Abstract

The configuration-fixed constrained triaxial relativistic mean-field approach is extended by including time-odd fields and applied to study the candidate multiple chiral doublets (M\(\chi D\)) nucleus \(^{106}\)Rh. The energy contribution from time-odd fields and microscopical evaluation of center-of-mass correction as well as the modification of triaxial deformation parameters \(\beta, \gamma\) due to the time-odd fields are investigated. The contributions of the time-odd fields to the total energy are 0.1-0.3 MeV and they modify slightly the \(\beta, \gamma\) values. However, the previously predicted multiple chiral doublets still exist.

Since the prediction of existence of chirality in atomic nuclei in 1997 \cite{1} and later experimental observation of chiral doublet bands in 2001 \cite{2}, nuclear chirality has become one of the most interesting subjects in nuclear physics. Hitherto, extensive studies have been performed to understand the phenomena and explore their possible existence in $A \sim 100, 130$ and $190$ mass regions \cite{3, 4, 5, 6, 7}.

On the theoretical side, chiral doublet bands were first predicted by the particle-rotor model (PRM) and tilted axis cranking (TAC) model for triaxially deformed nuclei \cite{1}. Later on, numerous efforts have been devoted to the development of TAC methods \cite{8, 9, 10, 22} and PRM models \cite{12, 13, 14, 15} to describe chiral rotation in atomic nuclei. It is shown that triaxial deformation and high-$j$ valence particles and valence holes are essential for the formation of chirality in nuclei. Therefore, it will be very interesting to search for nuclei with these characters within the state-of-the-art nuclear structure models.

Relativistic mean-field (RMF) theory \cite{16, 17, 18, 19, 20}, which relies on basic ideas of effective field theory and of density functional theory has achieved great success in describing many nuclear phenomena for both stable and exotic nuclei over the entire nuclear chart. It thus provides us a microscopic way to study nuclear structure properties including the energy and deformation for not only the ground state but also the excited state for given valence nucleon configuration. In Ref. \cite{21}, a configuration-fixed constrained triaxial RMF approach was developed and applied to study the nuclear potential energy surface (PES). An interesting phenomenon – the existence of multiple chiral doublets (M$\chi$D), i.e., more than one pair of chiral doublet bands in one single nucleus, has been suggested in $^{106}$Rh and other odd-odd Rhodium isotopes \cite{22}. These predictions are based on the triaxial deformations of local minima and the corresponding proton and neutron configurations. In these studies, the time-reversal invariance was assumed from the beginning, namely, the time-odd fields were neglected.

Actually, the unpaired valence neutron and proton will generate nucleon currents and break the time-reversal invariance in nuclear state. Such effects have been found to be of great importance to reproduce the nuclear magnetic moment \cite{23}, inertia of moment \cite{24} as well as $M1$ transition rates in magnetic rotation nuclei \cite{25}. Therefore one has to examine the existence of M$\chi$D in odd-odd Rhodium isotopes with the presence of time-
odd fields.

In this work, the configuration-fixed constrained triaxial RMF approach will be extended by including time-odd fields, which is more suitable to study the triaxial structure properties of odd-mass and odd-odd nuclei. Taking $^{106}$Rh as an example, the effect of time-odd fields on the total energy, triaxial deformations $\beta, \gamma$ as well as configuration will be examined.

The detailed description of configuration-fixed constrained triaxial RMF approach with nucleon-nucleon interacting via meson exchange can be found in Ref. [21] and references therein. Only a brief outline, in particular with the presence of time-odd fields, will be given here.

The starting point of the RMF theory is the standard effective Lagrangian density constructed with the degrees of freedom associated with nucleon field ($\psi$), two isoscalar meson fields ($\sigma$ and $\omega_\mu$), isovector meson field ($\vec{\rho}_\mu$) and photon field ($A_\mu$). Under “mean-field” and “no-sea” approximations, one can derive the corresponding energy density functional, from which one finds immediately the equation of motion for a single-nucleon orbit $\psi_i(r)$ with the help of variational principle,

$$\{ \alpha \cdot [p - V(r)] + \beta m^*(r) + V_0(r) \} \psi_i(r) = \epsilon_i \psi_i(r), \quad (1)$$

where $m^*(r)$ is defined as $m^*(r) \equiv m + g_\sigma \sigma(r)$, with $m$ referring to the mass of bare nucleon. The repulsive vector potential $V_0(r)$, i.e., the time-like component of vector potential reads,

$$V_0(r) = g_\omega \omega_0(r) + g_\rho \tau_3 \rho_0(r) + e \frac{1 - \tau_3}{2} A_0(r), \quad (2)$$

where $g_i (i = \sigma, \omega, \rho)$ are the coupling strengths of nucleon with mesons. The time-odd fields $V(r)$ are naturally given by the space-like components of vector fields,

$$V(r) = g_\omega \omega(r) + g_\rho \tau_3 \rho(r) + e \frac{1 - \tau_3}{2} A(r). \quad (3)$$

The non-vanishing time-odd fields in Eq.(3) give rise to splitting between pairwise time-reversal states $\psi_\gamma$ and $\psi_2(\equiv \hat{T} \psi_\gamma)$, where $\hat{T}$ is the time-reversal operator. Each Dirac spinor $\psi_i(r)$ is expanded in terms of a set of three-dimensional harmonic oscillator (HO) basis in Cartesian coordinates with 12 major shells. The meson fields which provide the nuclear mean-field potentials are expanded in terms of the same HO basis as those of
Dirac spinor but with 10 major shells. The pairing correlations are greatly quenched by the unpaired valence neutron and proton in $^{106}$Rh and thus neglected. More details about the solution of Dirac equation (1) with time-odd fields can be found in Ref. [26].

A configuration-fixed quadrupole moment constraint calculation through $\beta^2$ was carried out to obtain the PES for each configuration, where $\beta = \frac{4\pi}{3AR^3_0} \sqrt{q_{20}^2 + 2q_{22}^2}$ and $\gamma = \tan^{-1}(\sqrt{2}q_{22}/q_{20})$ with $q_{20} = \sqrt{\frac{5}{16\pi}} (2z^2 - x^2 - y^2)$ and $q_{22} = \sqrt{\frac{15}{32\pi}} (x^2 - y^2)$. The same configuration is guaranteed during the procedure of constraint calculation with the help of “parallel-transport” [27], which enables one to decompose the whole PES into several parts characterized by the quantum numbers of corresponding configurations.

![FIG. 1: (Color online) The potential energy surfaces as functions of deformation $\beta$ in configuration-fixed constrained time-odd triaxial RMF calculations with PK1 set (solid line). The minima in the energy surfaces of each configuration are labeled with A, B, C, D, E, and F respectively according to their energies. The results by triaxial RMF calculation without time-odd fields (dashed line) are taken from Ref. [22].](image)

In Fig. 1 the energies are given as functions of deformation $\beta$ in configuration-fixed constrained time-odd triaxial RMF calculations with PK1 set [28] for $^{106}$Rh. The minima in the energy surfaces of each configuration are labeled with A, B, C, D, E, and F respectively. The PES plotted with dashed line in Fig. 1 are obtained by triaxial RMF calculation without time-odd fields. Furthermore the center-of-mass (c.m.) correction energy is estimated phenomenologically with $E_{\text{c.m.}}^{\text{phc.}} = \frac{3}{4} \times 41A^{-1/3}$, which remains to be

4
a constant for all configurations. Here the c.m. correction energy is evaluated microscopically by projection-after-variation in the first-order approximation, i.e.,

\[ E_{c.m.}^{\text{mic.}} = -\frac{1}{2mA} \langle P_c.m. \rangle, \tag{4} \]

where \( P_{c.m.} = \sum_i A p_i \) and \( A \) is the mass number. It is found that the time-odd fields and microscopic c.m. correction do not change significantly the topological structure of the whole PES but lower it down about 1.5 MeV. As a result, the energy of ground state is modified from -903.92 MeV to -905.33 MeV, which is much closer to the experimental data -906.72 MeV \[29\].

FIG. 2: (Color online) The energy from time-odd fields \( E_{\text{odd}} \) (upper panel), the energy difference between microscopic and phenomenological c.m. correction \( \Delta E_{c.m.} \) (middle panel), the summation of \( E_{\text{odd}} \) and \( \Delta E_{c.m.} \) (dashed line) and the energy difference \( \Delta E_{\text{tot.}} \) (solid line) between the corresponding potential energy surfaces in Fig. 1 (lower panel) for different configurations as functions of deformation parameter \( \beta \).

In Fig. 2 we plot the energy contribution from the time-odd fields \( E_{\text{odd}} \) \((= -\frac{g_\omega}{2} \int d^3r \omega(r) \cdot j_N(r))\), with the nucleon current given by \( j_N = \sum_i \psi_i^\dagger \alpha \psi_i \), the c.m. correction energy difference \( \Delta E_{c.m.} = E_{c.m.}^{\text{mic.}} - E_{c.m.}^{\text{phe.}} \) and total energy difference \( \Delta E_{\text{tot.}} \) between the present calculation and those in Ref. \[22\] as functions of deformation parameter.
β. The dashed line in lower panel of Fig. 2 denotes the summation of $E_{\text{odd}}$ and $\Delta E_{\text{c.m.}}$. All $E_{\text{odd}}$, $\Delta E_{\text{c.m.}}$ and $\Delta E_{\text{tot}}$ change moderately as functions of deformation parameter $\beta$ for given configuration. Furthermore, the main contribution to $\Delta E_{\text{tot}}$, i.e., the shift of whole PES in Fig. 4 is due to $\Delta E_{\text{c.m.}}$. The time-odd fields make the nucleus more bound and their contributions to energy range around 0.1-0.3 MeV. From the lower panel in Fig. 2 it tells us that the time-odd fields will modify the time-even mean-fields and lead to $\sim 0.1\text{MeV}$ contribution to the total energy for all the configurations.

**FIG. 3:** (Color online) The triaxial deformation parameters $\gamma$ as functions of $\beta$ in configuration-fixed constrained triaxial RMF calculations for $^{106}\text{Rh}$ without (left) or with (right) the time-odd fields. The shaded area represents favorable triaxial deformation for chirality. It shows that triaxial deformation parameters $\beta$ and $\gamma$ are not sensitive to the time-odd fields. In both cases, the valence nucleon configurations A, B and C have the favorable triaxial deformation for chirality.

In Fig. 3 we plot the triaxial deformation parameters $\gamma$ as functions of $\beta$ in configuration-fixed constrained triaxial RMF calculations for $^{106}\text{Rh}$ without (left panel) or with (right panel) the time-odd fields. The shaded area represents favorable triaxial deformation for chirality. It shows that triaxial deformation parameters $\beta$ and $\gamma$ are not sensitive to the time-odd fields. In both cases, the valence nucleon configurations A, B and C have the favorable triaxial deformation for chirality.

In order to label the configuration A, B and C, the main spherical component for the wave function of the valence nucleon has been obtained by expanding the Dirac spinor in terms of spherical HO basis with the quantum number $|nljm \rangle$. It is found that the influence of the time-odd fields for the composition of the Dirac spinor is negligible.

The total energies $E_{\text{tot}}$, center-of-mass correction energy $E_{\text{c.m.}}$, energy contribution from the time-odd fields $E_{\text{odd}}$, triaxial deformation parameters $\beta, \gamma$ as well as their cor-
TABLE I: The total energies $E_{\text{tot}}$, center-of-mass correction energy $E_{\text{c.m.}}$, energy contribution from the time-odd fields $E_{\text{odd}}$, triaxial deformation parameters $\beta, \gamma$ as well as their corresponding valence nucleon configurations for A-F in the configuration-fixed constrained triaxial RMF calculations with (without) time-odd fields. The values in parentheses are taken from Ref. [22].

In summary, the configuration-fixed constrained triaxial relativistic mean-field approach has been extended by including time-odd fields and applied to study the candidate $M\chi D$ nucleus $^{106}$Rh. The energy contribution from time-odd fields and center-of-mass correction has been studied in detail. It has been found that the time-odd fields contribute 0.1-0.3 MeV to the total energy and slightly modify the triaxial deformation parameters $\beta, \gamma$. It confirms the previous prediction of possible existence of $M\chi D$ in configuration-fixed triaxial RMF approach without time-odd fields. As one pair of doublet bands with $\nu h_{11/2}^1 \otimes \pi g_{9/2}^{-3}$ configuration has been observed experimentally, it will be very interesting to search for the candidate chiral doublet bands with configuration $\nu h_{11/2}^3 \otimes \pi g_{9/2}^{-3}$ and verify the prediction of $M\chi D$.
