adulthood was generally good. Children with functional single ventricles (HLH/MA, TA and DIV) experienced the highest mortality overall but for children surviving to one year of age, those with PA+VSD and CAVSD had the worst post-infant survival rates.

Primary cardiac diagnosis was an important independent predictor of mortality risk up to 15 years; children with TGA, COA and VSD had the lowest mortality risk. Higher mortality risk regardless of intervention was independently associated with female sex, preterm birth and having a cardiac defect in addition to the primary cardiac diagnosis. For children who had at least one procedure, higher mortality risk was associated with earlier age at...
first procedure, pre-procedural sepsis and hypertension (systolic BP > 100 mHg), post-procedural complications (including cardiac arrest, stroke, renal failure, seizures and sepsis) and increased duration of cardiopulmonary bypass or cardiac arrest.

Longitudinal cohort studies present important methodological challenges for survival analysis, including the need to model hierarchical data structures, repeated procedures, and to address missing data. An important strength of our study is the development of multilevel models that allowed us to link procedure-related factors across the child’s lifecourse and to explicitly order these in time. Children in the cohort underwent varying numbers of procedures, which did not occur at fixed ages, and earlier postoperative experience could influence later management. Despite recognition of the complexity of survival analysis in children with CHDs, for whom both predictors and mortality are time-dependent [11], examples of survival models including time-varying covariates are rare and few previous studies have explicitly stated the temporal ordering of childhood factors and their inter-relationships, directly or through mediating factors, with mortality. We addressed the methodological challenges of repeat observations, and also adjusted for the effects of clustering by cardiac centre, through the development of discrete-time hierarchical survival models [19,20] and multilevel multiple imputation [44,45] of missing values. The use of imputed datasets, by allowing us to include all cohort children and procedures in the analyses, reduced the likelihood of bias that can result from restricting analyses to the small proportion of children with complete data [21]. Our sensitivity analyses evaluating the effect of multiple imputation in comparison with complete-case datasets, demonstrated that imputed data contributed to greater precision in mortality estimates and ensured that the impact of less

Notes: Interrupted vertical lines represent survival at 1 and 12 years. The survival curve for all children within the cohort is represented by a dotted line. The survival curve for children with each specific cardiac diagnosis is represented by a solid line.

doi:10.1371/journal.pone.0106806.t007

This has now increased to detection of around one-third of cases [27], which may mean that more children born today would commence specialist care at birth than in our cohort. The findings from our cohort should therefore be interpreted with caution within specific diagnostic subgroups where surgical techniques or screening detection have altered significantly as there may be improved survival for children born today. Nevertheless we believe our results are still likely to remain relevant overall to children born and operated with CHDs today, particularly for diagnostic subgroups in which significant improvements in early postoperative survival have not been seen.

There are relatively few population-based observational cohort studies that describe mortality and survival up to age 12–15 years for children affected by CHDs (Table 9). Although we also present some findings from our model including children who remained unoperated at the time of death, the majority of these children died in the first month after birth, many had HLH and palliative care was chosen by some parents; management of such severe and complex cases has continued to advance in the last decade. Thus our main model excludes these unoperated cases and focuses on survival from birth for the majority of children in the cohort, who did undergo an intervention.

Reviewing all child CHD deaths in Bohemia between 1952 and 1979, Samanek reported that ‘natural’ survival before the widespread introduction of paediatric cardiac surgery was 67% at 15 years [28]. Three further studies investigated survival in large surgical cohorts [10,29,30], including a Finnish population-based study between 1953 and 1989 in which survival was reported as 78% at 45 years after surgery, significantly lower than for the unaffected population. Only three studies have reported survival after diagnosis in early life, including children who remained unoperated as well as those undergoing surgery, of which two present directly observed survival from diagnosis [31] [32]. These two studies, representing contemporary management, documented better overall survival (Table 10) than we observed but up to 40% of children survived without any interventions suggesting...
### Table 8. Multivariable survival analysis using multiple imputation (n = 3725*).

| Variable                                | Reference Category | Category                        | Hazard Ratio | 95% CI | P-value |
|-----------------------------------------|--------------------|---------------------------------|--------------|--------|---------|
| **Sex**                                 | Boys               | Girls                           | 1.51         | 1.24   | 1.84    | <0.0001 |
|                                         |                    |                                 |              |        |         |         |
| **Birth gestation**                     | Term (≥37 weeks)   | Preterm (<37 weeks gestation)   | 1.31         | 1.01   | 1.69    | 0.042   |
| **Non-cardiac malformations**           | None               | Downs Syndrome                 | 0.87         | 0.62   | 1.21    | 0.403   |

### Table 9. Population-based cohort studies reporting mid- and long-term survival for children with congenital heart defects.

| Lead author, publication year | Region/State, Country | Period | Study population (n) | Method/Design; Outcome measure | Period of follow-up | Survival/mortality |
|-------------------------------|------------------------|--------|----------------------|-------------------------------|--------------------|--------------------|
| Morris, 1991 [29]             | Oregon, US             | Operated 1958–1989 | Children aged <18 years (n = 2,701) | Retrospective review of paediatric cardiac procedures (for 8 CHD types); Death after surgery | Up to 25 years after surgery | Varying by CHD: 64% survival at 15 years after surgery (transposition) to 98% survival (atrial septal defect) |
| Samanek, 1992 [28]            | Bohemia, Czech Republic | Diagnosed 1952–1979 | Deaths aged ≤15 years (n = 946) | Retrospective review of death registrations; Death ≤15 years old | Up to 16 years of age | 71% survival at 1 year of age; 67% survival at 15 years of age |
| Meberg, 2000 [31]             | Vestfold County, Norway | Diagnosed 1982–1996 | Children diagnosed clinically or at post-mortem (n = 360) | Prospective follow-up after diagnosis; Death ≤18 years old | Mean 9.5 years (range 3–18 years) | Overall 12% mortality at end of follow-up |
| Nieminen, 2001 [10]           | Finland                | Operated 1953–1989 | Children aged ≤15 years old at surgery (n = 6,461) | Retrospective review of paediatric cardiac procedures (all CHDs); Death after surgery | Mean 22 years after surgery (range 9–45 years) | Overall 7% surgical mortality; 78% survival at 45 years after surgery |
| Wren, 2001 [9]                | Northern Region, UK    | Born 1985–1994 | Children diagnosed clinically or at post-mortem (n = 1,942) | Prospective follow-up from birth/diagnosis; Death ≤15 years old | Up to 16 years of age | 82% survival at 1 year of age; Predicted 78% survival to 16 years of age |
| Moons, 2009 [32]              | Belgium                | Born 2002 | Children diagnosed clinically (n = 921) | Prospective follow-up from birth/diagnosis; Death ≤5 years old | Up to 5 years of age | 96% survival at 5 years of age |
| Larsen, 2011 [30]             | Western Region, Denmark | Operated 1996–2002 | Children operated for CHD (n = 801) | Prospective follow-up after cardiac surgery; Death after surgery | Median 8.2 years after surgery (range 6–12 years) | 86% survival at 8.2 years after surgery |

doi:10.1371/journal.pone.0106806.t009
that, in comparison with the UKCSCHD, they included a higher proportion of mild CHDs that were compatible with survival without intervention.

Surgical case series have highlighted important associations between increased postoperative mortality risk and factors such as low birth weight [33,34], preterm birth [35], sudden clinical deterioration in the neonatal period [36,37], and procedure-associated complications, including sepsis and renal failure [38]. Several studies have demonstrated the detrimental impact of longer intra-procedure duration of cardiopulmonary bypass and cardiac arrest [39–42], also observed in our cohort, although most previous authors estimated the effect at a single procedure only rather than repeated exposure over multiple procedures. Moreover, Kang has cautioned that longer duration of cardiopulmonary bypass may only reflect technically more difficult surgery [41].

Although our findings indicate that girls with CHDs are at significantly higher risk of death, published evidence for sex differences in mortality for individuals with CHDs remains inconclusive. Morris [29] demonstrated that girls with COA and TGA had higher mortality prior to intervention, whereas Fyler [43] reported a higher death rate for boys during the first year of life. Other authors have highlighted that girls experience higher perioperative mortality related to paediatric cardiac surgery [39–42], also observed in our cohort, although most previous authors estimated the effect at a single procedure only rather than repeated exposure over multiple procedures. Moreover, Kang has cautioned that longer duration of cardiopulmonary bypass may only reflect technically more difficult surgery [41].

In accordance with previous reports [32,53], we found no independent influence on mortality associated with Down’s syndrome. Eskedal [52] has highlighted that children with CHDs who have non-cardiac malformations other than Down’s syndrome experience higher mortality than those with isolated cardiac defects. In our cohort, non-Down’s non-cardiac malformations were significant predictors of mortality when children who died without intervention were included in the analysis, suggesting that these malformations do contribute to mortality in this subgroup.

It is now over a decade since the Bristol Inquiry addressed concerns about the care of children receiving cardiac surgery at the Bristol Royal Infirmary [54]. Expert evidence presented to the Inquiry emphasised the lack of data on long-term outcomes relevant to children and their families [55]. The Central Cardiac Audit Database (CCAD) now routinely collects national outcome data for cardiac procedures, including survival up to one year after paediatric cardiac intervention; these data are published through the National Institute for Cardiac Outcomes Research (NICOR) Congenital Heart Disease Portal [56].

While routine audit remains essential to monitoring outcomes for children receiving interventions for CHDs in the UK [57], a procedure-based system excludes children who never receive an intervention and often fails to capture late mortality and broader health outcomes, such as educational achievement or quality of life. Improved record linkage between multiple routinely collected data sources, supplemented by focused observational or clinical studies, could enrich current routine data collection and provide more efficient use of existing resources for extended follow-up.

Conclusions

The UKCSCHD has provided a unique opportunity to observe survival and wider health outcomes throughout childhood in a prospectively ascertained UK-wide cohort that is largely representative of contemporary management. We found that infant mortality under age one year for children with serious CHDs was over 30 times greater than for the general population, estimated at six per 1,000 live births [58]. It is also clear from our data that whilst children with CHDs were still most likely to die in infancy in this cohort, over 20% of CHD-related deaths in childhood took place after the first year of life. Surgical management of serious

Notes:

This table compares defect-specific survival reported in childhood within four population-based cohorts that include all children diagnosed in infancy even if no intervention was performed. Most studies present ‘observed’ cohort survival from diagnosis or first surgery during infancy, with the exception of:

*Samanek presents ‘natural’ survival in an era prior to widespread surgical correction.

Wren presents ‘predicted’ survival up to age 15 years based on observed survival to age 1 year and survival from 1 to 15 years estimated from a review of the published literature.

doi:10.1371/journal.pone.0106806.t010
CHDs carries an initial perioperative risk of death or neurological injury in childhood, but the altered physiology of the operated heart may also result in reduced ability to cope with ageing or cardiac stressors arising in adult life. Long-term survival and health outcomes are influenced by health events across the life course thus optimising the health experience of preschool age and school-age children with CHDs is as relevant to future improvements in survival and quality of life of adults with CHDs as successful early surgical repair. Crucially cardiac diagnosis also remained an important predictor of outcome particularly as this influenced the type of definitive procedure, whether this was palliative or corrective, and the age at which it was performed. However, we also identified procedure-related predictors of mortality that may be amenable to modification in order to effect further advances in survival or improve health outcomes after surgery. Investigation into the biological mechanisms contributing to higher mortality for girls is warranted to explore the potential for improving future outcomes and reducing health inequalities.

Acknowledgments

We are very grateful to the local cardiologists and members of the British Congenital Cardiac Association (BCCA) within the UKCSCHD collaboration centre without whom this study would not have been possible: We are very grateful to the local cardiologists and members of the British Congenital Cardiac Association (BCCA) in each UKCSCHD collaborating centre, without whom this study would not have been possible: Dr S Advani, Dr F Bu’Lock, Dr B Craig, Dr P Daubeny, Dr G Derrick, Dr M Elliott, Dr R Franklin, Dr J Gibbs, Dr B Knight, Dr J Lin, Dr A Magee, Dr R Martin, Dr P Miller, Dr S Qureshi, Dr E Rosenthal, Dr A Salmon, Dr I Sullivan, Dr P Thakker, Dr J Thomson, Dr D Wilson, Dr A Wong. UKCSCHD collaborating centres included: Belfast, Birmingham, Bristol, Cardiff, Edinburgh, Glasgow, Leeds, Leicester, Liverpool, London, Manchester, Newcastle, Nottingham, Oxford and Southampton. We would also like to thank Dr Huiqi Pan for her advice and support for the preparation of the MLWiN models and the UKCSCHD research assistants (Ms Ugochi Nwulu, Dr Carly Rich and others) for their valuable contribution and hard work. In addition, we appreciate very much the support that we received from Heartline (parent support group).

Author Contributions

Conceived and designed the experiments: RLK CD CB CW. Performed the experiments: RLK CD CB CW. Analyzed the data: RLK AW HG. Contributed reagents/materials/analysis tools: HG. Wrote the paper: RLK. Reviewed and developed the analyses: RLK CD CB CW AW HG. Reviewed and agreed the manuscript: RLK CD CB CW AW HG.
