Abstract

Context. We seek clarification of the nature of X–ray sources detected in M 31. Here we focus on CXOM31 J004253.1+411422, the brightness of which suggests that it belongs to the class of ultraluminous X–ray sources.

Aims. We determine the X–ray properties of sources detected in the XMM–Newton / Chandra monitoring program. We investigate spectral properties and search for periodic or quasi–periodic oscillations. A multi–component model is applied to the spectra obtained from XMM–Newton data to evaluate the relative contributions from thermal and non–thermal emission. The time dependence of this ratio is evaluated over a period of forty days.

Methods. We simultaneously fit data from XMM–Newton EPIC-pn, MOS1 and MOS2 detectors with (non–thermal) powerlaw and (thermal) multicolored blackbody.

Results. The X–ray spectrum is best fit by the combination of a thermal component with $kT \sim 1$ keV and a powerlaw component with photon index approximately 2.6. From combined analysis of Chandra, Swift and XMM–Newton data, the unabsorbed total luminosity of this source decreases from $\sim 3.8 \times 10^{39}$ erg s$^{-1}$ in the first observation to $\sim 0.5 \times 10^{39}$ ergs s$^{-1}$ over a period of three months. The decay closely follows an exponential decline with a time constant of 32 days. The source spectrum evolves significantly, exhibiting a faster decline of the thermal component. We do not find evidence of any significant temporal features in the power density spectrum. The presence of a thermal component at $kT \sim 1$ keV in conjunction with a non–thermal high energy tail, is also consistent with spectral properties of other ULXs in the “high state”.

Conclusions. Our analysis indicates that the underlying source of this first ULX in M 31 is a black hole of mass, $M \geq 13 M_\odot$, accreting near the Eddington limit, that underwent a transient outburst followed by an exponential decay reminiscent of transients associated with galactic X–ray novae.

Key words. Galaxies: individual: M 31 – X–rays: stars – X–rays: binaries

1. Introduction

Ultraluminous X–ray sources (ULXs) are very bright point sources with an X–ray luminosity of $L_x > 10^{39}$ erg s$^{-1}$, which exceeds the Eddington luminosity for compact objects with mass of approximately 10 $M_\odot$. This source class was first identified by the Einstein Observatory in the eighties (Fabbiano 1989). These sources are not associated with the center of galaxies and thus do not belong to the class of super–massive black holes. On the other hand, they are too bright to be associated with stellar mass black holes with $M < 10 M_\odot$, accreting below the Eddington rate. An exciting possibility is that the underlying sources of ULXs are intermediate mass black holes (IMBHs), in the mass range $10^2 - 10^4 M_\odot$, accreting at sub–Eddington rates (Miller & Colbert 2004). For example, observations of an ULX in NGC5408 suggested a mass of $\sim 100 M_\odot$, indicating a possible existence of IMBHs (Fabian & Ward 1993). However, a recent study of this source’s variability indicates that the mass is likely below 100 $M_\odot$ (Middleton et al. 2011). Although the identification of ULXs as IMBHs has not yet been firmly established, one should contemplate the theoretical progenitors, that could result in producing such objects. Several theories have been suggested for the formation of IMBH. Madau & Rees (2001) studied the collapse of Population III stars, while others considered the collapse of massive stars (in young super–massive star clusters) e.g. Portegies Zwart et al. (2004). Another possibility is that the masses are much less than 100 $M_\odot$, but that the source accretes at Super–Eddington rate, as suggested by Begelman (2002). Yet another factor to be considered is deviations from the common assumption of isotropic emission as suggested by King et al. (2001). Along these lines for anisotropic emission, Reynolds et al. (1997) proposed a link between ULXs and extreme beaming, as observed in galactic micro–quasars. The nature of the ULX class remains unclear, which is in part due to the fact that the sample size is still rather small.

To better understand the ULX phenomenon, an increase in sample size and careful consideration of spectral and sample properties is desirable. The ULX sources are mainly found in star forming galaxies. Until recently, no ULX had been identified in M 31. Our ongoing monitoring program for resolving super soft source states of optical novae in the central area of M 31 (P.J. Wolfgang Pietsch) with XMM–Newton and Chandra HRCT yielded a transient source, which, as discussed in this paper, represents the first recognized ULX in our companion galaxy.

* Based on observations obtained with XMM-Newton, an ESA Science Mission with instruments and contributions directly funded by ESA Member States and NASA.

1 www.mpe.mpg.de/m31novae/xray/index.php
We present the time development of the outburst and the spectral analysis of a ULX in M 31 using XMM–Newton, <i>Chandra</i> and <i>Swift</i> data over a period of approximately three months (Sect. 2), followed by the summary of the results in Sect. 3. Conclusions are presented in Sect. 4.

The spectroscopic data were then obtained by XMM–Newton from December 28, 2009 until February 02, 2010 in five distinct observations using the European Photon Imaging Camera (EPIC). EPIC–pn (Strüder et al. 2001), MOS1 and MOS2 (Turner et al. 2001) CCD detectors are mounted on the three X–ray telescopes on XMM–Newton. The exposure times as well as the raw count rates obtained with these detectors are presented in Table 1. The XMMSAS version 10.0.0 was used to filter the standard pipeline event files, to generate images, light curves, spectra and the appropriate detector response functions. The event files for all three cameras, pn, MOS1 and MOS2 were analyzed with the following parameter settings: For spectrum generation, we set FLAG = 0 to reject bad pixels, and PATTERN ≤ 4 for pn and ≤ 12 for MOS1 and MOS2 event files were allowed to reduce noise in the data. Light curves were derived to investigate the variability in the source. Barycenter correction was performed using the barycen task in XMMSAS. The light curves were then corrected from various effects such as bad pixels, GTIs, vignetting using epic1ccorr. As an example

2. Observations and data analysis

CXOM31 J004253.1+411422 was discovered with <i>Chandra</i> HRC–I in a 19 ks observation on 2009 Dec 17.89 UT (Henze et al. 2009). The source position was determined to be R.A (J2000) = 00:42:53.15, Dec. (J2000) = +41:14:22.9, using the catalog of X–ray sources in M 31 assembled by Kaaret (2002) for relative astrometry. Figure 1 shows the position of the source with respect to other X–ray sources near the center of M31 in an XMM–Newton color image. A transient optical counterpart with m(F435W) = 23.8 mag was identified in HST observations (Garcia et al. 2010). The X–ray source was first detected with <i>Chandra</i> HRC–I. Level 2 event files were analyzed using (Chandra Interactive Analysis of Observations; Fruscione et al. 2006) to obtain count rates as shown in Table 1. An adapted version of the XMMSAS tool emldetect was used to estimate background-corrected and exposure-corrected fluxes and count rates (see Henze et al. 2010). Continuous monitoring of this source was then carried out by <i>Swift</i>–XRT from December 22 ~ 27, 2009. The data were analysed using the HEASoft XIMAGE package (version 4.5.1) with the sosta command (source statistics) for estimations of count rates. We took into account the XRT PSF of the sources that we computed with the command psf, as well as exposure maps that were created with the XRTPSF tool. The XRT software task xrtexppmap within XIMAGE. The count rates obtained from <i>Swift</i>–XRT and <i>Chandra</i> HRC–I before and after the XMM–Newton observations were converted to unabsorbed fluxes using energy conversion factors (ecfs), which were computed using fakeit in XSPEC assuming the best fitting spectral model for the first and last XMM–Newton observations, respectively, and using publicly available instrument response files. We obtain $e_{\text{HRC-I-1}} = 6.3 \times 10^{10}$ cts erg$^{-1}$ cm$^{-2}$ and $e_{\text{HRC-I-2}} = 7.7 \times 10^{10}$ cts erg$^{-1}$ cm$^{-2}$, respectively. For the <i>Swift</i>–XRT data, the ecf has been computed to be $1.57 \times 10^{10}$ cts erg$^{-1}$ cm$^{-2}$.

3. Results

Our initial spectral fitting for XMM–Newton data used a broken powerlaw model (BKNPOWER in XSPEC), but the $\chi^2$/d.o.f.
The luminosity derived from this simple fit indicated the fact that this source is a member of the ULX class. For these objects, an alternative, often better fitting model is a combination of a non–thermal (power law) and thermal component (Gladstone et al. 2009). To explore this possibility we applied a model that combines a non–thermal powerlaw component (P0) with a multicolored blackbody component (DISKKB). The thermal component is associated with an accretion disk around a central black hole as developed by Mitsuda et al. 1984 and Makishima et al. (1986). This model gave a significantly improved fit, indicated by $\chi^2$/ d.o.f. values in Table 2.

Table 1. Observations log

| Telescope/instrument | Obs ID  | Date (UT) | Exptime (ks) | Rate$^d$ (ct s$^{-1}$) | $L_{\text{unabs}}^x$ (10$^{39}$ erg s$^{-1}$) |

Notes. $^a$ External absorption column density. $^b$ Temperature of inner–disc from DISKKB. $^c$ Photon index from powerlaw model. $^d$ R$_{in}$ is inner radius of the multicolored blackbody disk, and $i$ is the inclination angle. $^e$ Absorbed luminosity contribution from the powerlaw model (hard component) in (0.2–10 keV) energy band. $^f$ Absorbed luminosity from the multicolored disk component within (0.2–10 keV) energy band. $^g$ Total unabsorbed luminosity from the source within (0.2–10 keV) energy band.

In addition to the intrinsic two component model, the source flux must be corrected for extinction by foreground gas in the Milky Way and the local gas along the line of sight through M 31. Extinction was modelled using the Tuebingen–Boulder ISM absorption model (TBABS) (Wilms et al. 2000). The hydrogen column density ascribed to the Milky Way was fixed to 5.32 x 10$^{20}$ cm$^{-2}$ (Dickey & Lockman 1990), whereas the column density for the host galaxy was included as a free parameter. However, the derived value of the column density in M 31 must thus be considered with caution because we do not have information about the actual metallicity along the line of sight through M 31 and simply assume the Milky Way template expressed in terms of a standard cross–section per hydrogen atom.

$=$ 2953.96/1174 clearly indicated that this is not a satisfactory model.
To illustrate this fitting procedure, Fig. 3 shows the XMM–Newton EPIC data for first of our five observational epochs. The decomposition of the X–ray spectrum into the model components in physical units is shown in Fig. 4.

**Figure 3.** Combined powerlaw and multicolored blackbody fit to the joint set of data from EPIC–pn (black), MOS1 (green), MOS2 (red) with χ^2/ d.o.f. = 1318.87/1165 for the observation 0600660201 with XMM–Newton. The model parameters obtained from this spectral fit are presented in Table 2.

**Figure 4.** The theoretical model underlying the data fit (solid line) in Fig. 3 is shown in decomposition between the thermal (dash-dotted line) and the non–thermal (dotted line) component.

To convert fluxes to luminosities, we assume a source distance of 780 kpc (Holland 1998; Stanek & Garnavich 1998) and isotropic emission. The resulting luminosities during the XMM–Newton observations are about 10^{39} erg s^{-1}, which places this source in the mid range of known ULXs (Gladstone et al. 2009). Table 2 summarizes the derived luminosities (from XMM–Newton only) as well as the effective inner disk radius. As a function of time, both the non–thermal (L_{po}) and thermal (L_{BB}) component decrease, but the latter decreases more rapidly (see Fig. 5). Table 1 lists the calculated luminosities derived from count rates associated with observations of Chandra and Swift–XRT. The total unabsorbed luminosity declined from about 3.7 x 10^{39} to 0.5 x 10^{39} erg s^{-1} during the period of observation. We note that this source was initially more luminous than the total X–ray luminosity of M 31 in the (0.1–2.4) keV band sampled by ROSAT (Supper et al. 1997). Furthermore, this source was at least one order of magnitude brighter than any of the 45 X–ray transients detected in M 31 by Chandra and XMM–Newton from October, 1999 to August, 2002 (Williams et al. 2006).

**Figure 5.** Temporal variation of the total unabsorbed luminosity (L_{unebb}) as per observations of XMM–Newton. The decomposition into the powerlaw (L_{po}) and blackbody component (L_{bb}) reveals a distinct evolutionary behavior of these two components. The time zero corresponds to Chandra HRC-I observation ID 10886 (see Table 1).

From the X–ray spectrum fits of the first XMM–Newton observation (when the source was nearly brightest and we had the best quality data), we extract an estimate of the mass of the black hole following the formalism given by Makishima et al. (2000). Under the assumption of a geometrically flat and optically thick accretion disk, these authors derived the following relation:

\[ M = \frac{R_{in}}{8.86 \alpha} M_\odot, \]

where \( R_{in} \) is the inner radius of the accretion disk, measured in km and \( \alpha \) is a dimensionless parameter that relates the inner radius to the Schwarzschild radius via \( R_{S} = 3\alpha R_{S} \).

For the bolometric luminosity emitted by the accretion disk, Makishima et al. (2000) find (their eqt. 9):

\[ L_{bol} = 7.2 \times 10^{38} \left( \frac{L}{0.41} \right)^{-2} \left( \frac{\kappa}{1.7} \right)^{-4} \alpha^2 \left( \frac{M}{10M_\odot} \right)^{\frac{1}{2}} \left( \frac{T_{in}}{keV} \right)^{4} \]

erg s^{-1}

where \( T_{in} \) is the temperature characterizing the inner accretion disk. The remaining parameters specific to their model are here chosen to take their standard values as indicated by the normalization. The spectral fit yields the products of \( R_{S} \) and the square root of the cosine of the inclination angle of the disk, as well as temperature, \( T_{in} \), and the bolometric luminosity (which we assume to be unabsorbed L_{ab} component (= 1.6 x 10^{39} erg...
s\(^{-1}\)) integrated from 0.2–10.0 keV). From the two equations above, we can therefore determine the mass and inclination angle, although significant uncertainties in both quantities are associated with the model parameters, \(a\), \(\xi\) and \(\kappa\) fixed to the values 1, 0.41 and 1.7, respectively (see Makishima et al. 2000). The \(\alpha\) parameter has been defined above and \(\xi\) is a correction factor, reflecting the fact that \(T_{in}\) occurs at a radius somewhat larger than \(R_{in}\). The specific value adopted here was motivated by Kubota et al. (1998). The final parameter, \(\kappa\) represents the ratio of color temperature to effective temperature and the value adopted here has been taken from Shimura & Takahara (1995). With these caveats in mind, we find a mass of 13 M\(_{\odot}\) with a statistical uncertainty of about 4%. This implies an inner radius of \(R_{in} = 124\) km. From the fitting parameter \(R_{in} \sqrt{\cos(i)}\) (see Table 2), one then infers an inclination angle of \(i \sim 80^\circ\). The assumption of a non-rotating Schwarzschild black hole (\(\alpha = 1\)) can lead to a significantly underestimated black hole mass as the extreme case of a maximally rotating Kerr black hole (\(\alpha = 1/6\)) allows for a more massive central object approaching the realm of IMBH. Note, that this increase with black hole spin relies on the assumption that the inner edge of the accretion disk can be identified with the location of the innermost stable circular orbit (ISCO). However, determining the inner edge of a black hole accretion disk is a far more complex issue, e.g. Abramowicz et al. (2010).

As described in Sect. 2, we searched for an underlying periodicity in each of the observing runs over a range of frequencies limited by the temporal extent of the observation and the binning time of 100 s. The observed count rates (e.g. Fig. 2) display fluctuations within the range expected from counting statistics. None of the power density spectra reveal a significant feature.

## 4. Discussion and conclusions

The intrinsic luminosity of the source is consistent with those found for other ULXs in nearby galaxies. The presence of a thermal component at \(kT \sim 1\) keV in conjunction with a non–thermal high–energy tail, is also consistent with spectral properties of other ULXs. The temperature and photon index of M 31 source fall in the center of observed distributions for ULXs (Winter et al. 2006), lending additional support to a ULX nature.

We compared various properties of this ULX with a selected sample from the XMM–Newton archival study of ULXs by Winter et al. (2006) in 32 nearby galaxies with distance < 8 Mpc and unabsorbed luminosities, \(L_x > 10^{38}\) erg s\(^{-1}\) in the 0.3 – 10 keV energy range. Motivated by the observed properties of black hole binaries in the Milky Way, these authors classified their sample into two subsets, "low state" and "high state", based on their respective spectral properties. Low state sources were characterized by a single powerlaw X–ray spectrum, while high state sources required an additional multicolored blackbody with powerlaw. Since the spectra described in Sect. 3 clearly exhibit the best fit when a powerlaw is combined with multicolored blackbody, this source should be classified as "high state" ULX. Therefore we limit our comparison to 19 of high state ULXs in their sample. This sample is slightly reduced because we selected the brightest epoch out of multiple XMM–Newton observations, and those were not always available in Winter et al. (2006).

Figure 6 displays the resulting set of "high state" ULXs in the \(L\)–\(T\) plane. As Winter et al. (2006) pointed out, the temperature distribution is possibly bimodal. The ULX in M 31 belongs to the high-T group, which is commonly believed to represent the class of stellar mass black holes. The low–T group is characterized by a larger range of X–ray luminosities and has been tentatively attributed to the hypothetical class of IMBHs (Winter et al. 2006). Although the sample size is still very small, it appears that a physical gap between these two groups exists. If that is the case, an explanation may be related to different formation scenarios for these groups. As Winter et al. (2006) suggested, one possibility is associated with the unique features of pair instability supernovae (PISNe) in the early universe (Population III origin, Heger et al. 2003). The mass of \(\sim 13\) M\(_{\odot}\) derived in Sect. 3 suggests that we are dealing with a normal stellar remnant, one that could have been formed later in the universe, provided \(\alpha\) is not significantly less than unity due to rotation.

As described in Sect. 2, we searched for an underlying periodicity in each of the observing runs over a range of frequencies limited by the temporal extent of the observation and the binning time of 100 s. The observed count rates (e.g. Fig. 2) display fluctuations within the range expected from counting statistics. None of the power density spectra reveal a significant feature.

![Figure 6](image-url) **Figure 6.** Temperature vs Luminosity for 19 selected ULXs from Winter et al. (2006) along with the candidate ULX (red) in M 31. The M 31 source is a member of the "high temperature" subgroup.

![Figure 7](image-url) **Figure 7.** For the same sample shown in Fig. 6, a comparison of photon index vs temperature reveals that the M 31 ULX cools significantly, but remains within the range covered by the "high temperature" group. The labels 1 through 5 correspond to the chronological entry of XMM–Newton observations as listed in Table 1.

Figure 7 shows the "high state" ULXs distribution in the T–\(\Gamma\) plane. The low–T group shows a large range in photon index, resembling the large range in luminosity, however we note that the uncertainties in this parameter are very large. In con-
Figure 8. Variation of the total unabsorbed luminosity ($L_{unabs}$) of ULX in M 31 as observed by Swift–XRT, Chandra HRC–I and XMM–Newton resembling an exponential decay with a time scale of 32 days. The time zero corresponds to Chandra HRC – I observation ID 10886 (see table 1).

In contrast to the previous figure, here we show the temporal evolution of the M 31 ULX, while for other ULXs, no evolution has been shown. Over a time span of forty days of observations with XMM–Newton, the spectral evolution clearly exhibits cooling, but almost no change in the shape of the power-law component. Referring back to Fig. 5, the drop in the temperature is also accompanied by a significant change in the luminosity of this component. The power-law component, on the other hand, exhibits a declining luminosity as well, but not as rapid as the thermal one. The overall evolution of this transient is thus a combination of a strongly varying thermal component and a significantly less varying non–thermal part.

Combining all data obtained with Chandra, Swift and XMM–Newton indicates that the X-ray luminosity of this source follows closely an exponential decline (see Fig. 8) with a time constant of 32 days. A continuation of this trend is evident from data taken 150 days after the outburst when the source was detected at $L_{unabs} \sim 10^{38}$ erg s$^{-1}$ (Barnard et al. 2011). This observed exponential decline of the luminosity is consistent with those determined for the class of galactic X–ray novae (Chen et al. 1997), which show FRED (Fast Rise Exponential Decay) like light curves, though the FR part in our case was missed. However, the light curves of this source class often exhibit more complex behaviour than a simple exponential decay.

In summary, the Chandra discovery of CXOM31 J004253.1+411422 has established it as the first member of the class of ULXs in M 31. Follow up observations with Swift and XMM–Newton revealed an exponential decline, reminiscent of the late time evolution of Galactic X–ray novae. Spectral analysis of the XMM–Newton data suggests that this source was in a "high state" at the time of observation, and that the underlying source is likely a stellar mass black hole accreting near the Eddington limit.

Acknowledgements. The XMM project is supported by the Bundesministerium für Bildung und Forschung / Deutsches Zentrum für Luft- und Raumfahrt (BMBF/DLR) and the Max-Planck Society. We thank the Swift team for their help with scheduling the TOO observations. M. Henze acknowledges support from the BMWI/DLR, FKZ 50 OR 1010.
