Abstract

Young exoplanets are attractive targets for atmospheric characterization to explore the early phase of planetary evolution and the surrounding environment. Recent observations of the 10 Myr young Neptune-sized exoplanet K2-33b revealed that the planet’s transit depth drastically decreases from the optical to near-infrared wavelengths. Thao et al. suggested that a thick planetary haze and/or stellar spots may be the cause; however, even the best-fit model only barely explains the data. Here, we propose that the peculiar transmission spectrum may indicate that K2-33b possesses a circumplanetary dust ring: an analog of Jupiter’s dust ring. We demonstrate that the ring could produce a steep slope in the transmission spectrum even if its optical depth is as low as \( \sim 10^{-2} \). We then apply a novel joint atmosphere-ring retrieval to K2-33b and find that the ring scenario could well explain the observed spectrum for various possible ring compositions. Importantly, the dust ring also exhibits prominent ring particle absorption features of ring particles around \( \sim 10 \, \mu m \), whose shape and strength depend on the composition of the ring. Thus, future observations by JWST-MIRI would be able to test not only the ring hypothesis but also, if it indeed exists, to constrain the composition of the ring—providing a unique opportunity to explore the origins of the dust ring around its parent planet, soon after the planetary system’s formation.

1. Introduction

Transmission spectroscopy is a widely used method to explore the physical and chemical nature of exoplanetary atmospheres. The spectral features of the gas molecules tell us the chemical composition of exoplanets, which provide valuable constraints on atmospheric physics, chemistry, and planet formation (for recent reviews, see Madhusudhan 2019; Zhang 2020; Guillot et al. 2022). The “spectral slope,” the gradual increase in the transit radius toward the blue, also encapsulates information on atmospheric clouds and hazes (Lecavelier Des Etangs et al. 2008; Pinhas & Madhusudhan 2017; Ohno & Kawashima 2020). Given the success in probing previously unexplored wavelength ranges by JWST (JWST Transiting Exoplanet Community Early Release Science Team et al. 2022), transmission spectroscopy will continue to be an important observational method for exoplanetary atmospheres.

Young exoplanets (<1 Gyr) are attractive targets for studying atmospheric processes and surrounding environments in the early phase of planetary evolution. One of the best examples is K2-33b, a super-Neptune-sized \((R \sim 5 \, R_{\oplus})\) exoplanet orbiting a pre-main-sequence \((\sim 10 \, \text{Myr old})\) M dwarf with an orbital period of 5.424 days (David et al. 2016; Mann et al. 2016). Recently, Thao et al. (2022) obtained the transmission spectrum of K2-33b by combining transit observation data of K2, MEarth, the Spitzer Space Telescope, and the Hubble Space Telescope. They found that its transit depth suddenly decreases from optical to near-infrared wavelengths by a factor of \( \sim 2 \). Such a steep spectral slope is typically attributed to unocculted stellar spot (e.g., McCullough et al. 2014; Louden et al. 2017) and/or aerosol opacity (e.g., Pinhas & Madhusudhan 2017; Ohno & Kawashima 2020). However, Thao et al. (2022) found that the stellar spot alone cannot explain the extreme slope of K2-33b, as the model requires a spot coverage (71%) much larger than limits from the stellar spectrum (<20%). Thao et al. (2022) argued that photochemical haze might explain the extreme slope if the planetary mass is less than \( \sim 5 \, M_{\oplus} \) based on the haze formation framework of Gao & Zhang (2020). However, Kushnirskina et al. (2018) performed hydrodynamical simulations of atmospheric escape from K2-33b and suggested that the mass should be \( >7 \, M_{\oplus} \); otherwise, the planet would have lost its atmosphere through hydrodynamic escape even at the \( \sim 10 \, \text{Myr} \) age.

In this Letter, we propose an alternative scenario that may explain the peculiar transmission spectrum of K2-33b: a circumplanetary dust ring (CPDR hereafter). All giant planets in the solar system are known to possess tenuous CPDR that consist of micron-sized dust particles (see Burns et al. 2001 and references therein). A lifetime of the circumplanetary small dust is short: the orbital decay timescale of micron-sized dust is \( \sim 0.1 \, \text{Myr} \) for a Jovian ring (Burns et al. 2001) and even shorter for close-in exoplanets because of a strong Poynting–Robertson drag (Schlichting & Chang 2011). Thus, CPDRs are believed to be sustained by continuous replenishment of dust particles, such as the capture of interplanetary dust (e.g., Colwell et al. 1998; Mitchell et al. 2005) and impact ejecta from circumplanetary objects, e.g., moons (e.g., Burns et al. 1999; Kriger et al. 1999, 2000; Krivov et al. 2002). In particular, the latter has been suggested as a viable origin of a Jovian dust ring...
obtains the gradient of the spectral slope as

\[
\frac{d}{d\lambda} \frac{R_{\text{obs}}}{H \ln \lambda} \propto \frac{S_{\text{ring, out}} \rho_f^2 \tau_{\text{ring}}}{2 R_{\text{eff}}^2 H^3} \tau_{\text{ring}},
\]

where we have used Equation (44) of Ohno & Fortney (2022), the transit depth of the ring exoplanet can be well approximated by

\[
\frac{R_{\text{eff}}^2}{R_{\text{obs}}^2} = \frac{\pi R_{\text{eff}}^2}{3} + S_{\text{ring, out}} (1 - e^{-\tau_{\text{ring}}}),
\]

where \( R_{\text{eff}} \) is the effective transit radius of a planet without a ring, \( S_{\text{ring, out}} \) is the area of the ring projected onto the stellar disk subtended by the area overlapped with the planetary disk, and \( \tau_{\text{ring}} \) is the line-of-sight optical thickness of the ring. Differentiating this equation with respect to wavelength, one obtains the gradient of the spectral slope as (Equation 44 of Ohno & Fortney 2022)

\[
\frac{d}{d\lambda} \frac{R_{\text{obs}}}{H \ln \lambda} \propto \frac{S_{\text{ring, out}} R_{\text{eff}}^2}{2 R_{\text{eff}}^2 H^3} \tau_{\text{ring}} \gamma.
\]

where we have assumed that \( dS_{\text{ring, out}}/d\lambda = 0 \) for simplicity, which is valid if the projected minor axis of the inner edge of the ring is larger than the planetary radius. For \( \tau_{\text{ring}} \ll 1 \), with an approximation of \( e^{-\tau_{\text{ring}}} \approx 1 \) for clarity, Equation (2) can be approximated by

\[
\frac{d}{d\lambda} \frac{R_{\text{obs}}}{H \ln \lambda} \approx \frac{dR_{\text{eff}}}{d\lambda} + \frac{S_{\text{ring, out}} \tau_{\text{ring}}}{2 R_{\text{eff}} H}.
\]

In this Equation, the first term expresses the atmosphere contribution, while the second term expresses the ring contribution. Assuming a power-law opacity of the ring as \( \tau_{\text{ring}} \propto \lambda^{-\gamma} \), we obtain

\[
\frac{1}{H} \frac{d}{d\lambda} \frac{R_{\text{obs}}}{H \ln \lambda} \approx \frac{\alpha}{1 - \beta} + \frac{S_{\text{ring, out}} R_{\text{eff}}^2}{2 R_{\text{eff}}^2 H^3} \tau_{\text{ring}} \gamma,
\]

where we have used \( dR_{\text{eff}}/d\ln \lambda = \alpha \gamma / (1 - \beta) \) for the atmospheric component that is derived by assuming the atmospheric opacity of \( \kappa \propto \lambda^{-\gamma} P^{-\beta} \) with \( \beta < 1 \) (Ohno & Kawashima 2020).

Importantly, the slope generated by the ring is scaled by the projection area of the ring \( S_{\text{ring, out}} \) whose length scale is comparable to the planetary radius. Thus, the ring potentially produces a spectral slope much steeper than that expected for ring-free planets, which is scaled by the atmospheric scale height. The ring may have an outer edge around the Roche radius (e.g., Piro & Vissapragada 2019) given by

\[
R_{\text{roche}} \approx 2.46 R_p \left( \frac{\rho_p}{\rho_i} \right)^{1/3} = 2.46 \left( \frac{3M_p}{4\pi \rho_i} \right)^{1/3},
\]

where \( R_p \approx R_{\text{eff}} \) is the planetary radius, \( \rho_p \) is the planetary bulk density, and \( \rho_i \) is the density of the ring particle. The effect of the ring is maximized in the extreme case of a face-on ring with a ring’s inner edge close to the planetary radius, i.e., \( S_{\text{ring, out}} = \pi (R_{\text{roche}} - R_p^2) \approx \pi R_p^2 \). Thus, we may crudely evaluate the maximal effect of the ring component as

\[
\frac{1}{H} \frac{d}{d\ln \lambda} \frac{R_{\text{obs}}}{H \ln \lambda} \sim \frac{R_{\text{roche}}^2}{2 R_{\text{eff}}^2 H^3} \tau_{\text{ring}} \gamma \sim 1700 \frac{R_{\text{roche}}^2}{R_{\text{eff}}^2} \left( \frac{H}{400 \text{ km}} \right)^{-1} \left( \frac{R_{\text{eff}}}{R_{\text{Jupiter}}} \right).
\]

Equation (6) indicates that the ring could cause a steep slope if the optical depth is greater than \( \sim 10^{-3} \). For example, for \( \gamma = -4 \) and \( \rho_p/\rho_i = 1 \), even an optically thin ring of \( \tau_{\text{ring}} = 10^{-2} \) yields a spectral slope of \( H^3 dR_{\text{eff}}/d\ln \lambda \sim \tau_{\text{ring}} \).

Figure 1 schematically summarizes how the ring affects the transmission spectrum. The ring acts to produce a flat transmission spectrum regardless of its optical properties. A moderately optically thin ring, say \( 10^{-3} \ll \tau_{\text{ring}} \ll 1 \), significantly affects the shape of the transmission spectrum, depending on the ring’s optical properties. If the ring’s opacity has a power-law dependence on wavelength, the ring produces a spectral slope that can be much steeper than that produced by atmospheric processes (Equation (6)). As shown later, an optically thin ring also produces an absorption feature of the ring particles in the spectrum (see also Ohno & Fortney 2022). When the optical depth of a ring is too low, say \( \tau_{\text{ring}} \ll 10^{-3} \), a ring does not affect the transmission spectrum. We note that a whole spectrum potentially contains multiple regimes because the ring’s optical depth can depend on wavelength. For example, if the ring optical depth suddenly decreases from 10 at visible to 0.1 at near-infrared wavelengths, a planet could show a flat spectrum at visible, a ring-free atmospheric spectrum at near-infrared, and a steep slope at intermediate wavelengths.

2.2. Exoplanetary Transmission Spectra with a Circumplanetary Dusty Ring

We numerically demonstrate that an optically thin CPDR could produce an extreme spectral slope. We first compute the synthetic ring-free transmission spectrum of a hypothetical K2-33b-like planet using a publicly available radiative transfer code, CHIMERA (Line et al. 2013). We consider a hypothetical Jupiter-mass planet around a Sun-like star with a Jupiter radius
at 10 bar pressure level and an isothermal solar composition atmosphere of $T = 1000$ K under thermochemical equilibrium. Then we include the effect of the ring following a postprocessing prescription described in Ohno & Fortney (2022). The outer edge ($R_{\text{out}}$) of the ring is fixed to the Roche radius with a particle density of $\rho_p = 3 \text{ g cm}^{-3}$. For the inner edge ($R_{\text{in}}$), we introduce the ring width parameter ($W$) as

$$R_{\text{in}} = (1-W)R_{\text{out}}. \quad (7)$$

We also vary the inclination of a ring $\phi = \pi/2 - i_r$, where $i_r$ is the inclination of the ring plane with respect to the sky plane (see also Akinsanmi et al. 2020). For example, the face-on and edge-on rings have angles of $\phi = 90$ and 0 deg, respectively. We computed the ring opacity using the publicly available Mie theory code PyMieScatt (Sumlin et al. 2018). We assume a log-normal particle size distribution given by

$$dN/a = \frac{N}{\sqrt{2\pi \sigma^2}} \exp\left[-\frac{\ln^2(a/a_\mu)}{2 \sigma^2}\right], \quad (8)$$

where $N$ is the column number density of the ring particles, which is associated with the surface density as $\Sigma = \int (4\pi a^3 \rho_p/3) (dN/da) \, da$. In this study, we adopt the SiO$_2$ optical constants for a fiducial model and test other various optical constants in Section 3, as the composition of the exoplanetary ring is unknown. We use refractive indices compiled by Kitzmann & Heng (2018) unless otherwise noted.

Figure 2 shows the spectrum with CPDR for various ring surface densities. The corresponding ring optical depth is also shown in the bottom panel. The ring produces a flat spectrum with a transit depth much larger than the ring-free spectrum when the ring is optically thick, in agreement with previous studies (Alam et al. 2022; Ohno & Fortney 2022). Once the ring becomes optically thin, the transit depth rapidly drops to the depth of the ring-free planet. This sudden drop appears as an extreme spectral slope in the transmission spectrum, as seen in the middle panel of Figure 2. The ring effect eventually becomes negligible at $\Sigma \lesssim 10^{-8} \text{ g cm}^{-2}$, equivalent to $\tau_{\text{ring}} \lesssim 10^{-3}$ (see bottom panel). These results are consistent with the analytic prediction presented in the previous section.

The CPDR produces significant absorption features around 9 and 12.5 \text{ \mu m}. The amplitude of the feature depends on the ring surface density and thus optical depth. In some cases, the feature shows a top-hat shape rather than a sharp absorption peak. This stems from the fact that the ring becomes optically thick around the absorption feature, which results in the transit depth being limited by the physical size of the ring. This top-hat shape of the absorption feature could be a unique signature of the CPDR.

3. Application to Transmission Spectrum of K2-33b

We investigate whether the CPDR model can explain the transmission spectrum of K2-33b. Since many parameters have been uncertain, we conduct a joint atmosphere-ring retrieval on the transmission spectrum of K2-33b presented by Thao et al. (2022) that constrains both atmospheric and ring properties simultaneously in a Bayesian framework. We combine the chemically consistent atmospheric retrieval of CHIMERA with the postprocessing ring prescription of Ohno & Fortney (2022) to perform this new atmosphere-ring retrieval. The parameters retrieved are the ring surface density $\Sigma$, mean particle size $a_r$, size distribution width $\sigma$, inclination $\phi$, width $W$, atmospheric metallicity [M/H], C/O ratio, planetary mass $M_p$, and 10 bar radius $xR_{\text{p}0}$, where $xR_{\text{p}0} = 0.03545R_{\text{p}}$ is the radius of K2-33b at Spitzer bands (Thao et al. 2022). Note that the planetary mass is also a free parameter since the current observations could only put an upper limit on the mass of $3.6 M_{\text{Jup}}$ due to the large spot-induced radial velocity (RV) jitter (David et al. 2016; Mann et al. 2016). We adopt the stellar properties of K2-33 described by Thao et al. (2022): $M_{\star} = 0.571 M_{\odot}$, $R_{\star} = 1.017 R_{\odot}$, and $T_{\text{eff}} = 3540$ K. For simplicity, we fix the atmospheric pressure-temperature profile to that calculated by an analytical model of Guillot (2010) with atmospheric infrared opacity of $\kappa_{IR} = 0.01 \text{ cm}^2 \text{ g}^{-1}$, visible-to-infrared opacity ratio of 0.2, planetary equilibrium temperature of $T_{\text{eq}} = 768$ K, and intrinsic temperature of $T_{\text{int}} = 100$ K. We apply the Nested Sampling method with pymultinest (Buchner et al. 2014), which is a Python implementation of MULTINEST (Feroz et al. 2009), to estimate the posterior distribution of each parameter. We adopt uniform prior distributions and 500 livepoints.

We summarize the retrieval result for the SiO$_2$ ring in Figure 3. The CPDR model could reasonably explain the overall transmission spectrum of K2-33b ($\chi^2 = 16.85$, the number of data points is 18), including the sharp drop in transit.

---

**Figure 1.** Schematic illustration showing how the circumplanetary ring affects the atmospheric transmission spectrum.

**Figure 2.** Spectrum with CPDR for various ring surface densities. The ring effect rapidly drops to the depth of the ring-free planet. This sudden drop appears as an extreme spectral slope in the transmission spectrum.

**Figure 3.** The CPDR model could reasonably explain the overall transmission spectrum of K2-33b ($\chi^2 = 16.85$, the number of data points is 18), including the sharp drop in transit.
wavelengths. The Spitzer data points at 3.6 and 4.5 \(\mu m\) lead to a preference for a higher metallicity (\(\sim 30\times\) solar) and a subsolar C/O so that the CO\(_2\) and/or CO features dominate over the CH\(_4\) feature, although the uncertainty is large. Future observations with wider wavelength coverage and better precision, along with the observational constraint on planetary mass, would provide better insight into the atmospheric properties of K2-33b.

It is worth noting that the CPDR model prefers a relatively high planetary mass, say \(\geq 7\ M_\oplus\) (see the posterior in Figure 3), compared to the aerosol scenario. This is because a more massive planet can have a larger Roche radius. This trend is opposed to the aerosol scenario, which instead prefers a lower planetary mass (\(< 5\ M_\oplus\); Thao et al. 2022), as the aerosol scenario requires a large atmospheric scale height to cause a large variation in the transit depth. The preference for a high planetary mass is compatible with the requirement for atmospheric stability suggested by Kubyshkina et al. (2018). All CPDR models also predict silicate features with amplitudes of up to \(\sim 1000\ ppm\). Therefore, the presence or absence of the feature directly tests whether a CPDR causes the extreme optical slope of K2-33b. Such observations, which would be accessible by JWST-MIRI, would provide further information on the atmospheric and surrounding environment of the young exoplanet K2-33b.

While we have assumed the optical constants for SiO\(_2\) for the CPDR, the actual composition of the CPDR remains unknown. The CPDRs in the solar system are possibly formed via impact ejecta from their satellites (e.g., Burns et al. 1999, 2001). Thus, if the CPDR does exist, we anticipate that the composition of the CPDR is similar to the crustal composition of parent bodies, e.g., exomoons and/or remaining satellitesimals. If true, the assumption of SiO\(_2\) may be reasonable, as the crusts of rocky objects in the inner solar system primarily consist of SiO\(_2\) (\(\sim 46–66\ wt\%), McLennan 2020 and references therein). We investigate the impact of different compositions of the CPDR by repeating the retrieval with various optical constants: representative olivines, which include Mg\(_2\)SiO\(_4\) and Fe\(_2\)SiO\(_4\); moderately abundant crustal minerals, which include Al\(_2\)O\(_3\), FeO, and MgO; astronomical silicate (Draine 2003). As shown in Figure 4, we find that all the mineral compositions tested here could explain the extreme optical slope of K2-33b while each mineral produces a distinct spectral feature around \(\sim 10\ \mu m\), except for FeO. We note that a pure FeO composition is likely unrealistic, as the mass fraction of FeO is up to \(\sim 20\ wt\%\) in solar system crustal rocks (McLennan 2020) and predicted to be \(\sim 50\ wt\%\) (the remainders are mostly SiO\(_2\) and MgO) even in a hypothetical coreless planet where the iron core did not form (Elkins-Tanton & Seager 2008). Thus, similar to the spectroscopy of dust tails of disintegrating rocky exoplanets (Bodman et al. 2018; Okuya et al. 2020), future observations of absorption features at the mid-infrared wavelength would also provide a unique opportunity to explore the origins of CPDRs and their possible parent bodies.

**4. Summary and Discussion**

We have shown that the optically thin CPDR could explain the extreme spectral slope of the 11 Myr young exoplanet K2-33b. The advantage of the CPDR scenario is that it prefers a high planetary mass (say, \(\geq 7\ M_\oplus\)), which is compatible with the requirement of atmospheric stability (Kubyshkina et al. 2018). Our model predicts that the CPDR exhibits a prominent

---

**Figure 2.** (Top) Transmission spectra of a Jupiter-mass planet with a CPDR. Different colored lines show the spectra for different ring surface densities. We assume optical properties of SiO\(_2\) with a mean particle size and size distribution width of the CPDR as \(a_r = 0.1\ \mu m\) and \(\sigma = 0.5\). The ring’s inclination and width are fixed to \(\phi = 30\ deg\) and \(W = 0.5\). (Middle) The same as the top panel, but with a different vertical scale. (Bottom) The normal optical depth of the ring. The gray dashed and dotted lines denote the optical depth of 1 and \(10^{-3}\) to indicate the optically thin regime.
silicate feature at ∼10 μm, which would be testable by JWST-MIRI. It is important to disentangle which haze or CPDR scenario is true from future observations. If the haze with a lower planetary mass scenario is true, it may challenge the current understanding of atmospheric escape, which is essential to understand overall planetary evolution. Exoplanetary rings have not been conclusively detected yet, though several studies have suggested a few candidates (for a review, see Heller 2018), such as a putative ringed planet J1407b (e.g., Mamajek et al. 2012; van Werkhoven et al. 2014; Kenworthy & Mamajek 2015), and a cool extremely low-density giant planet HIP 41378f (Santerne et al. 2019; Akinsanmi et al. 2020; Alam et al. 2022; Belkovski et al. 2022). Thus, the detection of the absorption feature of the CPDR, if it is, would make K2-33b a very promising candidate for the first exoplanetary ring system. Since the CPDR is possibly maintained by impact ejecta from the planet’s moon(s), if the CPDR scenario is true, the absorption feature of the CPDR may provide a unique opportunity to study the composition of exomoons, providing insights into their formation and evolution processes.

Figure 3. Corner plot showing the results of atmosphere-ring retrieval on the transmission spectrum of K2-33b obtained by Thao et al. (2022). The colored regions in the 2D posteriors denote 1σ, 2σ, and 3σ intervals. The right top panel also shows the median transmission spectrum and its 1σ and 2σ uncertainties. The CPDR model succeeds in explaining a factor of 2 variation in the transit depth from optical to near-infrared wavelength. Prominent absorption features across the range from 8 to 30 μm are due to ring particle absorption.
A more general implication of this study is that a CPDR might provide an explanation for some other peculiar transmission spectra that cannot be explained by atmospheric processes. For example, a low-density super-Neptune HATS-8b shows an extreme spectral slope that is steeper than the nominal Rayleigh slope by a factor of $\sim 27$ (May et al. 2020). Since this extreme slope could not be fully explained by stellar spots and aerosols (May et al. 2020), a CPDR may provide an explanation. Although it is unclear to what degree CPDRs are ubiquitous in the exoplanetary system, it is worth considering the possibility of these and other peculiar transmission spectra.

Since we have adopted a highly simplified CPDR model, further studies will be warranted on the formation processes of CPDRs around exoplanetary environments. Even a moderately optically thin (e.g., $\tau_{\text{ring}} \sim 10^{-2}$) CPDR can noticeably affect the transmission spectrum. Thus, it would be important to investigate what the typical CPDR expected for exoplanets is from a theoretical standpoint. Meanwhile, the ring may leave other observable signatures (see, e.g., Santos et al. 2015; Zuluaga et al. 2015; Aizawa et al. 2017; de Mooij et al. 2017), such as forward scattering in a transit light curve (Barnes & Fortney 2004) and a radial velocity anomaly (Ohta et al. 2009). Future investigations by theoretical and observational studies would help to understand the observational consequences of CPDRs and their implications on their formation and evolution processes.

We thank Callie Hood for the helpful comments on the use of CHIMERA. The authors also thank the anonymous referee for helpful comments on the manuscript and Dave Charbonneau, Adam Kraus, Gregory Sloan, and Andrew Vanderburg for suggesting that the chromatic transit depths seen for K2-33 b might be due to a planetary ring.
