Abstract

Corallimorpharia is a small Order of skeleton-less animals that is closely related to the reef-building corals (Scleractinia) and of fundamental interest in the context of understanding the potential impacts of climate change in the future on coral reefs. The relationship between the nominal Orders Corallimorpharia and Scleractinia is controversial—the former is either the closest outgroup to the Scleractinia or alternatively is derived from corals via skeleton loss. This latter scenario, the “naked coral” hypothesis, is strongly supported by analyses based on mitochondrial (mt) protein sequences, whereas the former is equally strongly supported by analyses of mt nucleotide sequences. The “naked coral” hypothesis seeks to link skeleton loss in the putative ancestor of corallimorpharians with a period of elevated oceanic CO2 during the Cretaceous, leading to the idea that these skeleton-less animals may be harbingers for the fate of coral reefs under global climate change. In an attempt to better understand their evolutionary relationships, we examined mt genome organization in a representative range (12 species, representing 3 of the 4 extant families) of corallimorpharians and compared these patterns with other Hexacorallia. The most surprising finding was that mt genome organization in Corallimorphus profundus, a deep-water species that is the most scleractinian-like of all corallimorpharians on the basis of morphology, was much more similar to the common scleractinian pattern than to those of other corallimorpharians. This finding is consistent with the idea that C. profundus represents a key position in the coral <--> corallimorpharian transition.

Key words: naked coral hypothesis, gene order, mitochondrial genome, coral evolution.

Introduction

Understanding the evolutionary history of the Scleractinia and relationships between corals and other members of the anthozoan subclass Hexacorallia should enable a better understanding of how it has been influenced by climate in the past and thus enable better predictions of the likely impacts of climate change (Romano and Palumbi 1996). Of the six Orders of hexacorals, only members of the Scleractinia develop continuous external calcified skeletons (Daly et al. 2003). The Scleractinia suddenly appear in the fossil record in the middle Triassic, about 240 Ma, but the range of morphological variation seen in the Middle Triassic fossils is comparable to that of extant scleractinians (Romano and
Palumbi 1996). Molecular phylogenies based on both mitochondrial (mt) and nuclear (nucl) genes imply a deeper divergence (~300 Ma—in the Late Carboniferous) of extant scleractinians into two major clades, the “Complexa” and the “Robusta” (Romano and Palumbi 1996; Romano and Cairns 2000; Chen et al. 2002; Le Goff-Vitry et al. 2004; Fukami et al. 2008; Barbeitos et al. 2010; Kitahara, Cairns, and Miller 2010; Kitahara, Cairns, Stolarski, et al. 2010; Kitahara, Cairns, et al. 2012; Kitahara et al. 2012; Kayal et al. 2013). By adding deep-water species to existing molecular data sets and applying an appropriately calibrated molecular clock, Stolarski et al. (2011) demonstrated that two exclusively deep-sea families, the Gardineriidae and Micrabaciidae, form a “basal” clade that diverged at around 425 Ma, prior to the Complexa/Robusta split, pushing the evolutionary origin of scleractinians deep into the Paleozoic. These results support the scenario that scleractinians are the descendants of soft-bodied (corallimorpharian-like) ancestors that survived the mass extinction at the Permian/Triassic boundary and subsequently gained the ability to deposit calcified skeletons (Stolarski et al. 2011).

The “naked coral” hypothesis, first put forward by Stanley and Fautin (2001) to explain the sudden appearance of diverse scleractinian fauna in the middle Triassic, is based on the idea that the skeleton has been an ephemeral trait during coral evolution. Under this hypothesis, the Scleractinia were skeleton-less in the early Triassic, a time when carbonate deposition was suppressed globally (Stanley 2003). Consistent with the idea of skeleton ephemerality, some coral species can undergo reversible skeleton loss under acid conditions (Fine and Tchernov 2007). Strong phylogenetic support for the “naked coral” hypothesis came from analyses based on the alignment of concatenated proteins encoded by 17 complete mt genomes from hexacorallians (Medina et al. 2006); in their analysis, scleractinians were paraphyletic, corallimorpharians being more closely related to the Complexa than are Robusta, the interpretation being that the Corallimorpharia arose by skeleton loss from a scleractinian ancestor at a time (during the mid-Cretaceous) of high oceanic CO2 levels (Medina et al. 2006).

Although the “naked coral” scenario is supported by analyses of protein sequence data, phylogenetics based on mt nucleotide sequences instead strongly support scleractinian monophyly (Stolarski et al. 2011; Kayal et al. 2013; Kitahara et al. 2014). The fundamental disagreement between phylogenies based on nucleotide (fig. 1A) or amino acid (fig. 1B) sequence data for mt proteins stems from the fact that none of the available models for sequence evolution adequately account for the observed data (Kitahara et al. 2014). One possible explanation for this is the occurrence of a “catastrophic” event—a major and unpredictable change, such as sudden impairment of mt DNA repair processes (which are believed to be an ancestral trait within Anthozoa (Pont-Kingdon et al. 1998; Shearer et al. 2002; Brockman and McFadden 2012).

Given the intractability of coral/corallimorph relationships using conventional molecular phylogenetics, we explored the informativeness of mt genome architecture in this context. mt gene rearrangements occur relatively infrequently and have proven useful in resolving evolutionary relationships, both shallow and deep, across a broad range of organisms (e.g., Gai et al. 2008; Brockman and McFadden 2012; Kilpert et al. 2012). This study is based on the complete mt genomes of a total of 12 corallimorpharians (8 of which are novel), representing 3 of 4 currently described families (Daly et al. 2007; Fautin et al. 2007), and 32 scleractinians, and includes both the early diverging coral Gardenia hawaiiensis (Stolarski et al. 2011), and corallimorpharian, Corallimorphus profundus, which is considered to be the most coral-like of corallimorphians based on morphological grounds (Moseley 1877; den Hartog 1980; Riemann-Zünneck and Iken 2003). The results indicate that, by contrast with the Scleractinia, extensive rearrangements of the mt genome have occurred within Corallimorpharia. The most surprising finding, however, was that the mt genome of C. profundus is scleractinian-like, and is organized very differently to those of all other corallimorpharians for which data are available. Both nucleotide and amino acid sequenced-based phylogenetics unequivocally place C. profundus as an early diverging corallimorpharian, indicating that this organism most closely reflects the coral <-> corallimorpharian transition.

Materials and Methods

DNA Extraction, Polymerase Chain Reaction, Long Polymerase Chain Reaction, Cloning, and Sequencing

Genomic DNA was extracted from corallimorpharian samples that had been preserved in 95% (V/V) ethanol following Chen et al. (2002)—sampling information is summarized in table 1. Long-range polymerase chain reaction (L-PCR; Cheng et al. 1994) was used to amplify large (6–9 kb) and overlapping fragments covering the entire mt genomes of corallimorpharians and corals. For each species, either two- or three-specific primer pairs were designed on the basis of previously available partial sequence data for of rns, ml, and COI (Folmer et al. 1994; Romano and Palumbi 1997; Chen and Yu 2000; Lin et al. 2011) (supplementary table S1, Supplementary Material online). Reactions were set up in a total volume of 50 µl: 10 x LA PCR buffer, 2.5 mM MgCl2, 2.5 mM of each dNTP, 2.5 units of TaKaRa La Taq, 0.5 µM of each primer, and approximately 0.5 µg of genomic DNA. The L-PCR conditions were slightly modified from those recommended by the polymerase manufacturer as follows: 94 ºC for 1 min, then 30 cycles of 10 s at 98 ºC, 45 s at 62–63 ºC, 14.25 min at 68 ºC, and 10 min at 72 ºC. PCR products were recovered from the agarose gel using the TOPO XL gel purification...
method, cloned into a pCR-XL-PCR vector system using topoisomerase I (Invitrogen), and transformed into *Escherichia coli* (Top10) by electroporation. The nucleotide sequences were determined for complementary strains of two to six clones from each sample using primer walking on the same PCR product by an ABI 377 Genetic Analyzer (Applied Biosystems). The M13 forward and reverse primers were used to obtain the initial sequences from the ends of each insertion. The consensus sequences from three sequenced clones were present for each species.

### Genome Annotation and Sequence Analysis

Sequences were verified and assembled using SeqManII (DNASTar v5.0) or Sequencher v4.8 (Gene Codes Corporation) and then analyzed in Vector NTI v9.0 (InforMax). Open-reading frames (ORFs) of length more than 50 (amino acids) were translated using National Center for Biotechnology Information translation table 4 and compared with the databases using BlastX (Gish and States 1993). No novel ORFs were identified on this basis. MEGA v5.0 (Tamura et al. 2011) with a weighted matrix of Clustal W (Thompson et al. 1994) was used to align the identical putative ORFs and rRNA genes with previously published data. The 5'- and 3'-ends of the rRNA genes were predicted using the program SINA on the Silva ribosomal RNA database site (www.arb-silva.de, last accessed February 1, 2014) using the default settings (Pruesse et al. 2012). tRNAs were predicted using tRNAscan-SE search server v1.21 (Lowe and Eddy 1997). rRNA loci were identified on the basis of sequence similarity. Finally, Vector NTI v9.0 was used to generate maps of the mt genomes based on the assembled sequence data.

### Gene Order Phylogeny

The double cut and join (DCJ) distance metric (Yancopoulos et al. 2005), implemented in GRAPPA (Moret et al. 2002; Zhang et al. 2009), was used to calculate the pairwise DCJ and breakpoint distances (BPDs) from the gene order data and to generate pairwise distance matrices. Gene order phylogenies (DCJ and BPD) were estimated with FastME (Desper and Gascuel 2002).

Because gene order is a single character with multiple states (Shi et al. 2010), bootstrapping is not applicable, hence the reliability of each branch was estimated by applying a jackknife resampling technique that in each iteration randomly removed 25% of the initial orthologous gene sets. Note that, because the data set consisted of only 13 protein-coding genes, higher removal rates (e.g., 50%) are unable to resolve the tree branching order. Jackknifing was used to generate 1,000 matrices, which were imported into FastME and used to obtain 1,000 DCJ- and BPD-based trees. Finally, the CONSENSE program in the PHYLIP software package (Felsenstein 1989) was used to calculate majority-rule consensus trees with percent values at each node. Each value represents the percentage of trees supporting a clade defined by a node.

### Results

#### Characteristics of mt Genomes of Corallimorpharians and *Gardineria hawaiiensis*

The molecular characteristics of the mt genomes of a representative range (8) of corallimorpharians and the “basal” scleractinian *G. hawaiiensis* are summarized in table 1, along

with the publically available data for hexacorallians (42 species). All the corallimorpharian and scleractinian mt genomes, both those determined in this study and previous work, encode 13 protein-coding genes, 2 tRNA genes (trnM and trnW); but note that Seriatopora spp. have a duplicated trnW, the small (ms) and large (ml) subunit ribosomal DNA genes, and a COI group I intron. Corallimorpharian mt genomes range in size from 20,093 bp in Rhodactis sp. to 22,015 bp in Ricordea yuma and are significantly larger than those of both Complexa and Robusta corals due not only to the presence of COI group I intron (table 1) but also to differences in size of the intergenic spacers (IGSs) between the three lineages (supplementary fig. S1, Supplementary Material online). In fact, the mt genome architectures of the Corallimorpharia are less dense than those of Scleractinia; mt genome size correlates with the total size of the IGS ($r^2 = 0.5371$, $P < 0.001$; supplementary fig. S2, Supplementary Material online). Corallimorpharian mt genomes are characterized by the genes being discrete (i.e., nonoverlapping), whereas this is quite rare in the Scleractinia, where this is shown only with 2 (the complex corals, Siderastrea sp. and Fungiacyathus stephanus) of the 29 species for which data are available.

The mt genomes of scleractinians are smaller than those of corallimorpharians, but the size (19,429 bp) reported here for that of G. hawaiiensis is the largest known for a scleractinian. Two cases of gene overlap were observed in the G. hawaiiensis mt genome; ND4 and rns loci overlap by 1 bp, and ATP8 and COI overlap by 18 bp.

**Gene Order and Rearrangements**

The organization of the mt genomes of hexacorallian anthozoans is summarized as linear maps in figure 2 and potential rearrangement mechanisms discussed below. As in the Scleractinia, there is a canonical corallimorpharian gene arrangement (CII), but these two patterns are clearly distinct. Ten of 12 corallimorpharian mt genomes exhibited an identical gene arrangement (referred to as Type CII in fig. 3), the exceptions being those of Corynactis californica (Type CIII). In the Scleractinia, 27 of the 29 complete mt genomes have identical gene order, but again two cases of rearrangement are known (fig. 2). However, although noncanonical gene arrangements have been observed in both Corallimorpharia and Scleractinia, those in the latter involve relatively small changes (i.e., can be explained by single rearrangement events), the rearrangements within Corallimorpharia are much more extensive (fig. 2). At least four rearrangement events are required for the transition between Type CII and Type CI, up to six rearrangement events were identified between Type CII and Type CIII. In the case of scleractinians, far fewer rearrangement events can explain the two deviations from the canonical pattern (Type SII), which G. hawaiiensis shares with most of the
Scleractinia. *Madrepora oculata* (Type SIII) differs from the SII pattern only in having the order of the COII–COIII genes changed, whereas in *Lophelia pertusa* (Type SI), a block of genes (COB-ND2-ND6) has been rearranged (Type SI). The most surprising finding was that, in terms of gene organization, the mt genome of the deep sea corallimorpharian, *C. profundus* (Type CIII) was more similar to the canonical scleractinian organization (Type SII) than it was to other corallimorpharians. Only two rearrangements of blocks of genes are required to explain the SII–CIII transition (fig. 2). Thus, although *Corallimorphus* is unquestionably a corallimorpharian in terms of the sequences of mt genes, the organization of those genes is scleractinian-like, implying that it might represent a key transitional state.

Among metazoans, one unique characteristic of the mt genomes of hexacorallians is the presence of a self-splicing intron within the ND5 gene that contains a number of complete genes. In the case of the Zoanthidea, Antipatharia, and Actiniaria for which data are available, only two genes, ND1 and ND3, are contained in the ND5 intron, whereas in the Type CI, all of the genes (including trnM, but excluding trnW) are contained in the ND5 intron. In the Type CI pattern, nine protein-encoding genes are located in the ND5 intron, whereas in Types CII, SII, and SIII, the same ten protein-coding genes and rns are contained in the ND5 intron. In Type SI, the number of genes within the ND5 intron is reduced to 8 due to a rearrangement event between Type SI and these two types of mt genomes in the scleractinians (fig. 2).

### Discussion

The most surprising finding of this study was that the mt genome of the deep-sea corallimorpharian, *C. profundus*, more closely resembles scleractinians in gene organization than it does other corallimorpharians (fig. 3A and B). Although molecular phylogenetic analyses based on nucleotide or amino acid sequence data for mt proteins yield...
fundamentally different results with respect to the relationship between the “complex” and “robust” scleractinian clades, there is no disagreement concerning the monophyly of the Corallimorpharia nor about the early divergence of *Corallimorphus* within that clade (fig. 1; Kitahara et al. 2014). On morphological grounds, *Corallimorphus* is also considered the most coral like of corallimorpharians (Moseley 1877; den Hartog 1980; Riemann-Zürneck and Iken 2003).

FIG. 3.—mt gene order phylogeny of anthozoans. The trees shown are majority-rule cladograms generated using the CONSENSE program in PHYLIP (Felsenstein 1989). The numbers shown at the nodes indicate the percentages of 1,000 jackknife analyses supporting the topology shown in breakpoint and DCJ analyses, respectively. Numbers of species exhibiting the gene arrangement shown are indicated in parentheses. (A) Gene order phylogeny with *Lophelia* included. (B) Gene order phylogeny with *Lophelia* excluded. Note the weak support for the *Lophelia/Corallimorphus* clade in (A).
Mitochondrial Genome Rearrangements

Several authors (den Hartog 1980; Owens 1984; Cairns 1989, 1990; Faustin and Lowenstein 1992) have pointed out the level of similarity between Corallimorphus and members of the scleractinian family Micrabaciidae, which are characterized by a reduced skeleton, the fleshy polyp totally investing the rudimentary corallum. Molecular clock estimates imply that the micrabaciids and gardineriids diverged from the scleractinian lineage in the mid-Paleozoic, well prior to the Robusta/Complexa split (Stolarski et al. 2011). The similarity between the earliest diverging members of both the Scleractinia and Corallimorpharia in terms of both morphology and mt genome architecture (fig. 2) implies that Corallimorphus occupies a key position in the corallimorpharian <-> scleractinian transition. Corallimorphus therefore diverged either close to the point of the scleractinian/corallimorpharian divergence (under scleractinian monophyly) or at the point of skeleton loss (under the “naked coral” scenario).

If we accept that the organization of the mt genome in Corallimorphus most closely reflects the ancestral pattern (figs. 1 and 4), then extensive reorganizations are required to generate the consensus corallimorpharian architecture (CII in fig. 2) and that seen in Corynactis; in contrast, the rearrangements documented to date within Scleractinia require far fewer steps. In the case of Lophelia, the presence of a 67 bp direct repeat comprising the 3'-end of the ND1 and 5'-end of COB genes (Emblem et al. 2011) implies that the likely mechanism of reorganization was tandem duplication and random loss (Moritz et al. 1987; Zhang 2003), which may also account for the COII-COIII inversion seen in Madrepora (Lin et al. 2012). We were unable to identify signatures of duplication-mediated rearrangement in corallimorpharians; however, neither are there obvious examples of inversion of segments of the mt genome in this Order. Rather, extensive segmental reorganization without inversion has occurred within Corallimorpharia, possibly facilitated by the less compact nature of the mt genomes (reviewed in Boore and Brown 1998). This contrasts markedly with the situation in octocorals, where many successive inversion events explain the observed diversity of mt gene organization (Brockman and McFadden 2012).

Can comparisons of mt genome organization resolve the question of coral monophyly? Although the data presented here are consistent with monophyly of the Scleractinia, they do not exclude the possibility of an origin for corallimorpharians within the coral clade. Phylogenetic analyses based on gene order (fig. 3A and B) were ambiguous. Although both AA- and nt-based molecular phylogenetic analyses unambiguously support monophyly of the Corallimorpharia, the gene order analysis (fig. 3A and B) did not. We interpret the grouping of Lophelia and Corallimorphus in this analysis as an artifact resulting from superficial similarities in gene organization in these two organisms; although gene order is similar, the sequences of those genes are highly divergent. The idea that the grouping of L. pertusa with C. profundus is artifactual is supported by the relatively low DCJ and BPD confidence values (58/49) associated with this node (i.e., well below the 85% confidence interval recommended by Shi et al. 2010). When L. pertusa was removed from the analysis, the overall DCJ and BPD statistic performances at the nodes of Corallimorpharia and Scleractinia increased, particularly for the node of C. profundus and Scleractinia/M. oculata, where support increased from 94/75 to 97/82 (fig. 3). The mt genomes of the Robusta differ from both corallimorpharians and all other corals in several characteristics. First, within the larger Scleractinia/Corallimorpharia clade, the Robusta have the most compact mt genomes (size range 14,853–17,422 bp) as a consequence of having in general shorter intergenic regions and the largest number of overlapping gene pairs (three to six cases of overlaps). In contrast, corallimorpharians have the largest mt genomes (size range 20,092–22,015 bp), longer intergenic regions, and no cases of overlapping genes, with complex corals intermediate in these characteristics (genome sizes 17,887–19,387 bp; 0–2 overlapping gene pairs—most frequently a single case of overlapping genes). Second, the Robusta differ in structural comparisons of the ND5 group I intron (Emblem et al. 2011) as well as in molecular phylogenetics based on this feature. A group I intron interrupts the ND5 gene of all hexacorallians examined to date; these introns typically come and go during evolution but that in hexacorallians contains a variable number of genes and has become an essential feature. The hexacorallian ND5 intron has been “captured” in the sense that it is now dependent on host-derived factors for splicing, as indicated by the substitution of the oG (the last nucleotide of the intron) by oA (reviewed in Nielsen and Johansen 2009; Emblem et al. 2011). Although these characteristics are common across the
coral-coralimorpharian clade, the ND5 introns of robust corals have a more compact core and overlapping intron and ND5-coding sequences (Emblem et al. 2011). In some robust corals, ωA is replaced by ωC, indicating a higher level of dependency on host factors for processing and thus greater integration of intron and host. These qualitative factors, as well as molecular phylogenetics of the ND5 intron sequences, are most parsimoniously accommodated by scleractinian monophyly (Emblem et al. 2011). Third, of the three lineages, the mt genomes of Robusta have the highest (A+T) content and most constrained codon usage, one obvious consequence of which is that phenylalanine is overrepresented in the proteins that they encode, suggesting that mt DNA repair may be reduced in the Robusta (Kitahara et al. 2014).

The features outlined above, in which the Robusta differ from complex corals and corallimorphs, are derived characteristics—they serve to resolve the robust corals but do not unambiguously identify the sister group. Scleractinian monophyly explains all of the data most parsimoniously, but the alternative cannot yet be ruled out. The mt genome has been exhaustively mined for answers, but these must likely wait for the availability of appropriate nuclear markers.

**Supplementary Material**

Supplementary table S1 and figures S1 and S2 are available at *Genome Biology and Evolution* online (http://www.gbe.oxfordjournals.org/).

**Acknowledgments**

The authors thank members of the Coral Reef Evolutionary Ecology and Genetics Laboratory (CREEG), Biodiversity Research Center, Academia Sinica (BRCAS), and New Zealand Institute of Water and Atmospheric Research for assistance with sampling and field logistics. We also thank Philippe Bouchet (MNHN) who generously loaned the specimens of *Gardineria hawaiiensis* from the Paris Museum, and Bertrand Richer de Forges and IRD- Nouméa staff and collaborators for their great effort in collecting and preserving the New Caledonian specimen examined in the present study. The corresponding authors also thank two anonymous reviewers for their comments, which were very helpful in revising the manuscript. M.-F.L. gratefully acknowledges receipt of a James Cook University Postgraduate Research Scholarship (JCUPRS). M.V.K. acknowledges the support of the São Paulo Research Foundation (FAPESP) and São Paulo University Marine Biology Centre (CEBIMar). This study was supported by grants from the National Science Council (NSC) and Academia Sinica (Thematic Grants 2005–2010) to C.A.C., and from the Australian Research Council to D.J.M. Coral samples were collected under appropriate permits. This is the CREEG, RCBAS contribution no. 108.
