ABSTRACT Among the thousands of species that comprise marine bacterioplankton communities, most remain functionally obscure. One key cosmopolitan group in this understudied majority is the OM252 clade of Gammaproteobacteria. Although frequently found in sequence data and even previously cultured, the diversity, metabolic potential, physiology, and distribution of this clade has not been thoroughly investigated. Here, we examined these features of OM252 bacterioplankton using a newly isolated strain and genomes from publicly available databases. We demonstrated that this group constitutes a globally distributed novel genus (“Candidatus Halomarinus”), sister to Litoricola, comprising two subclades and multiple distinct species. OM252 organisms have small genomes (median, 2.21 Mbp) and are predicted obligate aerobes capable of alternating between chemoorganoheterotrophic and chemolithotrophic growth using reduced sulfur compounds as electron donors. Subclade I genomes encode genes for the Calvin-Benson-Bassham cycle for carbon fixation. One representative strain of subclade I, LSUCC0096, had extensive halotolerance and a mesophilic temperature range for growth, with a maximum rate of 0.36 doublings/h at 35°C. Cells were curved rod/spirillum-shaped, ~1.5 by 0.2 μm. Growth yield on thiosulfate as the sole electron donor under autotrophic conditions was roughly one-third that of heterotrophic growth, even though calculations indicated similar Gibbs energies for both catabolisms. These phenotypic data show that some “Ca. Halomarinus” organisms can switch between serving as carbon sources or sinks and indicate the likely anabolic cost of lithoautotrophic growth. Our results thus provide new hypotheses about the roles of these organisms in global biogeochemical cycling of carbon and sulfur.

IMPORTANCE Marine microbial communities are teeming with understudied taxa due to the sheer numbers of species in any given sample of seawater. One group, the OM252 clade of Gammaproteobacteria, has been identified in gene surveys from myriad locations, and one isolated organism has even been genome sequenced (HIMB30). However, further study of these organisms has not occurred. Using another isolated representative (strain LSUCC0096) and publicly available genome sequences from metagenomic and single-cell genomic data sets, we examined the diversity within the OM252 clade and the distribution of these taxa in the world’s oceans, reconstructed the predicted metabolism of the group, and quantified growth dynamics in LSUCC0096. Our results generate new knowledge about the previously enigmatic OM252 clade and point toward the importance of facultative chemolithoautotrophy for supporting some clades of ostensibly “heterotrophic” taxa.

Marine bacterioplankton constitute 10^4 to 10^7 cells per milliliter in seawater (1–3), spread across hundreds to thousands of operational taxonomic units (OTUs) (2). However, many of these bacterioplankton lineages have no assigned metabolic or ecological roles, and we know little more about them than their distribution in 16S rRNA gene surveys. While some of the dominant groups like SAR11 Alphaproteobacteria, Prochlorococcus cyanobacteria, and SAR86 Gammaproteobacteria rightly attract considerable attention (4–7), many taxa that occur at somewhat lower relative abundances, but nevertheless are cosmopolitan microbial community members of the global oceans, have received comparably little study. One of these groups, the OM252 clade of Gammaproteobacteria, was first described over twenty years ago in clone library sequences from surface waters overlying the continental shelf off Cape Hatteras, North Carolina (8). This group is widely distributed. OM252 16S rRNA gene sequences have been reported from Sapelo Island off the coast of Georgia (9), the Gulf of Mexico (10–12), Käne’ohe Bay in Oahu (13), the eutrophic coastal North Sea near Amsterdam (14), a lagoon in the Clipperton Atoll off the western coast of Mexico (15), and the Gulf of Lyon in the Mediterranean Sea (16). Sequences in GenBank with high percent identity to the OM252 clade have also come from near Cocos Island in the eastern tropical Pacific Ocean as well as the East China Sea. OM252 sequences also occur in less-saline waters, like the estuarine zone of the Jiulong River, China, and lakes with varying salinities in Tibet (17), as well as hypersaline environments, like the Salton Sea in California (18) and salterns in Spain (19). There are even reports that indicate OM252 bacteria may be at least transiently associated with marine invertebrate microbiomes (20, 21). Thus, it appears that OM252 bacteria inhabit a variety of habitats and may have a euryhaline lifestyle.

Despite the widespread distribution of OM252 bacterioplankton, they remain poorly studied. The first reported isolate, HIMB30, was obtained via high-throughput dilution-to-extinction (DTE) cultivation with a natural seawater medium inoculated from Käne’ohe Bay, Hawaii (22). The ~2.17 Mbp HIMB30 genome predicted partial glycolysis, a complete tricarboxylic acid (TCA) cycle, phototrophy via proteorhodopsin, carbon monoxide and sulfur oxidation, and CO₂ fixation via the Calvin-Benson-Bassham (CBB) cycle (22). However, these functions have not been demonstrated experimentally, nor have growth parameters, such as temperature or salinity tolerances, been investigated. We also do not know how representative the HIMB30 features above are for the clade. Even the phylogenetic position of OM252 within the Gammaproteobacteria remains in question. The first clone library sequence branched sister to the OM182 clone and Oceanospirillales sequences (8). The closest described organisms, Litoricola spp., share less than 90% 16S rRNA gene identity with HIMB30 (22). Furthermore, the gammaproteobacterial phylogeny continues to evolve, with many traditionally recognized groups no longer remaining monophyletic (23) and additional genomes from uncultivated organisms changing the topology (24). The current Genome Taxonomy Database (GTDB release 05-R595) indicates that these organisms belong to the family Litoricolaceae in the newly reconstituted order Pseudomonadales (24–26).

Our previous work combining cultivation and cultivation-independent methods demonstrated that OM252 was a prominent member of coastal northern Gulf of Mexico microbial communities (10, 12). Our 16S rRNA gene amplicon data indicated at least two distinct amplicon sequence variants (ASVs) within the single observed OM252 OTU across 6 sampling sites and 3 different years (12). That OTU was the 25th most abundant bacterioplankton taxon in the high-salinity community (salinities of >12) observed in the 3-year data set. OM252 thus represented an important medium-abundance organism in that coastal environment. Furthermore, our artificial media facilitated ready cultivation of OM252 members, with over 30 strains isolated over the course of 17 experiments (12).

To improve our understanding of the physiology, ecology, and evolutionary relationships of the OM252 clade, we sequenced the genome of one representative isolate, LSUCC0096, and performed comparative genomic analyses with this organism,
HIMB30, and 23 other publicly available environmental genomes. In parallel, we characterized physiological aspects of LSUCC0096 relevant to OM252 biology. OM252 comprised at least two subclades (I and II), both of which had a globally cosmopolitan distribution. OM252 clade members share many of the same metabolic features; however, there is subclade differentiation in the capacity for predicted sulfur-based chemolithoautotrophy. LSUCC0096 had a wide tolerance for salinity, growing from low salinity brackish water to nearly double the salinity of seawater. Furthermore, we showed that LSUCC0096 could grow under chemolithoautotrophic conditions with thiosulfate as the sole electron donor and estimate the energetic consequences of this metabolism on growth rates. Contrary to existing nomenclature in GTDB, our comparative genomic data support the designation of OM252 as a separate genus from Litoricola, which we propose as “Candidatus Halomarinus,” along with names for three species within the genus. These results expand our understanding of the genomic diversity, distribution, and lifestyles within the OM252 clade and provide the first cellular and physiological data for these organisms. They also raise new questions about the relationship between facultative chemolithotrophy and OM252 ecology.

RESULTS

Isolation and genome sequencing. LSUCC0096 was isolated as part of a series of DTE experiments using water samples from across the southern Louisiana coast (10). The specific sample from which we obtained LSUCC0096 came from surface water in the Bay Pomme d’Or near the Mississippi River Birdfoot delta (salinity, 26; 7.7°C; pH 7.99). LSUCC0096 was grown for genome sequencing in JW1 medium (10). Illumina MiSeq PE 250-bp sequencing generated 242,062 reads. Assembly with the A5 MiSeq pipeline resulted in 4 scaffolds with a total length of 1,935,310 bp, N50 of 1,442,657 bp, 30X median coverage, and a GC content of 48.5% (Table 1). Annotation by IMG predicted 2,001 protein-coding genes and 46 RNA genes—one copy of the 5S, 16S, and 23S rRNA genes and 36 predicted tRNA genes. The genome was estimated to be 96.17% complete with 0.37% contamination and a coding density of 95% (via CheckM [27]) (Table 1).

Taxonomy. Initial blast searches of the 16S rRNA gene sequence to GenBank identified LSUCC0096 as a gammaproteobacterium, with the closest cultivated representative being the OM252 clade organism HIMB30 (22). To better understand the phylogenetic breadth of this group, we identified 23 nonredundant good- or high-quality metagenome-assembled genomes (MAGs) and single-amplified genomes (SAGs) closely related to HIMB30 and/or LSUCC0096 based on average nucleotide identity (ANI) and monophyletic grouping within the Genome Taxonomy Database (GTDB) (see Table S1 in the supplemental material). Phylogenetic inference using 16S rRNA gene sequence phylogenies produced different results depending on taxon selection (see Fig. S1 and S2 in the supplemental material). Even though the tree contains most of the major families designated by GTDB in the Pseudomonadales, the relationship of the Ecophysiology of “Ca. Halomarinus” May/June 2021 Volume 6 Issue 3 e00276-21 msystems.asm.org 3
Litoricolaceae does not match the release RS89 topology ([http://annotree.uwaterloo.ca/](http://annotree.uwaterloo.ca/)); accessed February 2021), which placed Litoricolaceae sister to the Saccharospirillaceae and Oleiphilaceae. However, the bootstrap support for the relationships with SAR86 and the branch leading to the rest of the Pseudomonadales was poor (Fig. 1; Fig. S3). Subclade structure within the OM252 clade (subclades I and II) (Fig. 1) corresponded to subgroups circumscribed via FastANI during our taxon selection (Table S1). Within subclade I, a monophyletic group of genomes (UBA12265 to UBA8357) (Fig. 1) represented a single species according to the 95% ANI species cutoff (28), with multiple additional species in both subclades (Table S1). The isolates HIMB30 and LSUCC0096 shared only 80.3% ANI, making them distinct species.

Pairwise blast of the 16S rRNA gene from all nine OM252 subclade I members for which the gene was recovered with five Litorica representatives from multiple species (Fig. S1 and S2), corroborated the phylogenetic separation of these groups: no Litorica sequence had greater than 89.8% identity with any OM252 genome, whereas the range

*Genomes shaded according to subclade (SC).
FIG 1 Phylogenomic tree of the *Pseudomonadales* and OM252. Maximum-likelihood tree based on 78 concatenated single-copy genes within the *Pseudomonadales* (as designated by GTDB) and selected other Gammaproteobacteria, with Alphaproteobacteria and (Continued on next page)
of identity within OM252 subclade I was ≥98.5% (Table S1; no legitimate 16S rRNA genes were recovered from subclade II). Thus, OM252 subclade I constitutes a distinct genus from Litoricola based on pairwise 16S rRNA gene identity alone (29). The monophyletic relationship of subclades I and II in the phylogenomic tree, the presence of multiple distinct species within both subclades based on ANI, as well as the comparative branch length distances between subclades I and II versus Litoricola support inclusion of subclades I and II into the same group. Finally, there is a considerable difference in the GC content of all OM252 genomes (both subclades) compared with Litoricola (47 to 51% versus 58 to 60% [26, 30], respectively). Thus, we propose the provisional genus name “Candidatus Halomarinus” for the OM252 clade. Since HIMB30 was the first reported isolate from OM252, this would be the type strain. However, since it is not currently deposited in international culture collections, we propose the species name as “Candidatus Halomarinus kaneohensis” sp. nov. We also propose “Candidatus Halomarinus pomme-dorensis” sp. nov. for strain LSUC0096 and “Candidatus Halomarinus littoralis” sp. nov. for the species cluster comprising UBA12265 to UBA8357 in Fig. 1. We provide genus and species descriptions below.

**Distribution.** We previously reported the distribution of the OM252 clade within the 16S rRNA gene amplicon data associated with three years of sampling in support of DTE experiments from the Louisiana coast (12). The single OM252 OTU was moderately abundant (relative abundance up to ~1%) at salinities of ≥5, regardless of site. We also identified two amplicon sequence variants (ASVs) associated with the OM252 clade—one which was generally much more abundant than the other. LSUC0096 matched the more abundant, and more frequently cultivated, ASV5512 (12), representative of subclade I. ASV5512 was found across a range of salinities but was more prevalent in salinities above 12, where it was one of the top 50 most abundant ASVs in the 3-year data set. The other OM252 ASV, 5507, was much less abundant but matched the distribution of ASV5512 (12).

We expanded our assessment of OM252 genome abundance and distribution using metagenomic read recruitment for the global oceans. OM252 members from both subclades recruited reads from metagenomic samples across the globe (see additional supplemental figures). The two most abundant taxa were represented by the subclade II MAGs TOBG-NAT-109 and GCA_002480175 (see Fig. S4 in the supplemental material). The two most abundant subclade I taxa were represented by the SAGs AG-905-C17 and AG-900-B21. Genomes from the isolate strains LSUC0096 and HIMB30 were the third and sixth ranking by median recruitment values for subclade I. Recruitment to the “Ca. Halomarinus littoralis” cluster genomes was generally lower than that to other genomes in subclade I (Fig. S4). Assessment of recruitment-based abundance patterns to the entire OM252 clade revealed no strong relationships with latitude, salinity, temperature, region, or depth (see Fig. S5 in the supplemental material).

Individual genome recruitment was not influenced by salinity, but the salinity variation in the tested samples was quite limited (see additional supplemental figures). Some genomes showed trends consistent with recruitment based on temperature (see additional supplemental figures). For example, HIMB30 and LSUC0096 reads per kilobase per million (RPKMs) had significant negative relationships with temperature (linear regression, P values of 0.002 and 0.003, respectively). However, there was no consistent pattern for the genomes within a given subclade, and many genomes had no significant recruitment relationship with temperature (see additional supplemental figures). The vast majority of samples from the data set were from the epipelagic, and recruitment to OM252 genomes predominated in surface waters (see additional supplemental figures). We observed very high relative recruitment to HIMB30 and...
AG-898-O07 in bathy and abyssopelagic waters and intermediate relative recruitment in deep ocean samples to other genomes from both subclades (see additional supplemental figures), suggesting that some strains of OM252 may either preferentially or at least transiently inhabit the ocean interior. We also examined latitudinal distribution in recruitment. The data set had a bimodal distribution with the majority of sites occurring in the midlatitudes (see additional supplemental figures). Most genomes did not show recruitment patterns consistent with the sample distribution alone nor did we observe any clear relationships between subclade genomes with latitude (see additional supplemental figures). Separately, we recruited metagenomes from two coastal sites, namely, the northern Gulf of Mexico “dead zone” (31) and samples from the San Pedro shelf, basin, and Catalina Island in the Southern California Bight (32) (see additional supplemental figures). In contrast to the recruitment in the global oceans, the “Ca. Halomarinus littoralis” cluster of genomes was among the most abundant across these coastal sites (see Fig. S6 in the supplemental material). Thus, we hypothesize that the “Ca. Halomarinus littoralis” group represents a coastal adapted species within OM252.

**General genome characteristics.** The shared and variable gene content and corresponding metabolic functions of the OM252 genomes are shown in Table S1. Estimated genome completion spanned 51.6 to 96.2%, with LSUCC0096 being the most complete (Table 1). Median estimated complete genome size was 2.21 Mbp, median GC content was 49% (47 to 51%), and median coding density was 92% (82 to 96%) (Table S1). Genome sizes are comparable to the *Litoricola lipolytica* IMCC1097 genome, the nearest phylogenomic neighbor. However, the IMCC1097 genome has a much higher GC content (58.8%) than that of “Ca. Halomarinus.”

**Electron transport and energy conservation.** “Ca. Halomarinus” bacteria were predicted to be aerobic chemotrophs (Fig. 2; see also Table S1). No alternative terminal electron accepting processes were identified in either subclade (see Fig. S7 in the supplemental material). A second, high-affinity (cbb₃ type) cytochrome c oxidase was additionally present in seven subclade I genomes (Fig. 2; Table S1). Both subclades had sodium-translocating respiratory NADH dehydrogenases and Na⁺/H⁺ F-type ATPases, indicating the likely use of a sodium-motive force (Fig. 2). Most “Ca. Halomarinus” genomes contained proteorhodopsin (18/25) and retinal biosynthesis (19/25), with one notable exception being LSUCC0096. The proteorhodopsin gene in HIMB30 is located in an indel region with neighboring sections syntenic to the second largest contig in the LSUCC0096 genome (see progressiveMauve alignment in the supplemental material). Therefore, it appears that the gene is truly absent from LSUCC0096 rather than missing as a result of the genome being incomplete.

**Carbon.** Both subclades had predicted genes for the Entner-Doudoroff pathway, the TCA cycle, gluconeogenesis, most of the genes of the pentose-phosphate pathway, and fructokinase (scrK) for fructose utilization (Fig. 2; Table S1). Six subclade I genomes, including HIMB30 and LSUCC0096, had an annotated mannose-6-phosphate isomerase for mannose utilization. No genome had an annotated phosphofructokinase gene for glycolysis through the Embden-Meyerhof-Parnas pathway. The coxMSL aerobic carbon monoxide dehydrogenase genes originally reported in HIMB30 (22) were conserved among most genomes (e.g., coxL in 16/25) in “Ca. Halomarinus,” except LSUCC0096 (Table S1). Similar to proteorhodopsin, this deletion in LSUCC0096 occurred with flanking regions of conservation to the HIMB30 genome and were not near any contig boundaries, making it likely that this is a true gene deletion in the LSUCC0096 genome. Subclade I, but not subclade II, had predicted genes for the glyoxylate bypass. Eighteen genomes also contained a predicted beta-N-acetylhexosaminidase (Fig. 2), a glycoside hydrolase of the CAZyme GH-20 family that may confer chitin-degradation capabilities on “Ca. Halomarinus” bacteria (33, 34).

Ten of the “Ca. Halomarinus” genomes in subclade I had a ribulose 1,5-bisphosphate carboxylase/oxygenase (RuBisCO) gene and the associated Calvin-Benson-Bassham pathway for carbon fixation (Fig. 2), making these organisms predicted facultative autotrophs. Phylogenetic analysis of the large RuBisCO subunit demonstrated
FIG 2 Metabolic reconstruction of the OM252 clade. Heatmap displays gene and pathway content according to the scale on the right. Subgroups of processes and key metabolic pathways are highlighted for ease of viewing. Subclades and species designations follow that in Fig. 1.
that all were type I RuBisCO genes; however, the LSUC0096 large subunit grouped away from that of HIMB30 and the other “Ca. Halomarinus” genomes for which a sequence was recovered (see Fig. S8 in the supplemental material). The LSUC0096 RuBisCO genes were located directly upstream of likely cbbQ and cbbO activase genes (35), whereas the HIMB30 RuBisCO genes were located upstream from a suite of alpha-carboxysome genes (csoS2, csoSCA, ccml, ccmK). Although we found carboxysome genes in other “Ca. Halomarinus” genomes (Fig. 2), none were annotated in the LSUC0096 genome. Conversely, the LSUC0096 cbbQ and cbbO genes had no matching orthologs in any of the other “Ca. Halomarinus” genomes. Thus, the LSUC0096 RuBisCO is in a unique gene neighborhood and likely had a separate evolutionary history from the other “Ca. Halomarinus” RuBisCO genes.

Multiple pathways for phosphoglycolate salvage have recently been investigated in the model chemolithoautotrophic organism Cupriavidus nectator H16 (36). We found annotated genes supporting the presence of the C7 cycle (glyA, hprA, and associated aminotransferases) and the malate cycle (aceB, maeB, pyruvate dehydrogenase aceEF) in “Ca. Halomarinus” genomes, but genes for the oxalyl-coenzyme A (oxalyl-CoA) decarboxylation route, as well as the gcl gene for the glyceraldehyde pathway, appeared to be missing.

N, P, and S. “Ca. Halomarinus” uses the P7 nitrogen response system, and 24 of 25 genomes had the amtB ammonia transporter (14 genomes had two copies), with ten genomes containing complete urea transporter genes (urtABCDE) and others with partial transporters (Fig. 2; Table S1). Urease alpha, beta, and gamma subunit genes were conserved in HIMB30 and LSUC0096 and five other genomes across both subclades (Fig. 2; Table S1), with partial urease genes found in more genomes. We found no genes for nitrogen fixation or any step of denitrification (Fig. S7). Complete or partial phosphate transporter genes (pstaABC) were conserved across 17 genomes, and 10 in both subclades were predicted to transport phosphonate (phnCDE) as well (Fig. 2). However, the phn C-P lyase genes were present exclusively in a subset of seven subclade I genomes. Both subclades had a predicted sqr gene for sulfide oxidation (but no others), and the sulfite dehydrogenase had variable distribution across the subclades as well (Fig. 2; Fig. S7). We also found sox genes (soxABCDXYZ) for thiosulfate oxidation in both subclades, with the exception of the species cluster “Ca. Halomarinus littoralis” in subclade I (Fig. 2), and all genomes contained at least one copy of a sulfite exporter (tauE) (Table S1). Thus, subclades I and II were predicted to carry out sulfide- and thiosulfate-based chemolithotrophy. Dimethylsulfiniopropionate (DMSP) demethylation and synthesis genes were missing from all genomes, although three genomes had predicted DMSP lyases (Fig. 2). We found no genes for sulfate reduction (Fig. S7).

Other features. The majority of “Ca. Halomarinus” genomes contained biosynthesis pathways for the bulk of essential amino acids, but none of the genomes contained genes for phenylalanine biosynthesis (Fig. 2). Thus, it appears that this auxotrophy is conserved across the clade. Branched-chain and polar amino acid ABC transporters were present in the majority of genomes, as was a glycine betaine/proline ABC transporter (Table S1). B vitamin biosynthesis was limited. Thiamine (B1) and riboflavin (B2) biosynthesis pathways were partially complete in genomes from both subclades (Fig. 2). Most genomes had predicted ribBAHE genes for riboflavin synthesis from ribulose-5P. Fourteen genomes contained the thiXYZ transporter for hydroxymethylpyrimidine (HMP), and 24 and 23 contained thiD and thiE, respectively (Fig. 2; Table S1). Thus, “Ca. Halomarinus” may synthesize thiamine from imported HMP. “Ca. Halomarinus” genomes appeared auxotrophic for biotin (B7), but possessed the biotin transporter (tauE) from the other “Ca. Halomarinus” genomes. Thus, the LSUCC0096 RuBisCO is in a unique gene neighborhood and likely had a separate evolutionary history from the other “Ca. Halomarinus” RuBisCO genes.
LSUC0096, contained all of the genes for molybdate (modABC, 4/25) and iron complex transport (fhuDBC, 2/25), although all but three genomes had a predicted fhuC (Fig. 2; Table S1). None of the genomes with ureases contained annotated nik transporters for nickel, despite it being the required cofactor for urease. Thus, nickel may be obtained by promiscuous activity from one of the other ABC transporters in the genome, or they may be misannotated (37).

Eighteen genomes from both subclades had genes for flagellar biosynthesis, and so we predict “Ca. Halomarinus” cells to be motile (Fig. 2). Consistent with a sodium-effective force in OM252 cells, many of the genomes contained sodium symporters for phosphate (8/25), acetate (15/25), and melibiose (25/25), as well as sodium antiporters for calcium (yarB, 23/25) and protons (nhaA, 15/25) (Fig. 2; Table S1). The latter may provide a useful means for converting the proton motive force generated by proteorhodopsin to a sodium motive force in some strains. There was also a proton-chloride antiporter (clcA) conserved in 23 genomes. We found peroxiredoxin in 21 genomes and catalase (katG) in six genomes spanning both subclades as well (Fig. 2; Table S1). Finally, almost all genomes had phbBC genes to synthesize (and degrade) poly-$\beta$-hydroxybutyrate (PHB), and two associated phasin genes were found in many genomes as well.

**Morphology and growth characteristics of LSUC0096.** Cells of LSUC0096 were curved-rod/spirillum shaped and approximately 1.5 µm long and 0.2 to 0.3 µm wide (Fig. 3; see additional supplemental figures). We also found evidence of a flagellum (Fig. 3; see additional supplemental figures), corroborating genomic predictions (above). Coastal Louisiana experiences dramatic shifts in salinity owing to a large number of estuaries in the region and tidal forcing through barrier islands, marshes, and different delta formations (38). Our previous 16S rRNA gene data suggested that OM252, and specifically the ASV5512 that matched LSUC0096, had a euryhaline
lifestyle, being found across a range of salinities but having greater prevalence in salinities above 12 (12). Therefore, we examined the salinity tolerance of LSUCC0096 through two complimentary methods as follows: first, by altering only the concentration of NaCl in the medium, and, second, by changing all major ion concentrations proportionally (Fig. 4A). LSUCC0096 grew in salinities between 5.79 and 63.5, with a maximum growth rate of 0.23 (±0.01) doublings/h at 11.6 under the proportional scheme. We detected no growth at salinities of 0.36 or 1.45 (see Fig. S9A in the supplemental material). Although there was an overlap of salinities from 8.66 to 34.8 between the two experiments, the growth rates were higher when the ion concentrations were altered proportionally compared to when only the concentration of NaCl was altered (Fig. 4A). LSUCC0096 also grew between 12°C and 35°C in the isolation medium JW1 with a maximum growth rate of 0.36 (±0.06) doublings/h at 35°C and a “typical” growth rate of 0.19 (±0.03) at 25°C (Fig. 4B). We did not detect growth at 4°C or 40°C (Fig. S9B).

**Thiosulfate-dependent chemolithoautotrophic growth.** We tested the ability of LSUCC0096 to grow under chemolithoautotrophic conditions with thiosulfate as the sole electron donor. We measured growth of LSUCC0096 across four consecutive transfers in modified JW1 medium with no added organic carbon (other than trace quantities of vitamins) and 100 μM thiosulfate. Inorganic carbon was present as bicarbonate (10 mM), used as the medium buffer (10). Growth curves from the fourth growth cycle are presented in Fig. 5. When grown under strict chemolithoautotrophic conditions, LSUCC0096 increased in cell density more than 2 orders of magnitude in a typical logarithmic growth pattern, albeit more slowly and to a lower cell density than when...
grown in chemoorganoheterotrophic conditions (Fig. 5). The positive controls from the fourth transfer had an average growth rate of \(0.20 \pm 0.01\) doublings/h, which is similar to growth rates found under normal growth conditions (Fig. 4), whereas the experimental replicates had a much slower average growth rate of \(0.07 \pm 0.01\) doublings/h (Fig. S9C). Growth yields under chemolithoautotrophic conditions were roughly 68% of that under chemoorganoheterotrophic conditions (\(1.26 \times 10^6 \pm 0.85 \times 10^6\) versus \(1.85 \times 10^6 \pm 1.29 \times 10^6\) cells/ml), although the variance overlapped. The overall Gibbs energies, \(\Delta G_r\), of organic carbon and thiosulfate oxidation under the experimental conditions were \(-113.2\) kJ (mol e\(^{-}\))\(^{-1}\) and \(-100.9\) kJ (mol e\(^{-}\))\(^{-1}\), respectively. We observed limited growth in the negative controls, but these were inconsistent and at much lower rates than for the experimental conditions (Fig. S9C). It is possible that storage compounds like PHB were not fully exhausted after four successive transfers, thus supplying the necessary energy and carbon for limited additional growth (39).

Nevertheless, in conjunction with the genomic data, our experimental results provide strong evidence that LSUCC0096 is capable of oxidizing thiosulfate as a facultative chemolithoautotroph.

**DISCUSSION**

We comprehensively examined the distribution, genomic diversity, and taxonomy of OM252 bacterioplankton using 25 genomes from two pure cultures (including our recently isolated strain LSUCC0096), 7 SAGs, and 16 MAGs. These organisms were generally characterized by genomes in the 2.2 Mb range, with \(\sim 49\%\) GC content and coding densities of \(\sim 92\%\), although the two most complete genomes, from isolates HIMB30 and LSUCC0096, had 94 and 95% coding density, respectively. Thus, OM252 genomes are slightly larger and less streamlined than SAR11 genomes but smaller than most Roseobacter spp. (40–42).

Images of strain LSUCC0096 indicate that these cells are curved-rod/spirillum shaped (Fig. 3; see additional supplemental figures) and somewhat larger than typical SAR11 cells (43). LSUCC0096 cells were also narrower and longer than Litoricola marina and Litoricola lipolytica, which were described as short rods with no mention of curvature (26, 30).
remains to be seen if LSUCC0096 morphology is conserved throughout the OM252 clade. 
*L. marina* and *L. lipolytica* were also reported to be nonmotile (26, 30), whereas OM252 genomes contain flagellar genes, and we found evidence of a polar flagellum in LSUCC0096 (Fig. 3, inset; see additional supplemental figures).

Phylogenetics with 16S rRNA genes and concatenated single-copy marker genes, as well as ANI comparisons, corroborated the sister relationship of OM252 with the genus *Litoricola* and defined two major subclades and several species boundaries within OM252. Currently, HIMB30 and several MAGs used in this study are classified as a *Litoricola* species in the Genome Taxonomy Database (GTDB). However, based on the depth of branching between *Litoricola* and OM252 within our trees, the ANI values among OM252 genomes, the pairwise 16S rRNA gene identities within the group and between OM252 and *Litoricola* (29), and the substantial difference in GC content between OM252 and *Litoricola* (47 to 51% versus 58 to 60% (26, 30), respectively), we argue here for distinguishing OM252 as a separate genus, which we propose as *Candidatus Halomarinus* gen. nov. Our whole-genome phylogeny is consistent with the current placement of *Ca. Halomarinus* within the *Litoricolaceae* and for the *Litoricolaceae* within the *Pseudomonadales*, as currently defined in GTDB (https://gtdb.ecogenomic.org/; accessed February 2021). Poor branch support at the internal nodes grouping *Litoricolaceae* with SAR86, and that group within the remainder of the *Pseudomonadales*, precludes us from commenting on the likely position of *Litoricolaceae* in that order (Fig. 1; see also Fig. S3 in the supplemental material).

“Ca. Halomarinus” bacteria are globally distributed in marine surface waters, and some strains can be found in benthic and abyssopelagic depths. The “Ca. Halomarinus littoralis” species cluster was more abundant in coastal waters (see Fig. S6 in the supplemental material) but recruited poorly from open ocean samples (see Fig. S4 in the supplemental material). Thus, certain species may have more restricted biogeography than others. Increases in taxon selection and additional coastal and estuarine metagenomic sampling will improve these types of assessments. We demonstrated that strain LSUCC0096 can grow over a wide range of salinities (5.77 to 63.6), although it appears to be adapted for brackish conditions with an optimal growth salinity of 11.6 (Fig. 4A). Our coastal 16S rRNA gene data previously demonstrated that the ASV matching LSUCC0096 had maximum abundances in salinities between 12 and 21 (12), and our growth data showed that it was incapable of growth in fresh water (see Fig. S9 in the supplemental material). Nevertheless, this organism also recruited marine metagenomic reads from all over the globe (see additional supplemental figures) and displayed considerable halotolerance. Although we measured growth at up to 5% NaCl (calculated salinity, 63.5), we did not actually find the maximum salinity beyond which the cells could not grow (Fig. 4A). The extensive salinity tolerance of strain LSUCC0096 corroborates culture-independent detection of the OM252 clade in very salty environments like the Salton Sea (18) and Spanish salterns (19), as well as their cosmopolitan distribution in the global oceans (see additional supplemental figures). Future work on additional “Ca. Halomarinus” isolates will expand our understanding of the halotolerance and optimal salinities for the various other species in the group. Thermal tolerances were more pedestrian, with LSUCC0096 exhibiting a mesophilic temperature growth range.

Comparative genomics predicted that “Ca. Halomarinus spp.” are obligate aerobes with the capacity for both chemoorganoheterotrophic and sulfur-oxidizing chemolithotrophic metabolism. In support of these predictions, both existing isolates, strains HIMB30 and LSUCC0096, were isolated under aerobic, chemoorganoheterotrophic growth conditions (10, 22). We predict that “Ca. Halomarinus spp.” can utilize TCA cycle intermediates, some sugars, and possibly amino acids as carbon and energy sources, although direct characterization of the suite of compounds that can be used needs further investigation. Given the possibility for using the storage compound PHB, either as both an energy and carbon source or as an energy source in conjunction with RuBisCO-based carbon fixation (39), these future experiments would require a CO₂-free headspace, an alternative buffer to the bicarbonate used in JW1, and probably five or more successive growth cycles to eliminate storage compounds.

“Ca. Halomarinus” appears to subsist on ammonia or urea as nitrogen sources, with phosphate as the primary source of phosphorus, and phosphonates as possible
substitutes for some strains, similarly to SAR11 (40, 44). However, many *Pelagibacterales* lack the PII system (45) that is present in OM252. *Ca. Halomarinus* spp.” can likely synthesize most amino acids except phenylalanine. We predicted that B vitamin synthesis is limited to riboflavin and thiamine via *thiDE* after import of HMP. Thiamine biosynthesis after HMP import is also similar to the *Pelagibacterales* (46), with the major difference being the presence of the *thiXYZ* HMP transporter in OM252. We also predict “*Ca. Halomarinus* spp.” utilize ferric iron and may additionally interact with copper, tungstate, zinc, and chromate. Thus, they have a similarly restricted set of metal transporters as SAR11 and far fewer than many *Roseobacter* spp. (47).

Most “*Ca. Halomarinus*” genomes had predicted genes for oxidation of reduced sulfur compounds, and subclade I organisms additionally had genes for autotrophy via the CBB cycle and RuBisCO. Corroborating these predictions, we demonstrated that the subclade I representative LSUCC0096 could grow for successive transfers under strict chemolithoautotrophic conditions with thiosulfate as the sole electron donor and bicarbonate as the sole available carbon source (excepting vitamins). The ability to switch between autotrophic and heterotrophic metabolism also has biogeochemical relevance because it means that these organisms can switch between serving as inorganic carbon sources and sinks. This behavior has implications for modeling marine carbon cycling since these organisms cannot be simply classified as heterotrophic. The pervasiveness of facultative lithoautotrophy among putative “heterotrophic” lineages deserves further investigation.

The relevance of facultative lithoautotrophy to both the carbon and sulfur cycles also places emphasis on understanding what may control these different lifestyles in nature. The experimental data from strain LSUCC0096 (growth rates and lag times after repeated transfers) suggest that heterotrophic growth will always be favored to lithoautotrophic growth in “*Ca. Halomarinus*” subclade I strains, and calculations indicate that this probably arises due to the energetics of anabolism rather than catabolism. The energy available from organic carbon oxidation was only about 12% greater than thiosulfate oxidation, yet the growth rate was nearly three times greater in the heterotrophic experiment. This divergence could be explained by the much larger difference in the energetics of biomolecule synthesis when the starting materials are inorganic compounds, such as CO\textsubscript{2} and NH\textsubscript{4}\textsuperscript{+}, versus a suite of organic compounds. The energetics of protein synthesis provide an illustrative example since bacterial cells are approximately 50% protein (48). If an environment is replete with amino acids, then microorganisms need only to obtain and polymerize them to build proteins. The Gibbs energy of peptide bond formation is \(\sim 40 \text{ kJ per mol}^{-1}\) (49). However, if the organisms must first synthesize amino acids *de novo* before polymerization, the cost is much greater. For instance, the \(\Delta G\) of alanine synthesis from CO\textsubscript{2} and NH\textsubscript{4}\textsuperscript{+} in an oxidizing environment is 1,380 kJ per mol\textsuperscript{-1}, and for more complex amino acids such as tryptophan, it is 5,320 kJ per mol\textsuperscript{-1} (50). Therefore, the LSUCC0096 cells in the thiosulfate experiment had to dedicate a larger flux of their catabolic energy to biomolecule synthesis than the heterotrophs who were essentially given all of the starting materials. These conclusions suggest that thiosulfate-based chemolithoautotrophy is utilized in nature when organic compound concentrations become limiting. However, more research is required to understand whether there is a complete metabolic switch to autotrophy (as opposed to some form of mixotrophy), and if so, whether it is strictly controlled by the relative availability of growth substrates or if some additional regulation is involved.

Another intriguing mystery is the source and temporal availability of thiosulfate and other reduced sulfur compounds in natural marine systems. Abiotic oxidation of sulfide results in the generation of stable thiosulfate in seawater, an effect that was enhanced by the presence of trace metals like Fe, Pb, and Cu (51). Thus, any source of sulfide could theoretically lead to production of thiosulfate if the sulfide is not first consumed by other microbes. Alternatively, thiosulfate may occur as a transient intermediate as a direct result of microbial metabolism, a process labeled the “thiosulfate shunt” in sedimentary systems (52). If it could escape into the oxic water column from systems with low or no oxygen, organisms like “*Ca. Halomarinus*” may be able to harvest...
energy from thiosulfate originating from cryptic sulfur cycling processes near oxygen minimum zones (OMZs) and sinking particles (53–55) or possibly also shallow sediments, where thiosulfate can persist in micromolar concentrations (56, 57). Researchers have been isolating thiosulfate-utilizing bacteria from seawater for over a century (58), and it has long been known that thiosulfate oxidizers occupy the marine water column and can connect this metabolism to carbon fixation activity (59–61). More recently, we have also learned that sox genes are common in the oxic marine water column (53, 62, 63). Indeed, many marine prokaryotes contain these genes, and thiosulfate oxidation can be used to stimulate growth under mixotrophic conditions and even anapleurotic carbon fixation (see, for example, references 64–67). Thus, a variety of microorganisms from oxic marine waters are poised for thiosulfate-based chemolithotrophy and sometimes autotrophy. The circumstances and controls on reduced inorganic sulfur compound use by obligate aerobes like “Ca. Halomarinus” in the oxic water column requires further study.

**Description of “Ca. Halomarinus” gen. nov.** “Ca. Halomarinus” (Ha.lo.ma.ri.nus G. masc. n. halo, salt, sea; L. masc. adj. marinus, of the sea; N.L. masc. n. Halomarinus salty, seagoing, in reference to the marine habitat and high salinity tolerance of the organisms).

Aerobic, chemoorganoheterotrophic, and chemolithotrophic, with sodium-translocating NADH dehydrogenases, capable of glycolysis, gluconeogenesis, and possessing a complete TCA cycle. Has genes for motility via flagella. Possesses the P$_r$-dependent nitrogen response system and genes for ammonia, phosphate, ferric iron, tungstate, copper, zinc, chromat transport. Has genes for synthesizing histidine, arginine, lysine, serine, threonine, glutamine, cysteine glycine, proline, methionine, leucine, tryptophan, tyrosine aspartate, glutamate, but is a phenylalanine auxotroph. Genes for synthesis of riboflavin (vitamin B$_2$) and thiamine (vitamin B$_1$) from HMP. Auxotrophic for vitamins B$_1$, B$_2$, B$_3$, B$_5$, B$_6$, and B$_12$. Has genes for poly-$\beta$-hydroxybutyrate production and degradation and peroxiredoxin. Estimated complete genome sizes between 1.49 and 2.68 Mbp, GC content between 47 and 51%, and coding densities between 82 and 96%.

The type species is **Candidatus Halomarinus kaneohensis**.

**Description of “Candidatus Halomarinus kaneohensis” sp. nov.** “Candidatus Halomarinus kaneohensis” (ka.ne.o.hen.sis N.L. n. Kāne‘ohe, a bay on the island of Oahu, HI, USA, from which the strain was isolated).

In addition to the characteristics for the genus, it has the following features. Has proteorhodopsin and retinal biosynthesis genes. Has a predicted cbb$_3$-type cytochrome c oxidase, genes for the glyoxylate shunt, urease, and the coxMSL aerobic carbon monoxide dehydrogenase genes. Is predicted to be capable of thiosulfate and sulfide oxidation as well as autotrophy via the Calvin-Benson-Bassham cycle.

The type strain, HIMB30, was isolated from seawater collected in Kāne‘ohe Bay, Oahu, HI, USA (21.460467, –157.787657) (22). The genome sequence for HIMB30 is available under NCBI BioProject accession number PRJNA47035. Estimated complete genome size of 2.26 Mbp, GC content of 50% from genome sequencing. The culture is maintained in cryostocks at the University of Hawai‘i at Mānoa by M. S. Rappé. We provide the *Candidatus* designation since the culture has not been deposited in two international culture collections and, therefore, does not satisfy the naming conventions of the International Code of Nomenclature for Prokaryotes (ICNP) (68). However, the characterization here is more than sufficient for naming recognition via genomic type material (69, 70).

**Description of “Candidatus Halomarinus pommixedorensis” sp. nov.** “Candidatus Halomarinus pommixedorensis” (pomme.d.or.en.sis N.L. n. Pomme d’Or, a bay in southern Louisiana, USA, from which the strain was isolated).

In addition to the characteristics for the genus, it has the following features. Cells are curved-rod/spirillum shaped, ~1.5 μm by 0.2 to 0.3 μm. Halotolerant, being capable of growth in salinities between 5.8 and at least 63.4 but not at 1.5 or below. Mesophilic, being capable of growth at temperatures between 12 and 35°C but not at 4 or 40°C. Has a maximum growth rate at 35°C in the isolation medium JW1 of 0.36 (±0.06) doublings/h. Has a predicted cbb$_3$-type cytochrome c oxidase and genes for the glyoxylate shunt, urease, and cobalamin transport. Has predicted genes for thiosulfate and sulfide oxidation as well as...
autotrophy via the Calvin-Benson-Bassham cycle. Grows under thiosulfate-oxidizing chemolithoautotrophic conditions at 0.07 (±0.01) doublings/h.

The type strain, LSUCC0096, was isolated from seawater collected at Bay Pomme d’Or, Buras, LA, USA (29.348784, −89.538171) (10). The GenBank accession number for the 16S rRNA gene of LSUCC0096\(^{1}\) is KU382366.1. The genome sequence is available under BioProject accession number PRJNA551315. The culture is maintained in cryostocks at the University of Southern California by J. C. Thrash. Estimated complete genome size of 2.01 Mbp and GC content of 49% from genome sequencing. We provide the Candidatus designation since the culture has not been deposited in two international culture collections and, therefore, does not satisfy the naming conventions of the ICNP (68). However, the characterization here is more than sufficient for naming recognition via genomic type material (69, 70).

**Description of “Candidatus Halomarinus littoralis” sp. nov. “Candidatus Halomarinus littoralis” (lit.to.r.a.lis L. adj), based on its relative abundance in coastal/nearshore waters.**

In addition to the characteristics for the genus, it has the following features. Has proteorhodopsin and retinal biosynthesis genes. Has an additional cbb\(_3\)-type cytochrome \(c\) oxidase. Is predicted to be capable of sulfide oxidation as well as autotrophy via the Calvin-Benson-Bassham cycle but not thiosulfate oxidation. Has predicted genes for the glyoxylate shunt and, therefore, does not satisfy the naming conventions of the ICNP (68, 69, 70). Additionally, it has the ability to utilize organic compounds as electron donors.

**MATERIALS AND METHODS**

**LSUCC0096 isolation, genome sequencing, and genome assembly.** Strain LSUCC0096 was isolated and initially identified via 16S rRNA gene PCR as previously reported (10) from surface water collected in Bay Pomme d’Or near the Mississippi River Birdfoot delta on 12 January 2015 (Buras, LA) (29.348784, −89.538171). DNA was extracted from cultures of LSUCC0096 that had reached max cell density (about 10\(^{8}\) cells ml\(^{-1}\)) growing in JW1 medium (10) at room temperature using a MoBio PowerWater DNA isolation kit (Qiagen, MA, USA) following the manufacturer’s protocols. TruSeq DNA-seq Library preparation and Illumina MiSeq (paired-end 250-bp reads) sequencing was completed at the Argonne National Laboratory Environmental Sample Preparation and Sequencing Facility, producing 242,062 reads (see Table S1 in the supplemental material). The genome was assembled using the A5 MiSeq pipeline (version 20150522) (71) with default settings. The LSUCC0096 genome was annotated at IMG (72) (Taxon ID 2639762503). For comparative genomics, we re-annotated the genome along with other analyzed genomes using Anvi’o (see below), and the scaffolds were also deposited in GenBank (see Data availability section).

**16S rRNA gene phylogenies.** The 16S rRNA gene of the LSUCC0096 genome was searched against both the NCB nucleotide and refseq_rna databases (accessed August 2018) using megablast v. 2.2.28+ with max_target_seqs 1,000 and -num_threads 16. A selection of best hits was generated from each blast search and combined with the LSUCC0096 and HIMB30 16S rRNA genes from IMG, along with those from five different Litoricola spp. and the original OM252 clone library sequence (GenBank accession number U70703.1) (8). Additional 16S rRNA genes from the OM252 MAGs and SAGs were obtained from the Anvi’o genome database (see above) using the command anvi-get-sequences-for-hmm-hits –external-genomes external-genomes.txt -o 16S.fastq -hmm-source Ribosomal_rRNAs --gene Bacterial_16S_rRNA (or --gene Archaeal_16S_rRNA). The 16S rRNA gene of TOBG-NAT-109 had the best blast (megablast online, default settings) hits to Bacteroides sequences and was removed from further 16S rRNA gene analyses. The remaining sequences were aligned with MUSCLE v3.6 (73), culled with trimal v1.4.rev22 (74) using the -automated1 flag, and the final alignment was inferred with IQ-TREE v1.6.11 (75) with default settings and -bb 1000 for ultrafast bootstrapping (76). Tips were edited with the nw_rename script within Newick Utilities v1.6.7 (77), and trees were visualized with Archaeopteryx (78). FASTA files for these trees and the naming keys are provided at https://doi.org/10.6084/m9.ﬁshare.14036573.

**Additional taxon selection.** The HIMB30 genome (22) was downloaded from IMG (Taxon ID 2504557021). To provide a more comprehensive analysis of the OM252 clade beyond the LSUCC0096 and HIMB30 genomes, we searched for metagenome-assembled genomes (MAGs) that matched LSUCC0096 and HIMB30 using the following methods. We downloaded MAGs reconstructed from the Tara Oceans data set (79, 80) and the northern Gulf of Mexico (31, 81). We identified all MAGs with an average nucleotide identity (ANI) of ≥76% to LSUCC0096 and HIMB30 using FastANI v1.3 (28) with default settings. These MAGs and the LSUCC0096 and HIMB30 genomes were then placed into the Genome Taxonomy Database (GTDb) tree (which also included additional MAGs constructed from the Tara Oceans data set (82)) with GTDBtk v0.1.6 (24, 112) and database release 86 (downloaded February 2019) using “classify_wf.” All genomes occurred in a monophyletic group including f.Litoricolaecae. The additional genomes from GTDB in this clade were downloaded. We then searched six representative genomes (LSUCC0096, HIMB30, GCA_002480175.1, GCA_002691485.1, UBA1114, UBA12265) against the
gamma proteobacteria single-amplified genomes (SAGs) generated from the GOR-Tropics collection (83) using FastANI as above. Finally, all genomes from this collection were compared to each other with FastANI again. Then we calculated the percent completion and contamination using CheckM v1.0.13 (27) using “linear_on.” We designated genomes as redundant if they had an ANI value of ≥99% with another genome. If a genome had a redundant match, we kept the genome with the highest percentage of completion and lowest percentage of contamination. Genomes with less than 50% estimated completion were discarded. The final genome selection statistics are in Table S1 and are available at https://doi.org/10.6084/m9.5.fgshare.14067362.

**Phylogenomics.** Based on the 16S rRNA gene phylogeny, we selected 208 genomes for a concatenated phylogenomic tree that spanned a variety of clades within the Gamma proteobacteria with members near OM252, plus 6 outgroup taxa from the Alphaproteobacteria and Betaproteobacteria. These, together with 26 putative OM252 genomes (total 240), were analyzed using the Anvi’o phylogenomics pipeline through profile hidden Markov model (HMM) assignment. Single-copy marker genes that had membership in at least half the taxa in the tree (120) were selected using “ani-get-sequences-for-hmm-hits –external-genomes external-genomes.txt –o temp.faa –hmm-source Rinke_et_al –return-best-hit –get-aa-sequences –min-num-bins-gene-occurs 120,” which returned a fasta file for each of the resulting 78 gene clusters. Each of these were aligned with MUSCLE v3.6 (73), culled with trimAl v1.4.rev22 (74) using the –automated1 flag, and concatenated with the geneStitcher.py script from the Utensils package (https://github.com/ballesterus/Utensils) as described (84). The final alignment had 29,631 amino acid positions, and the tree was inferred with IQ-TREE v1.6.11 (75) with default settings and -bb 1000 for ultrafast bootstrapping (76). Tree tips were edited with the nw_rename script within Newick Utilities v1.6 (77), and trees were visualized with Archaeopteryx (78) and FigTree v1.4.3 and edited with Adobe Illustrator. The concatenated alignment and naming key is provided at https://doi.org/10.6084/m9.fgshare.14036594.

**Pangenomics.** Upon inspection of the phylogenomic tree, one putative genome, GCA_002408105.1, branched outside of the OM252 group (Fig. 1). We therefore excluded it from pangenomic analyses. The final 25 OM252 genomes were processed via Anvi’o v5.3 (85) using the pangenomics workflow (86). This approach ensured that all genomes were subject to the same gene-calling and annotation workflow. Single-copy marker genes were assigned by Anvi’o-provided HMMs and NCBI Clusters of Orthologous Groups of proteins (COGs) were assigned, and Anvi’o-based gene calls were used for additional external annotation via InterProScan v5.33-72.0 (87) and KEGG assignments with GhostKOALA (88). All annotations are provided in Table S1 (https://doi.org/10.6084/m9.fgshare.14067362) as part of the pangenome summary generated via Anvi’o: “ani-summarize -p OM252/OM252panp-PAN.db -g OM252-GENOMES.db -C DEFAULT -o pan-PAN.db -t protein_only” (88). A phylogenomic pipeline was completed using the KEGG annotations from GhostKOALA and a custom set of HMMs deployed with the KEGG-decoder, KEGG-expander, and Order_Decode_and_Expand scripts used previously (89) from GhostKOALA and a custom set of HMMs deployed with the KEGG-decoder, KEGG-expander, and Order_Decode_and_Expand scripts used previously (89). HMM searches for this workflow were completed using HMMER3.1b1 (90). Gene function enrichments based on annotations and pangenome distribution were also calculated with Anvi’o. Using the phylogenomic clade structure (see below) that was also supported by ANI values, the subclades were imported into the Anvi’o database as layers using anvi-import-misc-data. Functional enrichments were then quantified for all of the various annotation sources via the following command: “for i in COG_CATEGORY Hamap ProSiteProfiles KeggGhostKoala SMART Gene3D TIGRfam COG_FUNCTION SPLD PANTHER Coils CDD Pfam MobiDBLite ProSitePatterns PiRsf Prints SUPERFAMILY ProDom; do anvi-get-enriched-functions-per-pan-group -p OM252/OM252panp-PAN.db -g OM252-GENOMES.db -category subclade –annotation-source $i -o $i.enriched-subclade; done.” $2.v4.0 (91) was used to align the HMB380 and LSUC-G006 genomes using default settings and GenBank files supplied from IMG. The OM252 Anvi’o pangenomic summary, including all annotations, is available in Table S1 (https://doi.org/10.6084/m9.fgshare.14067362). The enriched function files are available at https://doi.org/10.6084/m9.fgshare.14036579, and the progressiveMauve alignments are available at https://doi.org/10.6084/m9.fgshare.14036588.

**Metagenomic read recruitment and analyses.** Competitive recruitment of the metagenomic reads from Tara Oceans (2), BioGEOTRACES (92), and the Malapnsa Global Expedition (93), the Southern California Bight near Los Angeles (32), and the northern Gulf of Mexico hypoxic zone (31) to the OM252 genomes was completed using the protocol available at http://merenlab.org/data/tara-oceans-mags/. Reads were cleaned using illumina utils v2.6 (94) implementing the method described in reference 95. Mapping used Bowtie 2 v2.3.2 (96), processing with SAMtools v0.1.19-44428cd (97), and read filtering with BsamM v1.7.3 (http://ecogenomics.github.io/BsamM/) to include only recruited hits with an identity of at least 95% and alignment length of at least 75%. The count table for each sample was generated using the get_count_table.py script (https://github.com/edamame-course/Metagenome). Reads per kilobase per million (RPKM) calculations were performed using RPKM heater (https://github.com/thrash-lab/tpkm heaters) and log$_{10}$-transformed to improve visualization of recruitment across wide variations in abundance. RPKM calculations are available in Table S1 (https://doi.org/10.6084/m9.fgshare.14067362). Visualization of the data for individual genome recruitment was completed in R (https://github.com/thrash-lab/metaG_plots). OM252 community diversity was assessed using the skbio.diversity algorithmic suite v0.5.6 (https://scikit-bio.org/docs/latest/diversity.html). Recruited OM252 reads from 588 metagenomic samples including TARA (2), BioGEOTRACES (92), and Malapnsa Global Expedition (93) were normalized to transcripts per million (TPM) values and used analogously for count dissimilarities. TPM calculations were performed using (https://github.com/thrash-lab/diversity_metrics). Sampling metadata for latitude, ocean region,
depth, salinity, and temperature were collected to qualitatively assess the dissimilarity matrix in relation to designated intervals. Analysis of similarity (ANOSIM) correlation statistics were calculated for each metadata analysis treating absolute similarity of each OM252 community between samples as the null hypothesis to the alternative where community recruitment varies strongly with environmental metadata, such that ANOSIM = 0 \nabla absolute similarity \nabla ubiquitous and even distribution across samples and ANOSIM = 1 \nabla absolute similarity \nabla highly varied distribution strongly related to an environmental factor (e.g., temperature). Three-dimensional ordination plots were constructed to visualize the principal coordinate analysis (PCoA) along the three foremost axes. The PCoA plots for latitude, ocean region, depth, salinity, and temperature are available in Fig. S5 in the supplemental material.

**RubisCo phylogeny.** The predicted large subunit for both the LSUCC0096 and HIMB30 RubisCo genes were searched against NCBI nucleotide via the web (March 2019). The top 100 hits from each were screened for redundant sequences and combined with the 8 additional near-full-length homologs in the OM252 group identified via Anvi’o (anvi-get-sequences-for-gene-clusters -p OM252/OM252pang-PAN.db -g OM252-GENOMES.db -gene-cluster-id GC_00001582 -o GC_00001582.faa) and a set of RubisCo reference type genes (98). Genes were aligned with MUSCLE v3.6 (73), culled with trimAl v1.4.rev22 (74) using the -automated1 flag, and the final alignment was inferred with IQ-TREE v1.6.11 (75) with default settings and -bb 1000 for ultrafast bootstrapping (76). The final tree was visualized with Archaeopteryx (78). The fasta file, script, and tree file are provided at https://doi.org/10.6084/m9.figshare.14036597.

**Growth experiments.** Cell concentrations for all physiological experiments were measured via a Guava easyCyte 5HT flow cytometer (Millipore, MA, USA) as previously reported (10, 99), and cells were grown in acid-washed polycarbonate flasks. The growth temperature range was tested in the isolation medium, JW1 (10), in triplicate at 4°C, 12°C, 25°C, 30°C, 35°C, and 40°C using a refrigerator, Isotemp cooling incubator (Fisher), and benchtop heating incubators (Fisher) (all nonshaking). Salinity tolerance was tested using two different methods. First, we only altered the concentration of NaCl in the JW1 medium from 0 to 5%, producing a range of salinities from 8.66 to 63.5 (calculated from chlorinity according to $\text{S} = 1.80655 \times \% \text{CI} = 100$). In the second method, we altered the concentration of all major ions proportionally, producing a salinity range of 0.36 to 34.8 as previously reported (101). In both approaches, all other medium components (carbon, iron, phosphate, nitrogen, vitamins, and trace metals) were unaltered. All salinity growth experiments were conducted in triplicate and at room temperature.

We tested whether LSUCC0096 could grow under chemolithoautotrophic conditions by growing cells in base JW1 medium with 100 μM thiosulfate and all organic carbon sources excluded (aside from that possibly obtained via vitamins) for four consecutive growth cycles to eliminate the possibility of carryover from the seed culture grown in JW1. As a positive control, LSUCC0096 was grown in JW1 medium with the normal suite of carbon compounds (10). For a negative control, LSUCC0096 was grown in JW1 medium with no added organic carbon aside from vitamins. During the fourth and final growth cycle, a second negative control was added where organic carbon and vitamins were both excluded. Cells for each condition were grown in triplicate. Cultures were counted once a day for the first two cycles to ensure transfers could be completed at the end of log phase. For the third and fourth growth cycles, cells were counted every 12 h. The fourth growth cycle is depicted in Fig. 5. Strain purity and identity were verified at the end of experiments using PCR of the 16S rRNA gene as previously reported (10). Growth rates for all experiments were calculated with the sparse-growth-curve script (https://github.com/trash-lab/sparse-growth-curve) (113).

**Electron microscopy.** To preserve cells for microscopy, we fixed 100 ml of mid-exponential LSUCC0096 culture with 3% glutaraldehyde (Sigma Aldrich) and stored it at 4°C overnight. We filtered the cells onto a 25-mm-diameter 0.2-μm pore-sized Isopore polycarbonate membrane filter (Millipore Sigma) via vacuum filtration and performed ethanol dehydration by soaking the filter for 25 min in each of the following ethanol concentrations: 30%, 50%, 70%, 80%, 90%, 95%, and 100%. The filter was then put into a Tousimis 815 critical point dryer and sputter coated for 45 s in a Cressington 108 manual sputter coater. Cells were imaged using the JSM-7001F-LV scanning electron microscope at the University of Southern California Core Center of Excellence in Nano Imaging (http://cemra.usc.edu/) with a working distance of 6.8 mm and 15.0 kV.

**Energetics.** Overall Gibbs energies, ΔG, of thiosulfate and organic carbon oxidation,

\[
S_2O_3^{2-} + 2O_2 + H_2O \rightarrow 2SO_4^{2-} + 2H^+ \tag{1}
\]

and

\[
C_{3.46}H_{25}O_{12}N_0_{4}S_0_{0.0073} + 3.7 O_2 + 0.97 H_2O \rightarrow 2.6 H^+ + 3.46 HCO_3^- + 0.0073 HS^- + 0.84 NH_4^+ \tag{2}
\]

were calculated using

\[
\Delta G_r = \Delta G^0 + RT\ln Q_r \tag{3}
\]

where ΔG^0 and Q_r refer to the standard molal Gibbs energy and the reaction quotient of the indicated reaction, respectively, R represents the gas constant, and T denotes temperature in Kelvin. Values of ΔG^0 were calculated using the revised Helgeson-Kirkham-Flowers (HKF) equations of state (102–104),
the SUPCR92 software package (105), and thermodynamic data taken from a number of sources (106–108). Values of $Q_i$ are calculated using

$$Q_i = \Gamma_i a_i$$

(4)

where $a_i$ stands for the activity of the $i$th species, and $\gamma_i$ corresponds to the stoichiometric coefficient of the $i$th species in the reaction of interest. Because standard states in thermodynamics specify a composition (109, 110), values of $Q_i$ must be calculated to take into account how environmental conditions impact overall Gibbs energies. In this study, we use the classical chemical-thermodynamic standard state in which the activities of pure liquids are taken to be 1 as are those for aqueous species in a hypothetical 1 molal solution referenced to infinite dilution at any temperature or pressure.

Activities are related to concentration, $C_i$, by

$$a_i = \gamma_i \left( \frac{C_i}{C^0_i} \right)$$

(5)

where $\gamma_i$ and $C^0_i$ stand for the individual activity coefficient and concentration of the $i$th species, respectively, and $C^0_i$ refers to the concentration of the $i$th species under standard state conditions, which is taken to be equal to one molal referenced to infinite dilution. Values of $\gamma_i$ were computed using an extended version of the Debye-Hückel equation (111). Concentration of the species shown in equations 1 and 2 are those used in the media ($[O_2]$) = saturation in seawater at 25°C [205 µmol]; $[C_{org}]$ = 66.6 µM; $[HCO_3^-]$ = seawater (2 mmol); $[HS^-]$ = oxic seawater (0.5 mM).

Because it is not clear which organic compounds are being oxidized for energy, we calculated values of $\Delta G$, for this process by representing dissolved organic carbon (DOC) as a weighted average of all of the organic compounds in the medium recipe, shown on the left side of equation 2. This composite formula was used to calculate the standard state Gibbs energy of equation 2, $\Delta G^0$, according to the algorithm given in LaRowe and Van Cappellen (108), which relates the nominal oxidation of carbon, NOSC, in organic energies to their Gibbs energy of oxidation (the average weighted NOSC in the medium is $–0.26$).

**Data availability.** The LSUCC0096 genome is available on NCBI under BioProject number PRJNA551315, and IMG under Taxon ID 2639762503. The raw reads from which LSUCC0096 was assembled are available at the NCBI SRA under accession number SRR9598636. Cryostocks and/or live cultures of strains LSUCC0096 and HIMB30 are available upon request. Additional supplemental information, including files and additional supplemental figures, can be found on FigShare (https://figshare.com/projects/Ecophysiology_of_Co._Halomarinus_/98558).
